Abbreviations: ARVC/D, arrhythmogenic right ventricular cardiomyopathy/dysplasia; aVF, augmented voltage unipolar left foot lead; aVL, augmented voltage unipolar left arm lead; BSA, body surface area; LV, left ventricular; PLAX, parasternal long-axis view; PSAX, parasternal short-axis view; RV, right ventricular; RVOT, right ventricular outflow tract; SAECG, signal-averaged ECG.

Note: Diagnostic terminology for original criteria: this diagnosis is fulfilled by the presence of two major, or one major plus two minor criteria, or four minor criteria from different groups. Diagnostic terminology for revised criteria: definite diagnosis: two major or one major and two minor criteria, or four minor criteria from different categories; borderline: one major and one minor, or three minor criteria from different categories; possible: one major or two minor criteria from different categories. Hypokinesia is not included in this or subsequent definitions of RV regional wall motion abnormalities for the proposed modified criteria. A pathogenic mutation is a DNA alteration with ARVC/D that alters or is expected to alter the encoded protein, is unobserved or rare in a large non-ARVC/D control population, and either alters or is predicted to alter the structure or function of the protein or has demonstrated linkage to the disease phenotype in a conclusive pedigree.

reduction in systolic function, and widespread regional wall motion abnormality, corresponds to disease severity. CMRI enables the identification of intra-myocardial fat and late gadolinium enhancement, and may be sensitive in identifying early changes leading to the diagnosis of ARVC, although they also have a high rate of CMRI false-positive diagnosis of ARVC. Standardized imaging protocols are available on <http://www.arvd.org>. Right ventriculography is included as a major criterion in the presence of regional RV akinesis, dyskinesia, or aneurysm.

With greater understanding and recognition of the familial basis of ARVC, and identification of disease-causing genes, the clinical identification of relatives at risk has become central to management. Mutations are frequently detected in patients with ARVC, with greater than 70% of living probands in some series. However, the role of genetic testing remains to be fully established, limited by the uncertainty of the prognostic implications of genetically affected individuals, since penetrance is low, with marked intra-familial phenotypic diversity. Variable age-related expression of the disease is common, with an unpredictable minority suffering arrhythmic events without overt clinical disease. On the contrary, the majority of patients will not develop clinically significant disease, and those with clinical disease expression have a benign course. There is also the issue of detecting gene sequence variations with uncertain significance.

The prevention of SCD is the major role of therapy in patients with ARVC. In addition, since SCD is the first clinical manifestation of the disease in up to 50% of index cases, surveillance of family members is a crucial part of the management of this disease. Ventricular arrhythmias in patients with ARVC range from ventricular premature beats to sustained VT, and the frequency varies with the severity of the disease. The most common arrhythmia is sustained or non-sustained monomorphic VT which originates from the RV (inflow tract, apex, or outflow tract) and thus have a left bundle branch block morphology. VT from the outflow tract can be indistinguishable from that seen in idiopathic RV outflow-tract tachycardia.

The optimal strategies for preventing SCD, and indications for ICD therapy, are not well defined and, hence, risk stratification is challenging. The evidence available is based on small studies (non-randomized controlled studies) and the opinion of experts due to the relatively low prevalence of ARVC. Current guidelines recommend ICD implantation for secondary prevention of SCD in patients with sustained VT or VF, and aborted SCD. Primary-prevention ICD implantation is suggested in selected high-risk patients such as those with extensive disease, adverse family history, or unexplained syncope. Other putative risk factors that may predict an adverse prognosis include early onset structurally severe disease, and increased QRS dispersion (a difference of >40 ms between maximum and

minimum QRS values, occurring in any of the 12 ECG leads). Electrophysiological testing by programmed ventricular stimulation is currently not useful in the risk stratification of patients with ARVC, with conflicting results. Genotyping may help in the assessment of SCD, and certain recessive forms of ARVC have been suggested to be more malignant. It is crucial to note that the potential prognostic benefits offered by ICD therapy may be tempered by the significant risk of complications with some unique to patients with ARVC. Areas of RV myocardium can be perforated during placement of RV leads, and fibrofatty changes in the RV may interfere with adequate lead positioning and compromise sensing of arrhythmias. Hence, indiscriminate ICD implantation may not be beneficial to the majority of patients.

Antiarrhythmic drugs and radiofrequency ablation have not been shown to reduce the risk of SCD in ARVC, but are often used as adjuncts to ICD implantation in patients with frequent ventricular arrhythmias and ICD therapies. In addition, strenuous activity is discouraged in patients with ARVC, due to the proarrhythmic effect of sympathetic stimulation and the risk of disease progression with increased mechanical stress.

Absence of structural heart disease

SCD most commonly occurs in patients with structural heart disease. However, SCD may occur in patients with an 'apparently' normal heart. Failure to detect structural abnormalities may depend on the unknown or concealed nature of the underlying pathological processes along with the limits of our diagnostic tools. This accounts for approximately 10%–12% of cases amongst populations under the age of 45, with a significantly lower proportion when older subjects are included. Previously, these have been termed 'idiopathic', but more complete evaluation has identified the cause of death or SCA as being a primary electrical disorder in many of these patients. Over the last decade, molecular genetic research has established a link between a number of inherited lethal cardiac arrhythmias and their genetic basis, involving mutations in genes encoding for ion channels or other membrane components. These account for the majority of the inherited arrhythmogenic syndromes, and they will be reviewed here.

Long-QT syndrome

Long-QT syndrome (LQTS) is a disease of abnormal myocardial repolarization and is characterized by a prolonged QTc interval on the ECG; syncope; and SCD due to ventricular arrhythmias, typically torsades de pointes (TdP). The syndrome can be congenital or acquired. Acquired LQTS is largely due to drug therapy (see Box 120.1)

Box 120.1 Commonly prescribed agents that prolong QT interval and should be avoided in patients with congenital long-QT syndrome

Antiarrhythmics

- Amiodarone
- Sotalol

Antibiotics

- Erythromycin
- Clarithromycin
- Ciprofloxacin

Antihistamines

- Terfenadine

Antidepressants

- Fluoxetine
- Sertraline
- Amitriptyline

or electrolyte imbalances (e.g. hypokalaemia and hypomagnesaemia), although it may also be secondary to cerebral injury, myocardial disease, and hypothermia. These factors may also unmask the congenital syndrome in a previously asymptomatic individual. LQTS is a potential cause of avoidable SCD, and is thought to be responsible for a significant percentage of all SCD.

The exact prevalence of congenital LQTS is unknown, due to its highly variable disease expression, but current estimates range from 1 in 2000 to 1 in 3000. LQTS is certainly the most common of the inherited arrhythmogenic syndromes. Two phenotypic variants have been described—an autosomal dominant form (Romano–Ward syndrome), which accounts for 90% of LQTS cases, and an autosomal recessive form in association with sensorineural deafness (Jervell and Lange-Nielsen syndrome). Molecular genetic studies have revealed a total of at least 12 forms of congenital LQTS, and the ‘family’ concept of syndromes has been applied to the multiple LQTS genotypes (LQT1–12). They result from mutations which occur in genes of the potassium, sodium, and calcium channels, or the membrane adaptor,

and which are located on chromosomes 3, 4, 7, 11, 12, 17, and 21. In all genetic forms, decreases in the outward potassium currents or increases in the inward sodium or calcium current prolong the action-potential duration, resulting in the common phenotype in LQTS, prolongation of the QT interval. The LQT1 and LQT2 syndromes are the two commonest genetic variants, each accounting for approximately 40% of genotyped patients. The LQT3 syndrome accounts for about 10% of genotyped patients. In LQT1, a mutation in *KCNQ1*, which encodes the alpha subunit of the potassium channel gene, is responsible for a defect (loss of function) in the slowly activating component of the delayed rectifier potassium channel. In LQT2, a mutation in *KCNH2* causes a defect in the rapidly activating component of the delayed rectifier potassium current. In LQT3, a mutation in *SCN5A*, the gene which encodes the alpha subunit of the sodium channel, results in an increase (gain of function) in the late sodium current (I_{Na}). At present, 65%–70% of affected individuals will have an identifiable mutation one of the genes known to cause LQTS. In many families, LQTS exhibits incomplete penetrance and variable expressivity; this observation suggests that factors other than the primary mutation can modify the probability of symptoms.

The genetic basis for congenital LQTS is given in Table 120.2.

The diagnosis of LQTS is clinical and relates to the ECG, clinical findings (syncope), and family history (unexplained SCD). Measurement of the QT interval in the ECG is the primary investigation, with intervals of >450 ms in men, and >460 ms in women, being suggestive of QT prolongation. The QT interval is frequently automatically calculated and printed on the 12-lead ECG but, unfortunately, errors occur frequently, largely due to incorrect determination of the end of the T wave, and incorporation of the U wave into the measurement. The QT interval has to be corrected for the heart rate, and the most common correction used is the Bazett’s formula. Incorrect calculation of the QT interval may lead to a false-negative or a false-positive diagnosis. Due to the differential modification of the ionic currents in each cell type by mutations in each LQTS gene, there is a variety of QT-interval and T-wave morphology. Broad-based prolonged T waves are more commonly seen in the LQT1 syndrome, whereas low-amplitude T waves with a notched or bifid configuration are observed more frequently in the LQT2 syndrome. LQT3 patients have late-appearing T waves with a prolonged isoelectric ST segment. However, there are exceptions for all three genotypes, and the T-wave pattern may vary with time in the same patient with a specific mutation. Measurement of the QT interval following exercise testing or at time of relative bradycardia on 24-hour ambulatory ECG monitoring may be useful in

Table 120.2 Genetic basis for congenital long-QT syndrome

Type	Locus	Gene	Protein	Function	Frequency
LQT1	11p15.5	KCNQ1	KV7.1 α	I_{Ks} ↓	30%–35%

identifying those who carry an LQTS mutation but have a normal QT interval on a 12 lead ECG at rest.

Commonly prescribed agents that prolong QT interval and should be avoided in patients with congenital LQTS are given in Box 120.1.

The criterion for the diagnosis of LQTS was upgraded in 1993, and is detailed in Table 120.3. Relative points are assigned to various

ECG, clinical, and familial findings, and the score ranges from a minimum value of 0 to a maximum value of 9. The point score is arbitrarily divided into three probability categories: (1) ≤1, low probability of LQTS; (2) 2 or 3 points, intermediate probability of LQTS; and (3) ≥4 points, high probability of LQTS.

The risk of SCD in LQTS is attributed to the underlying risk of developing ventricular tachyarrhythmias. In LQTS, the long QT interval and an appropriately timed ventricular ectopic (R on T phenomenon) may lead to the occurrence of TdP, a form of polymorphic VT. The variation in the QRS morphology and axis in TdP takes the form of a progressive, sinusoidal, cyclic alteration of the QRS axis. The peaks of the QRS complexes appear to 'twist' around the isoelectric line of the recording, hence the term TdP, or 'twisting of points'. TdP is usually short-lived and spontaneously terminates, but episodes can occur in rapid succession and may degenerate into VF leading to cardiac arrest and potentially SCD.

The clinical course, triggers, and risk stratification of patients with LQTS are variable, with a significant genotype-phenotype correlation, which has been demonstrated in clinical and experimental studies. This is especially evident in the LQT1, LQT2, and LQT3 syndromes.

In LQT1 patients, cardiac events were most frequent during exercise, with swimming a common trigger. In contrast, in LQT3 patients, cardiac events principally occurred during sleep and rest, and exercise-related events are rare. In LQT2, there was no predilection to cardiac events during exercise or at rest, but a sudden startle in the form of an auditory stimulus is a specific trigger (see Figure 120.1). Exercise should be limited more strictly in LQT1 patients, especially swimming and diving.

The overall population-based risk of patients with expressed phenotypic evidence is low when the patients receive appropriate treatment, most usually with beta blockers. The international LQTS registry indicates an approximately 4% risk of mortality over 40 years (i.e. 0.1%/year). There are statistically significant differences in the incidence of cardiac events and SCD, correlated to the genotype, with those with LQT2 and LQT3 having a greater risk than those with LQT1. Other indicators of high relative risk of SCD include a personal history of aborted SCD; syncope; or QTc >500 ms. Gender and age also play significant roles in influencing the clinical course of LQTS.

With regards to SCD, absolute rates in the respective genotype groups are as follows: LQT1, 0.3%/year; LQT2, 0.6%/year; and LQT3, 0.56%/year (Priori et al., 2003). Based on published data, the risk in LQTS may be determined as high (presence of aborted SCD +/- ECG documented episodes of TdP), intermediate

(time-dependent syncopal history +/- QTc >500 ms), and low (those free of previous syncope, and QTc <500 ms) (see Figure 120.2). However, as mentioned, risk factors in LQTS are also time dependent and age specific and these features need to be incorporated in any risk-stratification process. Cardiac events probably occur more commonly in children, with boys having a higher risk of events during preadolescence and girls having higher event rates in adolescence and thereafter. Recent data indicate that a family history of premature SCD is not an independent risk factor for subsequent lethal events in an affected individual. Invasive electrophysiological study (EPS) is not helpful in risk stratification of SCD in patients with LQTS.

Beta blockers are the mainstay of the treatment of LQTS. Nadolol and propranolol, agents that block both beta-1 and beta-2 adrenergic receptors, are often preferred, based on long-term experience with their usage. They are most effective in LQT1 patients, in whom the prognosis is excellent if patients avoid QT-prolonging drugs, and specific triggers such as competitive exercise. Although beta blockers are least effective in LQT3 patients, these drugs may still be beneficial. The mechanism of action is likely due to the decrease of adrenergic-mediated triggers in this condition. Patients should continue beta blockade, including during pregnancy and peripartum. However, despite the beneficial effects of beta blockade, high rates of cardiac events have been reported in those receiving this therapy, although data from numerous studies suggest that non-compliance and the use of QT-prolonging drugs underlie most life-threatening 'beta-blocker failures'. Therefore, patients who remain symptomatic despite beta blockade should be considered for more invasive therapies.

Potentially useful but unproven pharmacological options such as calcium-channel blockers, flecainide, and mexiletine are used in those with continuing symptoms with ICDs in situ. Surgical left cervicothoracic sympathetic denervation (LCSd) should be considered in patients with recurrent syncope despite beta blockade, in patients with a contraindication or intolerance to beta blockade, and in patients with arrhythmia storms with an ICD. LCSd leads to a significant reduction in the frequency of aborted SCD and syncope in high-risk groups, although it does not produce complete protection. It does provide a reasonable alternative to ICD implantation, particularly in children, where the ICD-therapy-associated comorbidity can be high. An ICD is indicated in LQTS patients who have survived an aborted SCD (as secondary prevention) and/or who have repetitive episodes of syncope in the presence of pharmacological and non-pharmacological therapy, regardless of genotype (primary prevention).

Although antibradycardic pacing has been used in selected LQTS patients with sinus bradycardia, long-term follow-up data show that the incidence of SCD in these patients is still unacceptably high. Pacemakers are thought to be beneficial in preventing TdP by suppressing pause-dependent QT prolongation, which is recognized more frequently in LQT2 patients. Focal radiofrequency ablation of ventricular premature beats which trigger VT/VF in LQTS has been reported. Preventative measures are crucial in LQTS, and adrenergic

and auditory stimuli, and QT-prolonging drugs, should be avoided. Further prospective and comprehensive study on genotype–phenotype correlation is needed to improve the management and treatment of patients with LQTS.

Short-QT syndrome

Congenital short-QT syndrome (SQTS) is a relatively recently described, novel inherited disorder characterized by a very short QT interval and by susceptibility to atrial fibrillation and VF, and hence SCD. Although the link between a short QT interval and SCD had been previously suspected, only in the last decade has SQTS been defined as a clinical syndrome. The definitive link between short QT interval and familial SCD was described by Gaita et al. (2003), with a clinical report of two families with SQTS and a high incidence of SCD. The prevalence of SQTS is not known and it appears to be extremely rare. At present, only a few families and some sporadic individuals have been reported to exhibit SQTS. The following features characterize the syndrome:

- an autosomal dominant pattern of inheritance
- a corrected QT interval of ≤ 320 ms
- an increased risk of SCD due to VF
- atrial fibrillation which occurs at a young age
- short atrial and ventricular refractory periods at EPS
- structurally normal heart

Although the penetrance of SQTS is high, its clinical manifestations can be quite variable, even amongst members of the same family. However, in the largest SQTS study (Giustetto et al., 2006), the most frequent symptom of SQTS is cardiac arrest, which is also the most frequent clinical presentation of this syndrome. First presentation can occur at any age, from a few months old to 60 years old, with the median age of presentation being 30 years. Atrial fibrillation is also common in SQTS, and occurs in some 80% of patients with SQTS, even if they are young. Therefore, in young patients presenting with lone atrial fibrillation, SQTS should be considered as a possible cause of the arrhythmia.

The diagnosis of SQTS is based on the patient's symptoms (syncope and palpitations), family history (syncope, SCD, or atrial fibrillation occurring at <30 years of age), and 12-lead ECG. Secondary causes of a short QT, such as hyperthermia, hyperkalaemia, hypercalcaemia, acidosis, and alterations of autonomic tone, must be excluded. The ECG is characterized by a strikingly short QT interval (typically <320 ms) with a virtual absence of the ST segment, with tall, peaked, narrow-based, symmetrical T waves. In addition, as SQTS is often diagnosed in childhood, the criteria for diagnosing SQTS sometimes includes an age- and gender-adjusted cut-off for the QT interval (a QT interval that is less than 80% of the predicted value is accepted to be consistent with SQTS).

The clinical significance of an incidentally short QT interval is uncertain; however, some have suggested that patients with a QTc

<330 ms (in the case of men) or <340 ms (in the case of women) should be considered to have SQTS even if they have no symptoms, as such short intervals are very rare in the general population. In addition, whereas, in healthy individuals, the QT interval shortens as the heart rate increases, those with SQTS exhibit a paradoxical shortening of QT intervals during slow heart rates, and little shortening with higher heart rates. Hence, frequent ECGs, 24-hour ECG monitoring, and exercise ECG testing can be used to diagnose SQTS in patients with a relative tachycardia at baseline. Invasive EPS in patients with SQTS reveals extremely short atrial and ventricular effective refractory periods. Additionally, in >90% of patients, ventricular tachyarrhythmias (predominantly, VF and ventricular flutter) were inducible.

SQTS is an autosomal dominant syndrome which, in some cases, is caused by mutations in cardiac ion channels. These mutations can lead to either hyperfunction of the delayed rectifier potassium current (KCNQ1, KCNH2, and KCNJ2), or hypofunction of the calcium current (CACNA1C and CACNB2B). As a result, the repolarization period is extended and there is an increase in the transmural dispersion of repolarization, with consequent short atrial and ventricular effective refractory periods, causing susceptibility to atrial fibrillation and VF. (Curiously, four of the five genes associated with SQTS have also been implicated in LQTS; in that case, the mutations lead to hypofunction of the potassium current.) However, these mutations do not occur in all cases of SQTS. In addition, there is no genotype–phenotype correlation for SQTS, due to the relatively few cases described. Nonetheless, genetic testing may assist in the diagnosis of SQTS in symptomatic patients with an abnormal but non-diagnostic ECG.

Although SQTS is characterized by high lethality due to an increased risk of SCD from fatal arrhythmias, there is, at present, insufficient data for risk stratification; therefore, it can be difficult to assess the extent of the risk in asymptomatic patients, especially when there is no family history of SQTS. Although ICD therapy is the only effective treatment for SQTS, it can be associated with T-wave oversensing. Thus, pharmacological therapy may be indicated, to prevent inappropriate ICD discharges or as an alternative to ICD therapy in the young. It has been shown that quinidine and disopyramide can prolong the QT interval; however, further clinical trials are needed before these drugs can be recommended for routine use in SQTS treatment.

Brugada syndrome

Brugada syndrome (BrS) is a clinical entity characterized by the triad of right bundle branch block, coved ST elevation, and risk of SCD as a result of ventricular tachyarrhythmias in an apparently normal heart. It is thought to be responsible for up to 4% of all SCD, and up to 20% of SCD in people under the age of 50 with structurally normal hearts. The prevalence of BrS is estimated at 1–5 in 10 000 worldwide, and studies in heterogenous populations suggest that the majority of affected individuals are Asian. It has a significant male preponderance, being as much as nine times higher in one analysis, with men also having a higher rate of syncope and SCD in a large prospective registry study.

BrS is inherited in an autosomal dominant fashion with incomplete penetrance. Genetic analyses have led to the identification of causative mutations in the SCN5A gene, which encodes the alpha subunit of a cardiac sodium channel, resulting in a functional reduction in the availability of the sodium current (and hence the use of sodium channels blockers in unmasking the Brugada pattern ECG). Of note, other mutations in SCN5A have been found in a number of other cardiac conditions, including LQTS. However, sodium-channel mutations only account for a maximum of 30% of cases, and underlying structural myocardial abnormalities have now been described in what was initially thought to be a purely functional disorder, with a number of studies demonstrating fibrosis in the Brugada right ventricle, suggesting a degenerative process.

Abnormalities in repolarization and depolarization in the RV outflow tract, and heterogeneities of conduction within the epicardium and between the epicardium and endocardium, have been proposed to be responsible for the ECG abnormalities and predisposition to ventricular tachyarrhythmias. Ventricular arrhythmias in BrS take the form of VT, most originating from the RV outflow tract, or VF. BrS is usually diagnosed in adulthood, with the average age of presentation being 41. It is rarely diagnosed in children. Symptoms at presentation are syncope, nocturnal agonal respiration, ventricular tachyarrhythmias, and SCD.

A number of ambiguities surround the diagnosis of BrS, with the characteristic ECG pattern being only one component of the diagnostic criteria of BrS. Patients with ECG changes typical of BrS but with no other clinical criteria are said to have the Brugada pattern but not BrS. Further, the characteristic ECG changes are also

Figure 120.3 Three different types of Brugada ECG pattern.

Reproduced with permission from Wilde et al., Proposed Diagnostic Criteria for the Brugada Syndrome: Consensus Report, *Circulation*, Volume 106, Issue 19, pp. 2514-2519, Copyright © 2002 Wolters Kluwer Health, Inc.

dynamic, and often concealed. Three types of repolarization patterns (recorded in right precordial leads V1–V3) are recognized, either occurring spontaneously or following pharmacological provocation. The type 1 Brugada pattern, initially described by the Brugada brothers (1992), is characterized by a prominent, coved ST elevation which is >2 mm (0.2 mV) and followed by a negative T wave (Figure 120.3). The type 2 pattern is characterized by a saddleback ST elevation which is >2 mm and followed by a trough of >1 mm ST elevation and then a positive or biphasic T wave; it may represent a less severe phenotype. The type 3 pattern is characterized by a saddleback or coved appearance, with an ST elevation of <1 mm. There can be significant variation in the ECG patterns seen in a patient over time. The Arrhythmia Working Group of the European Society of Cardiology published a consensus statement in 2002 based on the available clinical data and molecular basis of BrS. The diagnosis of BrS should be strongly considered in the following two cases:

- the appearance of a type 1 ST elevation in more than one right precordial lead, in the presence or absence of a sodium-channel blocker (with no other factors that can account for the ECG abnormality) and one of the following:
 - documented VF
 - self-terminating, polymorphic VT
 - a family history of SCD (<45 years)
 - a type 1 ECG pattern in family members
 - inducibility of VT on electrophysiologic testing
 - syncope
 - nocturnal agonal respiration
- the appearance of type 2 or 3 ST elevation ('saddleback type') in more than one precordial lead under baseline conditions, with conversion to type 1 ST elevation following a challenge with a sodium-channel blocker, and one of the following features:
 - documented VF
 - self-terminating, polymorphic VT
 - a family history of SCD (<45 years)
 - a type 1 ECG pattern in family members
 - inducibility of VT on electrophysiologic testing
 - syncope
 - nocturnal agonal respiration

Drug-induced conversion of type 3 to type 2 ST elevation is considered inconclusive.

Clinical diagnostic evaluation to exclude other causes is crucial, as there are numerous factors that may contribute to ST-segment

elevation. Distinguishing between BrS and ARVC may be challenging, and any structural abnormalities may be found only at the time of autopsy. BrS should also be distinguished from early repolarization syndromes (with eventual J-wave elevation in the left precordial leads), and drug challenges might provide the clue for a proper diagnosis.

The role of genetic testing in diagnosing BrS is limited by the fact that only 18%–30% of BrS patients have mutations in the SCN5A gene, and not all patients with documented Brugada SCN5A mutations have BrS. The use of genetic testing is probably most useful in the context of screening of relatives with BrS patients who have documented specific SCN5A mutations.

The management of patients with BrS largely involves the prevention of SCD. SCD or an aborted SCD (SCA) may be the first and only clinical event in BrS, occurring in as many as a third of BrS patients. Arrhythmic events tend to occur between the ages of 22 and 65, with a nocturnal predilection. SCA is not usually related to exercise, with frequent spontaneous ventricular premature beats preceding an arrhythmia. Risk stratification usually begins with eliciting a history of associated symptoms (previous SCA or syncope).

The role of ICD implantation in secondary prevention in BrS is established, with previous SCA having the highest risk, and a Class I indication. Risk stratification for implantation of primary-prevention ICD (which is the only effective therapy for preventing SCD in BrS) remains controversial, particularly in entirely asymptomatic patients. The benefits of ICD therapy have to be balanced against the potential complications, especially in a younger population of patients, with the need for recurrent generator box changes, and the presence of endocardial leads which might be in situ for many decades. The use of a subcutaneous ICD, which would negate the need for an endovascular lead, may be an attractive alternative. There is a strong evidence base for the prognostic impact of syncope in BrS, and this is a Class IIa indication for ICD implantation. Data from published registries also suggest that a spontaneous (rather than drug-induced) type 1 Brugada ECG and male gender were predictors of arrhythmic events. Of note, familial history of SCD was not predictive of arrhythmic events.

The significance of the inducibility of ventricular arrhythmias during programmed electrical stimulation is not entirely clear. Although this investigation is recommended in the second consensus statement on BrS (endorsed by both the Heart Rhythm Society and European Heart Rhythm Association), several studies published since have shown no prognostic impact from the inducibility of ventricular

Figure 120.4 ECG abnormalities which are diagnostic or suspect of Brugada syndrome. Type 1 (coved-type ST-segment elevation) is the only diagnostic ECG in Brugada syndrome and is defined as a J-wave amplitude or an ST-segment elevation of ≥ 2 mm or 0.2 mV at its peak (followed by a negative T wave with little or no isoelectric separation). Type 2 (saddle-back-type ST-segment elevation), defined as a J-wave amplitude of ≥ 2 mm, gives rise to a gradually descending ST-segment elevation (remaining ≥ 1 mm above the baseline) followed by a positive or biphasic T wave that results in a saddle-back configuration. Type 3 is a right precordial ST-segment elevation (saddle-back type, coved type, or both) without meeting the aforementioned criteria.

arrhythmias. The current tools used for risk stratification are not precise, but careful individual patient assessment can yield an estimate of the risk of SCD, and this can be balanced against risks of ICD therapy.

There are pharmacological agents that have been proven to reduce the risk of SCD, including beta blockers and amiodarone. There is some data suggesting the beneficial effects of quinidine, although its use is limited by significant gastrointestinal side effects and prolongation of the QT interval. A multicentre trial of quinidine therapy in asymptomatic patients is currently in progress. Invasive ablative approaches (mapping and ablation of triggers of VF) have also been reported.

As with LQTS, a number of drugs are contraindicated in patients with BrS, as they can provoke the development of type 1 ECG changes. A comprehensive and up-to-date list is available on the website <http://www.brugadadrugs.org>. Fever can also provoke type 1 ECG changes and should be treated aggressively (Figure 120.4).

Catecholaminergic polymorphic VT

Catecholaminergic polymorphic VT (CPVT) is an inherited arrhythmogenic syndrome that is characterized by adrenergically mediated ventricular tachyarrhythmias manifesting in syncope, cardiac arrest, and SCD in young individuals in the absence of structural heart disease. Characteristically, CPVT-associated arrhythmic events are triggered by catecholaminergic stimulation. Thus, they occur under conditions of physical and also mental stress. Sudden noises, physical pain, fear, or sudden movements are all associated with catecholamine release, and can trigger arrhythmias in the setting of CPVT. It was first described by Coumel et al. (1978), but its genetic bases were only discovered in 2001. The prevalence of CPVT in Europe is 1 in 10 000, and it is an important cause of SCD in the young, with some reports suggesting that it may account for 1 in 7 cases of sudden unexplained death. The mean onset of symptoms is between 7 and 9 years of age, with no gender difference. However, it may also manifest in adulthood. SCD can be the manifestation of the disease in a subset of patients (10%–20%). In untreated patients, 8-year overall arrhythmic event rates of 58% and fatal or near-fatal rates of 25% have been reported, and these are higher in patients with aborted SCD.

Most cases of CPVT are caused by autosomal dominant mutations in RYR2, which encodes the cardiac isoform of the ryanodine receptor, which is a calcium channel. CPVT can also be caused by recessive mutations in CASQ2, which encodes the cardiac isoform of calsequestrin, a calcium-binding protein found in the sarcoplasmic reticulum; however, only ~2% of CPVT cases are due to CASQ2 mutations. Both RYR2 and CASQ2 are involved in the control of calcium release from the sarcoplasmic reticulum. Consequently, mutations in these genes lead to an inappropriate release of calcium from the sarcoplasmic reticulum, causing cytosolic calcium overload and thus delayed after-depolarization, triggered activity, and ventricular arrhythmias, especially when beta-adrenergic tone is increased. As with LQTS, CPVT is characterized by variable penetrance, although patients with CASQ2 mutations are thought to carry a greater risk of arrhythmia. In addition, silent mutation carriers (i.e. patients who have a mutation in RYR2 or CASQ2 but do not exhibit ventricular arrhythmia on exercise testing) are also at increased risk of arrhythmia.

The clinical diagnosis of CPVT is made on the basis of symptoms, a family history, and response to exercise or catecholamine infusion. Clinical symptoms can vary from mere palpitations to syncope and SCD. Unfortunately, individuals with CPVT often have normal resting ECGs, so diagnosis is difficult and, not infrequently, these patients are given a diagnosis of 'LQTS with normal QT'. Treadmill ECG or IV catecholamine infusions are the key investigation in terms of the clinical diagnosis, as the arrhythmias are usually reproducible. The 'textbook' arrhythmia with exercise is that of polymorphic or bidirectional VT (beat-to-beat alternation of the QRS axis), but patients may only develop increasing polymorphic ventricular extrasystoles. Although bidirectional VT has been thought to be the hallmark of this condition, this arrhythmia can sometimes occur in other channelopathies, for example LQTS, although this is usually associated with an abnormal resting ECG. Holter monitoring is indicated in the rarer cases where acute emotion represents a more powerful trigger. The

sensitivity (diagnostic yield) from genetic testing is reasonably high; it is approximately 80% in those with typical features, although a negative test does not remove the diagnosis. A positive test has important prognostic implications for the individual patient, and for screening of family members. There is no role for EPS in determining prognosis, as it has poor specificity and sensitivity for 'clinical' arrhythmias with and without catecholamine stimulation.

The risk stratification of SCD in various subgroups in CPVT is much less well defined than that of other inherited arrhythmogenic syndromes such as LQTS and BrS, due to the recent characterization and relative rarity of CPVT, and the current evidence is based on considerably fewer patients. Consequently, it can be difficult to determine whether a CPVT patient is at such low risk of serious arrhythmias that treatment is not required.

Beta blockers (nadolol and propranolol) are the most effective drugs for treating ventricular arrhythmias and preventing arrhythmic events. The use of beta blockade is suggested for all mutation carriers, even those without symptoms. This is due to the possibility of these mutations being highly penetrant, with fatal or near-fatal event rates being as high in family members as in probands. Some reports have suggested that beta blockade should be increased to such a dose as to ensure a maximum exercise heart rate of 110 bpm, based on its effectiveness in suppressing ventricular arrhythmias. As CPVT patients tend to be relatively young, fatigue and other side effects of beta blockers may cause significant limitations to daily life and influence therapeutic compliance. The outcome of exercise stress tests during monitoring are significantly associated with subsequent clinical events, including mortality. The use of calcium-channel antagonists of the verapamil type (L-type calcium-channel blocker) has not been proven to be efficacious in patients who have contraindications to beta blockade, or those who continue to have symptoms on beta blockade and so require additional treatment. An important new development is the discovery that flecainide (a Class Ic antiarrhythmic agent) has RYR2-blocking properties and so directly targets the molecular defect in CPVT. Flecainide greatly reduced the incidence of ventricular arrhythmia during treadmill ECG testing in patients with CPVT. It is unclear whether it is effective in genotype-negative CPVT, and whether it should be used as first-line therapy, either in concert with beta blockers or on its own; however, there is an ongoing randomized clinical trial addressing these questions prospectively.

LCSD may be useful in patients with uncontrolled ventricular arrhythmias on medical therapy, and in patients with ICD, to reduce appropriate ICD therapies. CPVT patients presenting with VF or an aborted SCD without a reversible cause should have an ICD implanted in addition to beta blockade and/or flecainide/LCSD. Patients experiencing exercise-induced ventricular arrhythmias syncope (when VT/VF has not been excluded as the cause) despite medical therapy and/or LCSD should be considered for ICD therapy also. It should, however, be noted that ICD use may have harmful effects in CPVT patients. Both appropriate and inappropriate therapies can trigger catecholamine release, subsequently triggering further VT/VF and resulting in multiple shocks, arrhythmic storms, and death. As such, ICD therapy does have a proarrhythmic potential. Thus, the prevention of VT is crucial even in ICD recipients.

As previously mentioned, CPVT patients are young, and so ICD therapy may produce significant problems. Due to the increased incidence of supraventricular tachyarrhythmias in CPVT patients, they are at an increased risk of receiving inappropriate therapies. This can be prevented with careful ICD programming. Although CPVT is a severe and often lethal disease, early diagnosis and proper treatment can greatly increase life expectancy. Exercise restriction along with medical therapy (and emphasis on importance of drug compliance) and ICD implantation in patients with recurrent symptoms have resulted in a favourable prognosis. The use of sympathomimetic agents is contraindicated in patients with CPVT.

121 Cardiac device therapy

Kim Rajappan

The term 'device therapy' is used in cardiology to refer to three different types of implantable cardiac-rhythm-management devices: pacemakers, implantable cardioverter defibrillators (ICDs), and cardiac resynchronization therapy (CRT) devices. There has been a steady increase in the number of patients receiving these cardiac devices; in relation to CRT devices, the increase has been almost exponential.

Pacemakers

Background information for pacemakers

Permanent pacemakers (PPMs) are implanted devices that sense intrinsic cardiac electric activity and, if this falls below a given rate, generate impulses to stimulate atrial and/or ventricular contraction.

How PPMs work

PPM systems consist of an implantable pulse generator (IPG) and pacing leads, placed transvenously in the myocardium of the right atrium and/or ventricle. Current leads are almost always bipolar (i.e. they have anode and cathode rings at the tip of the lead), so pacing and sensing only occurs at the tip, unlike unipolar leads, in which the cathode is at the tip, and the IPG acts as the anode. The main advantage of a bipolar lead is that there is much less chance of interference from extrinsic factors such as muscle artefact. The IPG is placed subcutaneously or submuscularly in the chest wall, most commonly in the left infra-clavicular position.

The pulse generator contains electronic sensing, timing, and output circuitry, and a battery (typically lithium-iodide, with a battery life of 7–10 years), housed in a steel case. The sensing circuitry detects intrinsic activity in the cardiac chamber in which the lead is placed. If no activity is detected over a specified interval, an impulse is generated (and may be visible on the ECG as a pacing artefact preceding the P wave or QRS complex). Depolarization of the cardiac chamber occurs by muscle-to-muscle spread of the impulse; with right ventricular pacing, this results in a broad QRS complex on the ECG, of left bundle branch block (LBBB) morphology.

There are three types of pacemakers:

- a single-lead atrial pacing system
- a single-lead ventricular pacing system
- a dual-lead atrial and ventricular pacing system

Single-lead atrial pacing system

In a single-lead atrial pacing system (which can be used with the pacing modes AAI or AAIR), the pacemaker senses and paces the right atrium. If no intrinsic activity is sensed (i.e. no P wave detected), the pacemaker paces the right atrium at its programmed rate. Use of the AAIR mode provides the capability to increase the atrial pacing rate in response to stimuli such as movement, conferring an increase in heart rate with exercise.

Single-lead ventricular pacing system

In a single-lead ventricular pacing system (which can be used with the pacing modes VVI or VVIR), the pacemaker senses and paces the right ventricle. If atrial activity is conducted through the conduction system and depolarizes the ventricles, the pacemaker is inhibited. If no intrinsic activity is sensed (i.e. no R wave detected), the pacemaker paces the right ventricle at its programmed rate. Use of the VVIR mode provides the capability to increase the ventricular pacing rate in response to stimuli such as movement, conferring an increase in heart rate with exercise.

Dual-lead atrial and ventricular pacing system

In a dual-lead atrial and ventricular pacing system (which can be used with the pacing modes DDD or DDDR), the pacemaker senses and paces both the right atrium and right ventricle. If no intrinsic activity is sensed in the right atrium, the pacemaker paces the right atrium at its programmed rate. If the intrinsic or paced atrial activity is not conducted to the ventricles within a preset interval, the pacemaker paces the right ventricle. Use of the DDDR mode provides a rate-adaptive capability.

Pacemaker programming

Programming the mode of a pacemaker can be performed non-invasively by an appropriately trained individual using the appropriate programmer for that device. As there are many pacemaker types, patients should carry with them a card providing information about their particular make and model. Most pacemaker generators have an X-ray code that can be seen on a chest radiograph; however, the chest radiograph may need to be zoomed onto the pacemaker generator for better resolution.

Indications for pacing

Indications for pacing (either temporary or permanent) can be divided into those where pacing can be used to prevent symptoms related to bradycardia, and those where pacing can be used to prevent asystolic arrest. International and national guidelines have been written about the indications for pacing; the following constitute a summary of these indications:

- complete atrioventricular (AV) block (third-degree block; whether symptomatic or asymptomatic)
- second-degree AV block Möbitz type II (whether symptomatic or asymptomatic)
- alternating left and right bundle branch block
- sick sinus syndrome
- symptomatic sinus bradycardia
- tachy brady syndrome
- atrial fibrillation with sinus node dysfunction (Figure 121.1)
- chronotropic incompetence (inability to increase the heart rate appropriately during exercise)

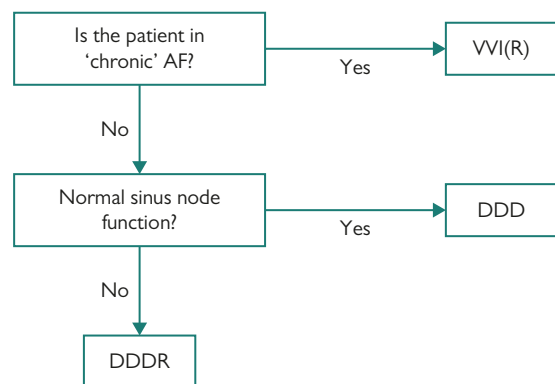

Figure 121.1 Choice of type of permanent pacemaker; AF, atrial fibrillations.

Note that first-degree AV block or Möbitz type I second-degree AV block (Wenckebach) are not clear indications for pacing. Neither is bundle branch block per se, even in the presence of axis deviation and prolonged PR interval, unless it is associated with presyncope/syncope.

Temporary emergency pacing is indicated for the treatment of significant and haemodynamically unstable bradyarrhythmias; for the prevention of bradycardia-dependent malignant arrhythmias when permanent pacing cannot be immediately performed (however, ideally, a permanent system should be implanted as soon as possible to minimize the risk of complications from having a temporary pacing lead); and, very occasionally, where there is a significant chance of recovery of normal conduction (e.g. transient AV block after an inferior myocardial infarction (MI)).

How to implant pacemakers

Pacemaker implantation is typically a day-case procedure. Most pacemakers are implanted in the prepectoral region, just below the clavicle. The most common access route for the pacemaker leads is via the axillary or subclavian vein. This may be through a direct puncture into the vein, or through the cephalic vein, which drains into the axillary vein.

There are a number of different types of pacemaker leads. Lead design has been a major area of development; however, at present the majority of leads consist of conducting coils that are surrounded by insulating material. The outer coating is predominantly made of polyurethane. The lead tips are held in place by one of two methods. The first method is 'passive' fixation, which uses small anchoring tips, or 'tines', which hook into the trabeculation of the tissue. Over a short period, these tips cause fibrotic tissue to form, which helps keep them in place. The second method, known as 'active' fixation, uses a small helical screw that extends out of the tip of the lead and holds the lead in position. The advantage of the active fixation method is that the lead can be inserted into any tissue, not just those areas that have trabeculation. This is often useful when it is necessary to place a lead on the right ventricular septum rather than on the right ventricular apex. The active fixation leads are also normally easier to extract if necessary. However, the passive fixation leads are easier to implant.

During pacemaker placement, the lead parameters are measured and checked to make sure they are optimal. The threshold for the pacing voltage is the minimal voltage (at a given pulse duration) required for depolarization ('capture') of the myocardium that a lead requires to capture myocardium, and the aim is to get readings as low as possible. The signal amplitude (i.e. the size of the intrinsic P or R wave) is also measured. The sensing on the lead is important, as it determines whether the pacemaker will or will not pace. The output and sensing are set high enough to reliably achieve myocardial capture, yet low enough to maximize battery life. Once the leads are in place, they are secured, the IPG is connected, and the entire system is inserted into a pocket which is fashioned in the prepectoral region. Programming of the pacemaker can then be performed remotely.

Temporary systems use an external pulse generator with skin pads or with transvenous leads. Transcutaneous temporary pacing can be instituted quickly, and is the preferred method for use cardiopulmonary resuscitation. Transcutaneous pacing may be uncomfortable, and the patient may require sedation (e.g. benzodiazepine). Once the patient is stabilized and central venous access is gained, transvenous temporary pacing provides a more reliable and comfortable method and is a good bridge to permanent pacing.

Complications of pacemakers

Pacemaker complications include lead displacement, with consequent pacemaker malfunction; cardiac perforation; complications associated with venous access; bleeding; and infection. The administration of antibiotics prior to and around the time of the procedure (including injection of antibiotics into the pocket) may reduce infection risk. However, only preprocedure antibiotics have clear evidence of benefit.

Pneumothoraces may require medical observation, needle aspiration, or even chest-drain placement. Erosion of the PPM through the skin, while rare, normally requires extraction of the entire system and

replacement after systemic antibiotics. Haematomas may be treated with direct pressure and observation, but occasionally require surgical drainage, carrying a risk of introducing infection. If lead displacement occurs, it typically does so within 2 days of implantation, and may be visible on chest radiography. Fluctuating lead impedance may also indicate lead displacement, lead impedance is normal when it is in contact with the endocardium, but infinite (or very high) when not. Free-floating ventricular leads may trigger malignant arrhythmias due to mechanical stimulation of the myocardium.

Device-associated deep vein thrombosis is rare. It typically presents with ipsilateral swelling of the arm. Treatment includes elevation of the arm, and anticoagulation.

Advanced Life Support protocols, including defibrillation, may safely be performed for patients with pacemakers. It is recommended that sternal pads are placed at a safe distance (10–15 cm) from the IPG—for a left-sided device, normal pad positions to the right of the sternum and at the apex should be fine. Anterior and posterior positions tend to be acceptable as well, particularly when used for elective cardioversion of atrial fibrillation in a patient with a cardiac device. Temporary pacing may very occasionally become necessary in cases of MI, as the programmed pacemaker output settings may be insufficient to stimulate ventricular contraction if the lead is close to or within the infarcted tissue. If a suitable programmer is available, the output from the permanent pacemaker can be increased and may overcome this.

Pacemaker malfunction may be suspected when a patient with a pacemaker reports presyncope or syncope, or the ECG does not show normal pacemaker function. With new algorithms to preserve intrinsic conduction, the ECG may suggest pacemaker malfunction, whereas, in fact, the appearances reflect normal programmed function. Types of pacemaker malfunction and their causes are summarized in Table 121.1. In suspected pacemaker malfunction, the details of the pacemaker should be checked (to determine if it is a single- or dual-chamber system, and the pacing mode), and a 12-lead ECG, with a long rhythm strip recorded. Chest radiography will establish the position of the leads and may provide evidence of lead fracture; lead fracture most commonly occurs from compression of the lead between the clavicle and the first rib, or entrapment in the subclavius muscle or the costoclavicular ligament, so the segment of the lead in these areas should be carefully examined.

Table 121.1 Types of pacemaker malfunction and their causes

Type of malfunction	Causes
No pacing stimulus when appropriate	Lead displacement Complete lead fracture Output failure due to complete battery depletion or component failure Oversensing
Oversensing (i.e. no pacing stimulus when appropriate, but pacing stimuli seen with fixed-rate pacing)	Inhibition of pacing due to inappropriate sensing of cardiac or non-cardiac electrical activity, with sensing of: <ul style="list-style-type: none"> ● P wave or T wave by the ventricular lead ● pectoral muscle or diaphragm contraction ● electromagnetic interference (e.g. diathermy) ● electrical noise created by partial lead fracture
Failure to capture (i.e. pacing stimulus present but not followed by P wave or QRS complex)	Poor connection between lead and pulse generator (loose set screw) Lead displacement Partial lead fracture or insulation break Myocardial perforation Inflammation or fibrosis at lead–myocardium interface Increase in pacing threshold due to effect of drugs (e.g. flecainide) or metabolic disorder (e.g. hyperkalaemia) Pacing stimulus delivered in ventricular refractory period because of undersensing
Undersensing (i.e. pacing stimulus seen when not appropriate)	Lead displacement Myocardial perforation Inflammation or fibrosis at lead–myocardium interface Low-amplitude P/R wave not sensed Sensing threshold too high

Full interrogation of the pacemaker should be done as soon as possible. Application of a magnet over the pulse generator closes a reed switch and turns off the sensing function. This results in fixed-rate pacing, and so can be used to distinguish between output failure and oversensing as causes of inappropriate pacing. Abnormal or changed lead impedance may indicate lead failure. A break in the lead insulation results in a very low impedance, while a complete lead fracture results in a very high impedance. Reprogramming of the pacemaker may be able to address the cause of pacemaker malfunction (e.g. achieve a correct sensing threshold), or provide a temporary solution pending revision of the pacing system. If pacemaker malfunction is confirmed, and the patient is at risk of presyncope/syncope, temporary pacing should be instituted prior to definitive management.

Pacemaker syndrome is the occurrence of dizziness or exertional breathlessness due to loss of AV synchrony, when a single-chamber ventricular pacemaker is inserted in the presence of sinus rhythm, and is treated by upgrading the system to dual-chamber pacing.

Twiddler's syndrome is caused by the (usually subconscious) manipulation of the pulse generator in its subcutaneous pocket, with twisting or coiling of the leads, resultant lead displacement or fracture, and pacemaker malfunction. This is managed by revision of the pacing system, with lead repositioning or replacement, suturing of the pulse generator to subjacent tissues, or placement of the generator in a submuscular pocket, together with counselling of the patient.

In a patient with a dual-chamber pacemaker, and intact retrograde conduction through the AV node, a ventricular extrasystole may result in atrial depolarization, which is sensed by the atrial lead and triggers ventricular pacing, initiating a self-sustaining re-entry circuit. The result is a regular broad-complex tachycardia, at the upper tracking rate of the pacemaker. Application of a magnet disables sensing by the pacemaker and terminates this arrhythmia (pacemaker-mediated tachycardia). Current pacemakers have algorithms to prevent this occurring.

Impact of PPMs on life expectancy and quality of life

In some patients (e.g. those with third-degree (complete) heart block), death is prevented by the insertion of a PPM. In others (e.g. those with tachy brady syndrome), the indication for PPM insertion is mainly to deal with symptoms and improve quality of life.

ICDs

Background information for ICDs

An ICD is designed to directly treat ventricular tachyarrhythmias. If the device senses a ventricular rate that exceeds the programmed threshold, the device may observe with no action, perform anti-tachycardia pacing, deliver a low-energy, synchronized shock, or deliver a high-energy unsynchronized shock (defibrillation). With anti-tachycardia pacing, the device fires a preset number of rapid pulses in succession, in an attempt to terminate the ventricular arrhythmia. This is usually painless. If unsuccessful or if the rate falls above the preprogrammed cut-off rate, the device will perform a cardioversion/defibrillation. Transvenous ICDs (TV-ICDs) are also equipped with a demand pacing system and so can act as a pacemaker as well. Subcutaneous ICDs (S-ICDs) can currently effectively only provide defibrillation, but do not have a lead in the venous system, avoiding all of the associated complications.

How ICDs work

The main difference between a pacemaker and a TV-ICD in terms of components is the presence of a capacitor in the latter. This is needed to store charge before delivering defibrillation and can be used on a chest radiograph as one of the means of distinguishing an ICD from a pacemaker (the others being that fact that ICDs are normally larger than pacemakers and that the ICD lead in the ventricle has one or more coils on it to deliver energy to the tissue). The S-ICD generator sits under the left arm near the mid-axillary line, with the lead running subcutaneously to the xiphisternum and up along the sternum towards the manubrium.

The pacemaker function and coding in a TV-ICD is the same as in a standard pacemaker. The tachycardia therapy delivered by the TV-ICD can be programmed in a variety of ways. Normally, one or more 'zones' are defined. For a defined range of ventricular rates, the ICD is programmed to behave in one of three ways: (1) do nothing and record the rhythm (a monitor zone); (2) deliver anti-tachycardia pacing; or (3) deliver a shock (possibly having delivered anti-tachycardia pacing already). The way in which the device is programmed depends upon a number of factors, including the original reason for the implant, whether or not ventricular tachycardia (VT) or VF has been seen before, and the age of the patient. The S-ICD has simpler programming as it only provides defibrillation.

Indications for an ICD

ICDs were first used for secondary prevention in patients who had had life-threatening ventricular arrhythmias and were survivors of cardiac arrest. Recent trials have shown that for selected patients, ICDs are beneficial for the primary prevention of sudden cardiac death as well. Trials have demonstrated that, in post-MI patients with reduced ejection fraction primary prevention with ICD over conventional medical therapy saved lives. Further studies have shown that primary prevention using ICDs in other patient groups (e.g. hypertrophic cardiomyopathy with high-risk features) is also beneficial.

In the case of post-MI patients, no mortality benefit was observed from placing ICDs in those with reduced ejection fraction until after 40 days post-MI, probably because death in this early period is more likely to be due to non-arrhythmic causes.

International guidelines exist regarding the indications for ICDs, but in different countries this may be determined by local policies/economic constraints; however, broadly speaking, the indications include the following:

- survival of cardiac arrest due to VF or haemodynamically unstable sustained VT, after evaluation to define the cause of the event and to exclude any completely reversible causes
- structural heart disease and spontaneous sustained VT (stable or unstable)
- syncope of undetermined origin with clinically relevant, haemodynamically significant sustained VT or VF induced at electrophysiological study
- left ventricular ejection fraction (LVEF) <35% due to prior MI, in patients who are at least 40 days post-MI and who are in New York Heart Association (NYHA) Functional Classes I–III
- non-ischaemic dilated cardiomyopathy with LVEF ≤35%, in NYHA Functional Class I–III patients
- non-sustained VT due to prior MI, LVEF < 40%, and inducible VF or sustained VT at electrophysiological study
- hypertrophic cardiomyopathy in patients who have a greater than 1% per annum risk for sudden cardiac death as assessed by the European Society for Cardiology risk calculator or similar risk scores
- specific individuals with inherited cardiac conditions such as long-QT syndrome or Brugada syndrome, who have an increased risk of sudden cardiac death

How to implant ICDs

Implantation of a TV-ICD is similar to that of a pacemaker. The main differences are as follows: first, a larger pocket is normally required for an ICD than for a pacemaker, as an ICD is larger than a pacemaker; second, because patients requiring ICDs will often have structurally abnormal hearts (e.g. scarring in the right ventricle, in a patient with arrhythmogenic right ventricular cardiomyopathy), placing the leads in positions with optimal pacing and sensing parameters may be more difficult for an ICD than for a pacemaker; and third, unlike the case with pacemaker implantation, after implanting the ICD, it is sometimes necessary to test its detection and treatment of VF by inducing VF and letting the ICD treat it. However, this test is being performed much less frequently, particularly with primary prevention devices, as ICDs have become very reliable, and the VF induction does carry a small risk of death.

An S-ICD is normally implanted under general anaesthetic and in a very different position to that for the TV-ICD. The generator is inserted into a pocket between serratus anterior and latissimus dorsi

on the left and the defibrillator lead is tunnelled from there to the midline at the xiphisternum and up along the sternal edge towards the head. Currently, it is necessary to always induce VF and test these devices.

Complications of ICDs

All of the complications that occur with pacemakers can also occur with TV-ICDs. In addition, because the hearts that these devices are implanted into often have structural abnormalities, it is more common to see problems with sensing and pacing (not only at implantation, as previously mentioned, but also later on). An S-ICD does not carry any of the risks that are associated with vascular access though.

The generators still remain larger for ICDs than for pacemakers, so erosion is slightly more common.

Inappropriate shocks, and shocks while the patient is conscious, are ICD-specific problems. If the ICD detects tachycardia that fulfils all programmed parameters requiring treatment with a shock, then it will deliver that therapy. The most common inappropriate shock comes from atrial fibrillation with a rapid ventricular response, as this condition is incorrectly detected and treated as either VT or VF by the ICD. There are a number of algorithms on ICDs that can be used to try and minimize this problem but none are completely fail-safe.

The ICD also cannot determine if the patient is conscious. Therefore, if an arrhythmia which the ICD deems should be treated with a shock occurs when the patient is conscious, then the patient will receive a shock while still conscious. Most patients describe this experience as being very painful, and receiving such shocks can cause significant psychological disturbance.

Failure of an ICD to deliver an appropriate shock may be caused by similar problems to a pacemaker if the sensing is incorrect (see Table 121.1). This could be caused by lead fracture, electromagnetic interference, or inadvertent ICD deactivation. Management includes external defibrillation, and antiarrhythmic medications. Ineffective cardioversion may result from an inadequate energy output from the device. This is much less common with modern devices, which produce higher energy shocks than older devices do. A rise in the defibrillation threshold may occur for a variety of reasons, including:

- the use of antiarrhythmic medications such as amiodarone, flecainide, or phenytoin
- infarction of the subjacent myocardium
- fracture of the lead insulation
- scarring at the lead implantation site
- lead displacement.

Many ICDs deliver a programmed set of therapies per arrhythmic episode, and the number of therapies per episode is program specific. If a delivered therapy does not terminate the arrhythmia, the device proceeds to the next programmed therapy. For example, say that a total of six attempts at defibrillation are attempted per episode of VF. The device attempts defibrillation with the first programmed therapy and then re-evaluates the cardiac rhythm. If the arrhythmia persists, the device will deliver the second programmed therapy, and so on, until all six attempts have been delivered. Once the final attempt has been delivered, the device will not deliver any further therapy until a new episode is recognized. Therefore, theoretically, the therapies may be exhausted before the arrhythmia is terminated. As a result, ICDs do not prevent all sudden deaths, and it is important to understand that cardiac arrest in a patient with an ICD is not necessarily a sign that the ICD malfunctioned: the device may have properly delivered the required shocks for the triggering rhythm but the shocks themselves may have been ineffective in resolving the arrhythmia. This highlights the very important point that the use of an ICD is not a guarantee that a patient will not die from VT/VF.

Impact of ICDs on life expectancy and quality of life

The main reason for implanting an ICD is to increase life expectancy. This may be for primary prevention or for secondary prevention (see 'Indications for an ICD'). Where there is also a pacing indication, or when a combined CRT defibrillator is implanted (see 'CRT devices'), there may be improvement in quality of life. However, many patients

will not see any change in quality of life at all and, owing to the risk of inappropriate or conscious shocks, quality of life may actually be reduced for some patients. End-of-life management is an increasingly important aspect of ICD patient care. Decisions need to be made around the time of a patient's end of life about what to do with the ICD programming to allow a dignified and comfortable death.

CRT devices

Background information for CRT devices

Heart failure is a complex condition caused by structural or functional cardiac disorders which impair the heart's ability to function efficiently as a pump to support physiological circulation. In a healthy heart, the ventricles contract synchronously (i.e. the walls contract almost simultaneously). In some people with heart failure caused by left ventricular (LV) systolic dysfunction, the left ventricle contracts dyssynchronously, either because of dyssynchrony within the ventricle itself (intraventricular dyssynchrony), or because of dyssynchrony with the right ventricle (interventricular dyssynchrony). If the contractions lack synchrony, the heart becomes less efficient as a pump. People with heart failure, who have a reduced LVEF, and, on an ECG have characteristic changes due to abnormal electrical conductivity (normally LBBB, with a QRS duration >150 ms) can be considered for CRT. Echocardiographic assessment, which measures aspects of mechanical dyssynchrony, can also be used to identify patients whose condition is likely to respond to CRT, although it has not proven to be very reliable or reproducible.

How CRT devices work

A conventional pacemaker may have either one or two leads normally. A dual-chamber pacemaker maintains AV synchrony. In contrast, a CRT device aims to restore ventricular synchrony. To do this, it is necessary to pace the left ventricle at two distinctly different sites, generally with the aim of forcing the two walls of the ventricle to actually contract almost simultaneously. The most common way to do this is to first implant a right ventricular lead (and an atrial lead if the patient is in sinus rhythm) in the standard way. This effectively paces the septal wall of the left ventricle. A lead is then implanted on the lateral wall of the left ventricle; when connected to the CRT generator, this can then force contraction of both walls to occur with minimal delay. An ICD component can also be added simply by using a right ventricular ICD lead and a CRT defibrillator generator (CRT-D) instead of a standard CRT pacemaker (CRT-P).

Indications for CRT devices

As with ICD implantation, national and international guidelines vary slightly on the indications for CRT. However, there is broad agreement that, in patients with a diagnosis of heart failure associated with LV systolic dysfunction (symptomatic heart failure at NYHA Functional Classes II–IV and an LVEF >35%), the use of CRT is based primarily on a diagnosis of electrical dyssynchrony, indicated by a widened QRS complex of more than 150 ms on a standard ECG (normally, an LBBB pattern). The confirmation of the presence of mechanical dyssynchrony by echocardiography may be used in patients with electrical dyssynchrony indicated by bundle branch block and a shorter QRS duration (between 120 and 149 ms) but has not been shown to be very useful outside of clinical research. This approach was the same as that provided by the inclusion criteria for the CARE-HF trial, one of the first multicentre studies looking at CRT implantation. Since then, numerous studies have reported a variety of criteria to apply; however, ultimately, the most consensus guidance is that response to CRT is best predicted simply by the LVEF and the QRS duration at implant. Increasing evidence suggests that both patients in sinus rhythm and those in atrial fibrillation benefit from CRT; however, in the latter group, it may be necessary to ablate the AV node to ensure biventricular pacing occurs most of the time. More recent trial data suggest that patients with less severe symptoms of heart failure but severe LV dysfunction and dyssynchrony may also benefit from CRT in terms of mortality and morbidity; however, only some of the guidelines have changed to recognize these findings. It is important to note that many of these patients do not need a pacemaker for

conventional bradycardia indications. The decision as to whether to implant a CRT-P or a CRT-D is normally based on whether or not the patient fulfils criteria for both, or just one. In some patients, when an indication for a pacemaker exists but LV function is known to be impaired, then use of a CRT device should be considered, in order to reduce the risk of progressive LV deterioration.

How to implant CRT devices

The implantation of the right atrial and right ventricular leads of a CRT is exactly the same as for a standard pacemaker or ICD. The LV lead is most commonly implanted via the coronary sinus (CS). This is accessed in exactly the same way as the right atrial and the right ventricular leads: via the subclavian vein. The CS os is posterior to the tricuspid valve in the right atrium and allows venous blood from the heart to drain into the right atrium. By entering the CS, a lead can then be passed retrogradely through it and into lateral branches that run along the lateral margin of the left ventricle (i.e. pacing the lateral wall of the left ventricle epicardially). The anatomy of the CS is somewhat variable. This, along with the presence of scarring in the left ventricle, may make implantation difficult or even impossible. Furthermore, the proximity of the left phrenic nerve means that electrical stimulation in this region may cause diaphragmatic twitching, thus rendering the device useless. If it proves impossible to implant the LV lead via the CS, then the lead may be implanted surgically on the epicardial surface, or endocardially using a different approach through the interventricular septum or a direct ventricular puncture. Modern technology, such as multipolar pacing leads, has meant that a number of the challenges that would have made CRT impossible in some patients in the past have now been addressed. Once all of the leads are in place, they are connected to a CRT generator and implanted into a pocket, as with a pacemaker or TV-ICD.

Complications of CRT devices

With CRT, the same complications at implantation are seen as with any pacemaker or TV-ICD implant. In addition, there is a small risk of damage to the CS but this rarely results in a serious complication, although it may mean that the LV lead cannot be inserted. In fact, implant failure related to the placement of the LV lead, together with post-operative lead dislodgement, are the most common problems seen in CRT.

The response to CRT is variable. Estimates of the proportion of patients who have a CRT device implanted successfully but do not experience an improvement in their condition range from approximately 10% to 50%. In some patients, non-response may be due to loss of biventricular stimulation, because of atrial arrhythmias or frequent ventricular extrasystoles, and suppression of these arrhythmias may be beneficial. Recognition of who will and will not respond remains a challenge and there is no difference between CRT-D and CRT-P devices with respect to the number of patients whose condition does not improve. However, the response rate is improving, due to ongoing research, particularly in the field of advanced cardiac imaging.

Impact of CRT devices on life expectancy and quality of life

CRT, via either a pacemaker device or a pacemaker-defibrillator device, improves life expectancy and the quality of life in patients who have heart failure due to LV) systolic dysfunction in NYHA Functional Classes II, III, and IV and who are in sinus rhythm with a broad QRS complex (>130 ms). For example, in the COMPANION study, all-cause mortality was reduced by 24% during a mean follow-up period of 16 months and, in the CARE-HF study, it was reduced by 36% over 29 months. On average, CRT results in an increase in functional capacity by one NYHA class, and reduces hospitalizations for heart failure.

Current European Society of Cardiology guidelines recommend CRT (Class I indication) for symptomatic patients with heart failure in sinus rhythm with a QRS duration >130 ms, and LBBB morphology, and a LVEF <35% despite optimum medical therapy; CRT should be considered (Class IIa) for those with QRS duration >150 ms and non-LBBB morphology.

Most patients for whom CRT is indicated also qualify for an ICD. However, the additional benefit of CRT-D over CRT-P is uncertain, and CRT-D is more expensive. Determining which device will be better for the individual patient is the subject of current research.

CRT can result in reverse remodelling, with reductions in LV volumes and functional mitral regurgitation, and improvement in LVEFs. While the occurrence of reverse remodelling is associated with a favourable effect on prognosis, symptomatic benefit from CRT can be seen in patients who do not demonstrate it.

Other device-related issues

Magnet inhibition

For most PPMs, placing a specific type of magnet over the device does not turn it off but instead temporarily 'reprograms' it into an asynchronous mode. Each pacemaker type has unique asynchronous rates (specific to the device's manufacturer and model) which indicate battery status: BOL (for **beginning of life**), ERI (for **elective replacement indicator**), and EOL (for **end of life**). Therefore, if the device parameters are known, a magnet can be used to determine whether the PPM's battery should be replaced. Further interrogation or manipulation of the device should only be performed by an individual competent to do so. A magnet can also be used to temporarily treat oversensing with a PPM.

When a magnet is applied to an ICD, it can temporarily turn off defibrillation and anti-tachycardia pacing therapy without altering the ICD's pacing ability. However, some devices can be programmed to not respond to magnet application and thus will need a device programmer to change the parameters. Indications for ICD deactivation are as follows:

- end-of-life care (after a discussion with the patient and family)
- inappropriate shocks
- during resuscitation
- during transcutaneous pacing (external pacing can cause an ICD to fire)
- during surgical procedures involving electrocautery

Resuscitation

If a patient enters a life-threatening cardiac arrhythmia, Advanced Life Support protocols should be initiated immediately. Although an ICD will attempt defibrillation, chest compressions should be continued. Note that some of the current may enter the rescuer; however, there has never been a reported case of rescuer injury from this, other than mild discomfort. VT and VF refractory to ICD defibrillation will require external defibrillation and/or antiarrhythmic medications, as dictated by Advanced Cardiac Life Support/Advanced Life Support protocols. If external defibrillation is required in a patient with a device, whether a pacemaker, an ICD, or a CRT, placing the electrode pads at least 10–15 cm away, and out of the shockwave reduces the risk of causing device failure. However, it is not appropriate to withhold therapy for fear of damaging the device in this emergency setting.

If rescuers are uncomfortable with ICD discharge during resuscitations, it is appropriate to deactivate the ICD with a magnet; the magnet can be removed to allow the ICD to again treat VF/VT if desired.

Central venous catheter placement

Pacemaker or ICD leads placed in the venous system often lead to surrounding thrombosis, with 20% of patients having complete occlusion at 2 years. This can make subsequent venous access difficult. Furthermore, during central line placement, if the metal guidewire contacts the lead system, there may be sufficient artefacts to trigger an inappropriate shock or inhibit pacing. Therefore, when placing central venous catheters either avoid the use of a metal guidewire or reprogram the device accordingly. Although the contralateral subclavian or internal jugular vein can be cannulated with care, femoral vein access is a much safer option in this circumstance.

Issues related to driving in patients with cardiac devices

In the UK, for driving advice for patients with cardiac devices, specifically refer to the DVLA guidelines on fitness to drive. For a standard driving licence (Group 1) in the UK, in general, any device procedure is associated legally with at least 1 week of driving restriction. With ICDs (TV-ICDs, S-ICDs, or CRT-Ds), a primary prevention implant carries a 1-month restriction, and a secondary prevention implant carries a 6-month restriction. If the patient receives an appropriate shock from an ICD, driving may be restricted for up to 2 years after the event, although, in many cases, the patient will be permitted to drive after 6 months. The restrictions on professional driving licences (Group 2) are much stricter: an ICD implant results in an immediate and permanent ban.

122 Drug-induced cardiovascular disease

Yoon Loke

Introduction

Many drugs can cause or exacerbate cardiovascular disease, and clinicians should be vigilant when prescribing potentially cardiotoxic medication to patients at risk, so that preventive measures and close monitoring can be implemented. Conversely, the possibility of drug-related disease should always be considered in patients with cardiovascular symptoms, so that culprit drugs can be identified and alternative therapies considered.

Congestive cardiac failure/oedema

Drugs can typically cause or worsen cardiac failure, either through a direct negative effect on the myocardium or by causing fluid retention via the renal–endocrine axis. Myocardial damage is a particular problem with cancer chemotherapy. Anthracyclines such as doxorubicin have a cumulative, dose-related toxic effect leading to cardiomyopathy and congestive cardiac failure which persists in the long term. Treatment with trastuzumab, a monoclonal antibody against the human epidermal growth factor receptor-2 (HER-2) in breast carcinoma can cause a decline in left ventricular function, and heart failure that may be reversible on cessation of therapy. Echocardiographic monitoring for left ventricular dysfunction is recommended for all patients receiving trastuzumab. Protein kinase inhibitors (such as imatinib and sunitinib) used in the treatment of malignant disease have also been reported to cause oedema and congestive cardiac failure.

While negatively inotropic drugs such as beta blockers and calcium-channel blockers (e.g. verapamil) are not directly toxic to the myocardium, they can lead to symptomatic deterioration in those with preexisting left ventricular dysfunction. Low doses should be used initially, with gradual upward titration as needed.

Some drugs can precipitate cardiac failure and symptomatic oedema in susceptible patients by causing fluid retention. This can be mediated by a negative effect on renal function (e.g. by NSAIDs) or through mineralocorticoid properties (e.g. via high doses of corticosteroids). Other drugs such as the thiazolidinediones (rosiglitazone, pioglitazone) appear to cause cardiac failure and peripheral oedema through increased intravascular volume via an unknown mechanism.

Ischaemic heart disease

Drugs can increase the risk of myocardial ischemia through coronary artery constriction, through prothrombotic effects on blood components, or by increasing cardiac workload and oxygen requirements. The fluoropyrimidines (fluorouracil, capecitabine) have been associated with ischaemic electrocardiographic findings in patients being treated for cancer. The triptans (such as sumatriptan), which are serotonin-receptor (5-HT-1B/1D) agonists used in the acute treatment of migraine, appear to have a marked vasoconstrictive effect due to stimulation of the serotonin receptors in the smooth muscle of the coronary arteries, thus leading to ischaemic symptoms.

Prothrombotic drugs include some selective cyclooxygenase-2 (COX-2) inhibitors (such as rofecoxib) which may have deleterious effects on platelet and endothelial function; these effects are mediated through decreased vasodilatory prostaglandins in the face of continued production of thromboxane. While cardiovascular toxicity may be a common threat amongst conventional and COX-2-selective NSAIDs, the magnitude of risk may vary depending on agent (e.g. diclofenac is thought to carry high risk, while naproxen is thought to carry less risk).

Erythropoietin-stimulating agents (such as epoetin, darbepoetin) have been associated with myocardial infarction, particularly with higher target haemoglobin levels in cancer patients and those with chronic kidney disease. This prothrombotic risk may arise from a more rapid or greater overall increase in haemoglobin, or through a dose-dependent drug toxic effect that has yet to be clarified.

Drugs that increase the cardiac workload and the myocardial oxygen requirement may precipitate ischaemia, especially in those with preexisting atherosclerosis. Short-acting calcium-channel blockers such as nifedipine are associated with myocardial infarction in those with coronary disease, possibly through vasodilation causing reflex tachycardia. Sympathomimetic drugs such as amphetamines, ephedrine, and cocaine have also been associated with myocardial infarction in younger patients. Historically, excessive use of short-acting beta-2 agonists in asthma has been linked to increased cardiovascular mortality, although there is no definite evidence of risk with newer bronchodilators.

Cardiac arrhythmias

By nature of their widespread effect on cardiac conduction, antiarrhythmic drugs themselves are major culprits in the genesis of many forms of cardiac arrhythmias. Digoxin, for instance, can induce both bradyarrhythmias and tachyarrhythmias. In patients who have known heart disease and who present with arrhythmia, the search for a culprit should start with the patient's list of medications, as a variety of factors (such as drug interactions and electrolyte disturbances) can tip the balance over from beneficial cardiac drug to dangerous arrhythmogenic agent. Toxicity from antidepressants and antipsychotics can also cause a diverse range of arrhythmias.

Bradyarrhythmias

Bradycardias commonly arise from drugs that block sympathetic activity or the atrioventricular (AV) node. Beta blockers are widely used in the community and are commonly associated with dose-dependent bradycardia, as are AV nodal blocking agents such as verapamil and digoxin. Amiodarone, sotalol, and flecainide are the other antiarrhythmic drugs which are highly likely to lead to bradycardias. This risk of bradycardia is heightened by the common practice of prescribing two agents to obtain satisfactory control of atrial fibrillation.

Tachyarrhythmias

Ventricular arrhythmias are a particular concern in patients receiving antiarrhythmic drugs, with agents such as flecainide now being restricted to patients who do not have underlying ischaemic or structural heart disease. However, the discovery of a relationship between the drug quinidine and QT interval prolongation and polymorphic tachycardia (torsades des points) has led to the realization that many other drugs, both cardiac and non-cardiac, are linked to tachyarrhythmia (see Table 122.1). While the incidence of torsades is very much lower with non-cardiac drugs, many of the implicated agents are widely used in the community, thus contributing to a potentially large burden of exposure in the population.

The underlying mechanism behind torsades appears to stem from blockade in transmission of a particular potassium current which is involved in myocardial repolarization and which known as the rapid component of the delayed rectifier, IKr. Drugs that block IKr can increase the duration of the action potential, manifesting in QT prolongation. However, QT prolongation itself has limited predictive value for torsades, as many patients have QT prolongation without serious harm, while some have dangerous arrhythmias despite minimal changes in their QT interval. Other mediating factors

Table 122.1 Drugs that are likely to be associated with prolongation of the QT interval

Clinical application	Class	Specific drug
Antiarrhythmic	Ia	Disopyramide Procainamide Quinidine
	III	Amiodarone Sotalol Dofetilide/ibutilide
Antibiotic	Macrolide	Erythromycin Clarithromycin
	Fluroquinolone	Sparfloxacin
Antimicrobial	Antimalarial aminoquinolone	Chloroquine
	Antimalarial phenanthrene-methanol	Halofantrine
	Antiprotozoal aromatic diamine	Pentamidine
Antihistamine	Second-generation H1-receptor blockers	Astemizole Terfenadine
	Antipsychotic	Phenothiazine
Butyrophenones		Haloperidol
Diphenylbutylpiperidines		Pimozide
Gastrointestinal	Prokinetic	Cisapride
	Dopamine antagonist	Domperidone Droperidol
Analgesic	Opioid agonist	Methadone

include hypokalaemia, drug interactions leading to toxic levels (usually through CYP3A4), genetic susceptibility, and the presence of structural heart disease. Indeed, while there is a long list of medications that are implicated in QT prolongation (see Table 122.1), only a relatively small proportion of patients experience serious harm. Preventive measures should focus on correction of electrolyte abnormalities, avoidance of polypharmacy with other drugs that can affect the QT interval or the p450 metabolic pathways, and optimization of the patient's cardiac condition.

Hypertension

Drug-induced elevation in blood pressure can stem from increased sympathetic activity or from interference with the renal–endocrine regulatory axis. Hypertension can occur with sympathomimetic agents such as the amphetamines and ephedrine. Similarly, serotonin–noradrenaline reuptake inhibitors (such as venlafaxine) used in treating depression can cause a dose-related rise of blood pressure by increasing sympathomimetic amines. Sibutramine, an obesity drug which blocks reuptake of serotonin, noradrenaline, and dopamine, is associated with clinically relevant elevation of blood pressure, and

the drug had to be withdrawn from the market after excess cardiovascular risk was detected in a large trial.

Inhibition of protective prostaglandins in the renal and endothelial systems can cause blood pressure elevation in patients exposed to NSAIDs, with a potential relationship to the increased risk of oedema and myocardial infarction discussed elsewhere in this chapter. The increase in blood pressure appears to be more prominent with agents such as rofecoxib, and affects susceptible patients with preexisting hypertension.

Valvular heart disease

Both regurgitant and stenotic lesions can arise as a complication of drug therapy. The implicated drugs are thought to have some effect on 5-HT_{2B} serotonin receptors or serotonin transporters in heart valves, thereby having an impact on fibroblast proliferation. In the past, drugs used in the treatment of migraine (ergotamine, methysergide) were the most prominent culprits, but these agents are seldom prescribed nowadays. Appetite suppressants (dexfenfluramine and fenfluramine, used alone or in combination with phentermine) were then linked with valvular heart disease, leading subsequently to the withdrawal of dexfenfluramine from the market. However, the threat of valvular complications from the fenfluramines has not been completely eliminated as a multitude of illicit slimming remedies containing fenfluramine and phentermine can be obtained from unlicensed sources. Pulmonary hypertension has also been reported with these drugs, which may arise as a direct toxic effect, or secondary to valvular disease.

Valvular heart disease has recently been noted in patients receiving pergolide and cabergoline, which are ergot-related dopamine agonists used in the treatment of Parkinson's disease. Based on their structural similarity to ergotamine, it is thought that these drugs have an agonist effect at the 5-HT_{2B} receptor, thus triggering valvular pathology. Patients should have cardiac assessments and echocardiography prior to treatment initiation, and will need regular monitoring clinically and with echocardiography while they remain on these agents (pergolide has been withdrawn in the United States, but is still available elsewhere). It is not yet clear if valvular lesions regress fully after treatment cessation.

123 Psychological management of coronary heart disease

Rhain Morris

Risk factors associated with coronary heart disease outcomes

Both anxiety and depression have been found to increase the risk of developing coronary heart disease (CHD) and lead to exacerbation of cardiac symptoms, with the latter subsequently impacting recovery/rehabilitation (e.g. leading to an increased number of readmissions to hospital, and an increased mortality risk following myocardial infarction (MI)). This may be due to pathophysiologic effects, such as vascular inflammation and autonomic dysfunction, and poor lifestyle/behavioural patterns, including non-attendance at cardiac rehabilitation classes and/or poor treatment adherence. Psychosocial factors such as stress, hostility, social isolation, socio-economic status, and psychological defensiveness can also affect the course of cardiac illness.

Psychological responses to MI

Depression is commonly associated with CHD but anxiety is often the first psychological response in the acute phase of MI, with the anxiety level bearing little relation to the severity of the infarct. Therefore, depression may initially mask anxiety. A study found that 31% of MI patients had elevated depression scores while in hospital, increasing to 38% at 4 months, and 37% at the 12-month follow-up. Similarly, prevalence for depression immediately following MI was 20%, with another 21% becoming depressed over the following year. A high anxiety rate has also been reported, with 26% of MI patients showing elevated anxiety in hospital, increasing to 42% after 4 months, and 40% at 1 year post MI. Women have also been found to be more anxious than men.

Following the cardiac event, some patients find the transition from a healthy self-perception to confronting their own mortality/fragility very stressful. Studies demonstrate that there are parallels between this transition and loss and bereavement: following an MI, patients often experience denial, anger, guilt, depression, and loneliness before acceptance. Indeed, individuals can also suffer loss of functioning, status, role, and identity. Psychological interventions can help this process considerably.

Associations between psychological distress and cardiac outcomes have therapeutic implications, highlighting the need for routine screening at regular intervals, ensuring early detection of psychosocial difficulties and appropriate service referral. Two standardized screening tools, the Hospital Anxiety and Depression Scale, and the Beck Depression Inventory, can be used at all stages in the care of cardiac patients.

Using a psychological approach in acute settings

During the acute phase of treatment, the volume of clinical interventions undertaken may hinder patient engagement in psychological treatment and the amount of information processing that is required. Uncertainty regarding future health may also further impede acceptance. However, interventions can be adapted to take such limitations into account. The majority of patients will not request or need focused psychological intervention during or following hospital stays, only time to adjust.

Recommendations, beneficial to all patients, exist; they outline the most helpful aspects of care at the acute stage of CHD and are defined by 'communication-based care', encouraging staff to develop positive/friendly relationships with patients by displaying empathy and warmth and by using active listening.

There are two basic areas of focus:

- informational care:
 - exploration of what the patient knows and wishes to know
 - memory facilitation through language, diagrams, and information aids
 - checking the patient's understanding of imparted information
- emotional care:
 - allowing the expression of emotional distress to help patients come to terms with their illness
 - facilitating safe feelings
 - share emotional responses

The enhancement of 'control and personal responsibility' is important in rehabilitation. In order for patients to feel involved in their treatment and empowered, an attitude of collaboration and respect needs to be conveyed, whereby staff work 'with' the patient, rather than doing treatment 'to' the patient.

As most of this care is delivered by nursing staff, it highlights the need for skills in both the identification of psychological distress and use of basic strategies to help the patient cope (e.g. stress management). This is particularly important during the transition from hospital to home, when psycho-educational input can help the patient and their family prepare.

Psychological and psychosocial interventions for CHD

The efficacy of psychological interventions in cardiac rehabilitation has been assessed in relation to a variety of outcome criteria, making any comparison between studies complicated. Nevertheless, the main studies are summarized in this section.

Cardiac rehabilitation, which incorporates psychosocial methods of intervention, has been demonstrated to reduce mortality. The main studies include an investigation of lifestyle changes and CHD; the Recurrent Coronary Prevention Project; the Ischemic Heart Disease Life Stress Monitoring Program; and the M-HART Study Group. These and consequent studies show psychosocial intervention is directly linked to reducing mortality and further cardiac events.

An initial study in 1983 investigated the effects of cardiac rehabilitation, utilizing a three-and-a-half-week rehabilitation program of diet, relaxation, and exercise in an attempt to reduce mortality in post-infarction participants, with good effect. Later studies such as the Recurrent Coronary Prevention Project looked at risk factors for Type A behaviour, yielding very positive results, even at a six-and-a-half-year follow-up, where participant mortality was greatly reduced. Most early psychosocial intervention studies predominately targeted lifestyle and behavioural factors, whereas recent studies focus more on cognitive aspects (e.g. stress/anxiety management) relating to an increased risk of CHD.

As part of the Enhancing Recovery in Coronary Heart Disease Patients study, researchers investigated whether cognitive behavioural therapy (CBT) delivered in individual and/or group formats could reduce high mortality and recurrent infarction levels associated

with depression and low perceived social support. Although intervention improved depression and low perceived social support, it did not increase event-free survival. However, the findings from this study have recently been reanalysed. This showed group **plus** individual therapy was associated with a 33% reduction in death or further infarction, compared to usual care or individual therapy alone.

In a review of nine psychological interventions conducted with patients after surgery for an implantable cardioverter defibrillator (ICD), researchers concluded that the most notable effects were reductions in anxiety, and improved exercise capacity. Although some studies found a decrease in depression and quality of life gains, this was a less robust finding. The review supports another study, which found that a brief cognitive-behavioural intervention for ICD patients improved quality of life, reduced incidences of anxiety/depression, and reduced the number of unplanned admissions at 6 months post surgery.

CBT has yet to be explored in relation to congestive heart failure (CHF) patients. However, research has demonstrated that basic relaxation skills can help reduce stress in CHF patients. More recently, there has been interest in the application of mindfulness-based cognitive therapy (MBCT) with CHD patients. Mindfulness encourages recipients to find distance from anxious/negative thinking and is an adjunct to cognitive techniques such as negative-thought identification. A review of an MBCT group for cardiac rehabilitation found favourable outcomes for awareness, acceptance, and within-group experiences. Lastly, CBT combined with antidepressants may be the most effective treatment for patients with cardiovascular disease and depression.

Psychology also has an important role in behaviour change. People are most likely to change when they believe they have the necessary resources to do so. Known as self-efficacy, this has important implications for cardiac rehabilitation. A problem-solving approach can be used to help individuals explore and resolve practical barriers to change. Furthermore, motivational interviewing, developed to help increase an individual's motivation to change, has relevance to many cardiac rehabilitation programmes, being widely used in populations requiring diet/exercise modification and, more recently, with CHF patients to improve self-care.

Overall, there is a paucity of research investigating the efficacy of psychological approaches with cardiac patients. Existing research has tended to focus on medical outcomes, rather than on the reduction of psychological distress per se. Although emerging evidence suggests CBT can be beneficial for cardiac patients suffering from anxiety and/or depression, a need exists for research to address the efficacy of a variety of psychological interventions in reducing psychological distress as a primary goal.

Benign cardiac symptoms

The characteristics of patients presenting with non-cardiac chest pain and benign palpitations have been investigated. This non-cardiac group

is more likely than others to be made up of young women reporting other physical symptoms and previous psychiatric problems. At the 6-month follow-up, they continued to report limited activities, concern about the cause of their symptoms (despite reassurance), and dissatisfaction with medical care. Importantly, a common feature of health anxiety is to seek frequent medical reassurance, which serves to maintain the person's preoccupation with their health. Health anxiety also has overlapping features with panic disorder. In another study, patients with benign palpitations were more likely to be female, with a higher prevalence of panic disorder and fear of bodily sensations.

Subsequently, a brief nurse-led psycho-educational intervention (based on CBT principles) was conducted, aiming to reduce disability in patients with benign palpitations. Patients completing the intervention showed significant increases in activity levels at the 3-month follow-up. In general, though, limited research has been conducted to investigate the efficacy of psychological interventions with this patient group.

There is, however, an existing body of literature which can be drawn from and applied to cardiology. The current evidence base supports treatment of health anxiety and panic disorder with specific cognitive-behavioural techniques. Lastly, the role of cardiologists in addressing these problems has been highlighted. It is recommended that cardiologists routinely address psychological factors (particularly anxiety) relevant to the aetiology and management of palpitations and/or chest pain. Such timely identification and explanation may help patients to resolve their uncertainty regarding their symptoms and ultimately reduce anxiety.

Summary

Psychological issues linked to health problems are varied and can be experienced briefly or chronically. Patients differ greatly in their responses to medical conditions; many use their own existing coping styles successfully, but a significant proportion struggle to cope with accepting their condition. Psychological support from the cardiac event and beyond is therefore an important aspect of care with this patient group.

124 Treatment of terminal cardiovascular disease

Dave Riley

Definition of the disease

This chapter is an introduction to the key components of the palliative treatment of terminal cardiovascular disease; more in-depth resources are listed in 'Further Reading' at the end of this chapter.

While definitions may vary, a person who may die within 6–12 months could be considered to be approaching the terminal stage of their illness, while those expected to die within a number of days or hours would be considered to be at the terminal stage. Either situation is a valid time to implement palliative treatment, but considering end-of-life care earlier provides opportunities that may otherwise be missed.

Aetiology of the disease

All serious cardiovascular disease can end with the patient dying, sometimes quickly, and sometimes, more distressingly, slowly. This is particularly so with heart failure, but can also be the case with profound coronary disease, extensive cerebrovascular disease, and peripheral vascular disease, and often these diseases interact with others, such as COPD, diabetes, and so on, all of which are made worse by increasing age, immobility, and possibly dementia.

Typical symptoms of the disease, and less common symptoms

The patient typically experiences a progressive worsening of exercise tolerance, culminating in symptoms at rest or on minimal exertion. This leads on to limited functional ability, with failing independence and interrupted sleep. A full palliative assessment incorporates a holistic approach to patient needs, including physical, social, and psychospiritual aspects.

Physical aspects include:

- breathlessness
- fatigue
- pain
- constipation
- nausea
- insomnia

Social aspects include:

- financial difficulties
- relationship difficulties
- personal care needs, including carers and equipment

Psychospiritual aspects include:

- anxiety
- depression
- fear
- existential distress, which may be religious, spiritual, or non-specific

Demographics of the disease

The incidence of heart failure has been estimated at 63 000 new cases annually in the UK. In 2001, just over 11 500 deaths due to heart failure were officially recorded in the UK.

However, the number of deaths attributed to heart failure in national mortality statistics is likely to be a huge underestimate.

Combining data on incidence and survival, the British Heart Foundation has estimated that, in 2001, the true number of deaths from heart failure in the UK was at least 24 000. This means at least 4% of all deaths in the UK are due to heart failure.

Natural history, and complications of the disease

The last several months of life are characterized by recurrent episodes of deterioration, either as a result of decompensated cardiac function or concomitant illnesses, and may lead to patients being admitted to the acute hospital setting more frequently. The last hours to days of life are characterized by a bed-bound patient with an altered level of consciousness, difficulty managing oral medication, and a poor oral intake. Sudden, relatively unpredicted death is also a risk.

Complications include:

- uncontrolled symptoms
- hospital admissions, with the associated burden of travelling, time away from home and family, investigations, and invasive treatment
- failing to die in the place of one's choosing
- ICD activation

Deteriorating renal function, low blood pressure, and hyponatraemia are common sequelae of poor cardiac output. However, quality of life takes precedent for those in the terminal stage; efforts to preserve renal function, blood pressure, and serum sodium levels may be at the expense of symptom control and quality of life.

Approach to diagnosing the disease

Recognizing a patient who is approaching the terminal stage can be challenging and uncertain; it should be a team-based decision. It requires a shift of mindset away from active treatments and to moving towards patient-centred care encompassing quality of life and the acceptance of the inevitability of death. This can be difficult for patients, family, friends, and healthcare professionals alike. The process of acceptance opens the way to preparing both patients and their loved ones for the impending death and helping patients with making an advance care plan.

The advance care plan should address:

- symptom control and comfort measures
- anticipatory prescribing of medication to manage exacerbations
- discontinuing inappropriate interventions
- needs for psychological and spiritual care
- care of the family (before and after the person's death)
- when, who, and how to call for help when there is a crisis or acute exacerbation, and what the options are for management

The plan should also include the person's preferences regarding:

- where they wish to be cared for at the end of life
- deactivation of an ICD
- documentation of a do not attempt resuscitation decision

Anticipatory prescribing for end-of-life medication is detailed in 'Treatment and its effectiveness'.

It is essential that the outcome of consultation be disseminated amongst each relevant member of the multidisciplinary team (e.g. GP, district nurse, out-of-hours GP service, ambulance service).

Other diagnoses that should be considered

Optimal management of cardiac failure must be ensured, including any reasons for poor concordance. That aside, a full assessment with a history and examination, plus investigations if appropriate, is required to identify any reversible cause of deterioration of symptoms. The differential diagnosis is large, but includes:

- suboptimal management or acute exacerbation of comorbidities, e.g.:
 - progressive renal impairment
 - anaemia
 - COPD
 - diabetes mellitus
- acute infection

'Gold-standard' diagnostic test and acceptable diagnostic alternatives to the gold standard

There is no tool or test available to accurately ascertain the terminal stage or the prognosis of patients with terminal cardiovascular disease. However, the Gold Standards Framework describes three triggers to aid in identifying the terminal stage:

- Would you be surprised if the patient were to die in the next 6–12 months?
- The patient makes a choice for comfort care only, not 'curative' care.
- Clinical indicators suggest advanced disease.

Other relevant investigations

Investigations should be driven first by the need (or indeed, necessity) to further define the underlying disease process (often no further investigations are needed) and, second, to clarify whether specific treatments designed to relieve symptoms have a role, for example, a chest X-ray may define how much of the symptoms are due to heart failure, and how much to pneumonia—this may be relevant if active treatment with antibiotics is appropriate, but clearly is not if such therapies are not under consideration. The underlying philosophy determining whether any investigations are appropriate is whether the results would lead to specific interventions that would improve the quality of death. If investigations will not lead to such an outcome, they should not be performed.

Prognosis and how to estimate it

Prognosis from heart failure is poor. Comparing 1-year survival rates for heart failure with those for a number of common cancers show that prognosis from heart failure is relatively poor. The 1-year survival rate for heart failure is worse than those for breast, prostate, or bladder cancer, better than those for lung or stomach cancer, and very similar to that for cancer of the colon.

Those patients with Stage III or IV heart failure and who have repeated hospital admissions and difficult-to-control physical or psychological symptoms are likely to die within 6–12 months.

Predicting prognosis becomes more accurate the nearer a person is to death.

Treatment and its effectiveness

Symptoms can be effectively managed in the majority of patients following an assessment of the cause, its impact on the patient, and the initiation of appropriate treatments. However, some symptoms cannot be resolved and supportive measures alone are required. If a patient has ongoing symptoms, intolerable side effects, or complex needs, the specialist palliative care team should be contacted for advice or review of a patient.

Anticipatory prescribing for end-of-life medication is given in Table 124.1. These are suggestions only; all prescribing must be on an individual patient basis.

Table 124.1 Anticipatory prescribing for end-of-life medication

Symptom	Drug	Dose	Route
Pain and breathlessness	Morphine	1.25–2.50 mg	Subcutaneous
Nausea	Haloperidol	500 µg–1.5 mg	Subcutaneous
Anxiety and agitation	Midazolam	2.5–5.0 mg	Subcutaneous
Respiratory secretions	Glycopyrronium	200–400 µg	Subcutaneous

Fatigue

Non-pharmacological management of fatigue includes:

- explanation and reassurance
- cardiac or palliative rehabilitation
- occupational therapist review re home adaptations, equipment, and mobility aids
- support and advice for carers, including a care package

The following is recommended for pharmacological management of fatigue:

- review medication which may contribute to fatigue and reduce, stop, or change to alternatives
- psychostimulant medication is not recommended

Dyspnoea

Non-pharmacological management of dyspnoea includes:

- explanation, reassurance
- cardiac or palliative rehabilitation
- occupational therapist review re home adaptations, equipment, and mobility aids
- use of a handheld fan
- psychological support
- complementary therapies
- support and advice for carers, including a care package

Recommendations for the pharmacological management of dyspnoea are as follows:

- nebulized saline 0.9% 5 ml, when necessary
- low-dose opiates: morphine sulfate solution 2.5 mg, 4 hourly
- lorazepam 0.5–1.0 mg sublingual when necessary (max 2 mg in 24 hours) for acute anxiety
- trial of oxygen via nasal cannulae

Pain

Non-pharmacological management of pain includes:

- explanation, and reassurance
- physiotherapy review
- occupational therapist review re home adaptations, equipment, and mobility aids
- complementary therapies

The following is recommended for the pharmacological management:

- the WHO Pain Relief Ladder (see Table 124.2)

Table 124.2 Pharmacological management

STEP 1	STEP 2	STEP 3
Regular Paracetamol 1g qds (Avoid NSAIDs as they can cause fluid retention & worsening renal function)	Regular Paracetamol 1g qds Plus a weak opioid, e.g.: codeine 30mg–60mg qds	Regular Paracetamol 1g qds Plus a strong opioid, e.g.: Morphine 2.5–5mg qds & prn

Reprinted from WHO, WHO Pain Relief Ladder, Copyright (2009). <http://www.who.int/cancer/palliative/painladder/en/>.

- all patients started on an opioid need a laxative co-prescribing (e.g. sodium picosulfate 5–10 ml, at night)

Constipation

Non-pharmacological management of constipation includes the following:

- encourage fluid intake and review the diet
- optimize mobility
- optimize privacy for toileting

The following may be used for pharmacological management of constipation:

- stimulant laxative (e.g. sodium picosulfate 5–10 ml, at night)
- softener laxative (e.g. sodium docusate 200 mg, once or twice per day), if stool is hard

Nausea

Non-pharmacological management of nausea includes:

- eating small meals
- avoiding preparing food

Pharmacological management of nausea includes the following:

- review medication that may contribute to nausea and reduce, stop, or change to alternatives
- for a systemic cause, haloperidol 500 µg–1.5 mg, once per day and as necessary (up to 5 mg/day)
- for gastric stasis, metoclopramide 10 mg, three times per day and as necessary

Anxiety

Non-pharmacological management of anxiety includes:

- full exploration of underlying cause and perpetuating factors
- explanation and reassurance to family and carers
- appropriate psychospiritual support; refer to specialists if needed

The following may be used for pharmacological management of anxiety:

- diazepam 2 mg as necessary, up to a maximum of three times per day
- lorazepam 500 µg–1.0 mg sublingual, for acute anxiety

Depression

Non-pharmacological management of depression includes:

- full exploration of underlying cause and perpetuating factors
- explanation and reassurance to family and carers
- appropriate psychospiritual support; refer to specialists if needed

The following is recommended for pharmacological management of depression:

- sertraline

Insomnia

Non-pharmacological management of insomnia includes:

- full exploration of underlying cause and perpetuating factors
- explanation and reassurance to family and carers
- appropriate psychospiritual support; refer to specialists if needed

The following is recommended for pharmacological management of insomnia:

- zopiclone 3.75–7.50 mg, at night

PART 4

Respiratory disorders

125 Normal respiratory function

Abdul Nasimudeen

Introduction

Respiration has two components: external respiration, which enables the absorption of O_2 and the removal of CO_2 , and internal respiration, which enables the utilization of O_2 and production of CO_2 and mediates gas exchange between the cells and their fluid medium. This chapter addresses the mechanics of respiration; gas exchange in the lungs; the pulmonary circulation; lung defence mechanisms; and the metabolic and endocrine functions of the lungs.

Mechanics of respiration

Inspiration and expiration

The lungs and chest wall are elastic structures that slide easily against each other but resist being pulled away. The pressure in the intrapleural space (the space between the lungs and the chest wall) is normally subatmospheric. The contraction of inspiratory muscles during the active inspiratory process results in an increase in intra-thoracic volume and a decrease in intra-pleural pressure. Lungs go into an expanded position, and negative pressure inside the airways aids airflow into the lungs. In end inspiration, lung recoil pulls the chest back to expiratory position, where recoil pressures of the chest wall and lung balance. Airway pressures are now slightly positive and this aids airflow out of lungs. Expiration is a relatively passive event, compared to inspiration.

Respiratory muscles

The diaphragm is the main muscle for inspiration and accounts for 75% of the change in the intra-thoracic volume during inspiration. It has three parts: the costal portion, the crural portion, and the central tendon into which the costal and crural fibres insert. External intercostal muscles are also important for inspiration, and the scalene and sternocleidomastoid muscles act as accessory muscles of respiration. Dilatation of bronchi during inspiration is controlled by the sympathetic system, and constriction during expiration is under parasympathetic control. The work of breathing performed by respiratory muscles involves both elastic work (e.g. stretching the lungs and the chest wall), which accounts for around 65% of the workload, and non-elastic work, such as viscous resistance (which accounts for 7% of the workload) and airway resistance (which accounts for 28% of the workload).

Lung volumes

The amount of air that moves into lungs with each inspiration is called the **tidal volume**. The **minute volume** is the tidal volume times the number of respirations per minute. The air inspired with a maximal inspiratory effort in excess of tidal volume is the **inspiratory reserve volume**. The volume expelled by an active expiratory effort after a passive expiration is the **expiratory reserve volume**, and the volume left in the lungs after a maximal expiratory effort is the **residual volume**. **Vital capacity** is the largest amount of air that can be expired after a maximal inspiratory effort and this is useful routinely as a measure of pulmonary function; **FEV₁** is the fraction of this vital capacity during the first second and is useful in diagnosing obstructive airways diseases.

Positional variation in ventilation

Both blood flow and ventilation per unit lung volume is greater at the base of the lung than at the apex in the upright position. The ventilation:perfusion (V/Q) ratio is low at the base and high at the apex, as the relative change in blood flow from the apex to the base

is greater than the relative change in ventilation. These differences are mainly due to gravity and tend to disappear in the supine position.

Compliance

The change in lung volume per unit change in airway pressure indicates the compliance of the lungs and the chest wall, and its normal value is approximately 0.2 l/cm H_2O . Compliance also depends on the lung volume. Compliance is decreased in conditions such as pulmonary fibrosis and pulmonary oedema, whereas it is increased in conditions such as emphysema. **Surfactant**, a lipid surface-tension-lowering agent produced by type II alveolar epithelial cells, lines the alveoli and is also an important factor affecting the compliance of the lungs.

Dead space

Gas exchange normally takes place in the terminal airways and hence the gas that occupies the rest of the respiratory system is not available for gas exchange. This area is called the **anatomical dead space**, and its volume is around 150 ml. The **physiological dead space** is the volume of gas not equilibrating with blood and, in healthy individuals, the two dead spaces are identical. The physiological dead space can be calculated from the **Bohr equation**:

$$\frac{V_D}{V_T} = \frac{PaCO_2 - PeCO_2}{PaCO_2},$$

where $PeCO_2$ is the partial pressure of CO_2 in expired air, $PaCO_2$ is the partial pressure of CO_2 in arterial blood, and V_T and V_D represent the tidal volume and the dead space volume, respectively. This equation can also be used to calculate the anatomical dead space by replacing $PaCO_2$ with the partial pressure of CO_2 in the alveoli (PAO_2).

Gas exchange in the lungs

Alveolar ventilation

Alveolar ventilation is the rate at which a volume of air participates in gas exchange in the alveoli, where the volume of air is equal to the difference between V_T and V_D and is normally around 350 ml. The partial pressure of alveolar oxygen (PAO_2) can be calculated via the alveolar gas equation:

$$PAO_2 = FIO_2(PATM - PH_2O) - \frac{PaCO_2}{R},$$

where FIO_2 is the fraction of inhaled air that is oxygen, $PATM$ is the prevailing atmospheric pressure, PH_2O is the saturated vapour pressure of water at body temperature and the prevailing atmospheric pressure, $PaCO_2$ is the arterial partial pressure of carbon dioxide, and R is the respiratory exchange ratio, assumed to be 0.8.

Alveolocapillary membrane diffusion

The diffusion of alveolar oxygen into capillaries completes gas exchange. The alveolar-arterial O_2 gradient reflects the effectiveness of this diffusion process and is equal to $PAO_2 - PaO_2$. This is normally less than 10–15 mm Hg.

Gases diffuse across the alveolocapillary membrane and achieve equilibrium at various times. Nitrous oxide (N_2O) is not bound to blood with a high partial pressure, and hence its uptake is mainly **flow limited**, whereas carbon monoxide (CO) has a high affinity to haemoglobin with low partial pressure, and its uptake is **diffusion**

limited. Oxygen has an intermediate affinity to haemoglobin, and its uptake is **perfusion limited**.

The diffusing capacity of the lung for a given gas is directly proportionate to the surface area of the capillary membrane and inversely proportionate to its thickness. The diffusion capacity of the lung for carbon monoxide is $\frac{V_{\text{co}}}{\text{PACO}}$, where V_{co} is the volume of carbon monoxide entering the blood, and PACO is the partial pressure of alveolar carbon monoxide.

Pulmonary circulation

Pulmonary blood vessels

The walls of the main pulmonary arteries are 30% thicker than the aortic wall, but smaller arteries have relatively thin muscles. Each alveolus sits in a pulmonary capillary basket with multiple anastomoses. The pulmonary vasculature is able to accommodate a blood flow equal to that of all other organs of the body. At any one time, pulmonary vessels carry 1 l of blood, of which less than 100 ml is in the capillaries. The pressure gradient in the pulmonary system is about 7 mm Hg and it takes a red blood cell about 0.75 s to traverse the pulmonary capillaries at rest. The normal pulmonary capillary pressure is about 10 mm Hg.

Positional variation in blood flow

Gravity plays an important effect on pulmonary circulation. In the upright position, the pulmonary capillary pressure of the upper lobes is close to the alveolar pressure; in the middle part of lungs, the pulmonary arterial and capillary pressures are greater than the alveolar pressure; and, in lower lobes, the alveolar pressure is lower than that in the pulmonary artery, capillaries, or venules. The V/Q ratio for the whole lung is about 0.8 (4.2 l/min of ventilation divided by 5.5 l/min of blood flow).

Regulation of pulmonary blood flow

Pulmonary blood flow is also affected by both active and passive factors. There is extensive autonomic innervation of the pulmonary vessels; in addition, the pulmonary vessels respond to several circulating humoral agents, such as adenosine, bradykinin, and so on. Stimulation of the cervical sympathetic ganglia reduces pulmonary blood flow by 30%. Exercise increases cardiac output and pulmonary arterial pressure, and the net effect is a marked increase in pulmonary blood flow.

Alveolar hypoxia resulting from bronchial obstruction causes pulmonary vasoconstriction, shunting blood away from the area of hypoxia. A rise in pH from a rising PCO_2 also produces pulmonary vasoconstriction, as opposed to the vasodilatation it produces in other tissues. Consequently, further bronchoconstriction occurs with further shift of ventilation away from the poorly perfused lung.

Lung defence mechanism

Lungs have a variety of defence mechanisms, which include anatomic defences to defend against particle deposition in upper airways, and functional defences, such as the clearance of particles through cough, mucociliary action, and cellular metabolism.

Anatomic defence mechanisms include nostril hairs, and mucus membranes in the nose and pharynx. Coughing is another defence against particles falling on the walls of the trachea and the bronchi. Cilia situated from the anterior third of the nose to the beginning of the bronchioles are instrumental in removing these particles as well. These cilia can beat at a rate of around 1000 cycles/min. Most particles $>2 \mu\text{m}$ are removed by these defences; particles $<2 \mu\text{m}$ are ingested by macrophages upon reaching the alveoli. Pulmonary alveolar macrophages are phagocytic, ingesting bacteria and other particles. They also help in processing inhaled antigens and play a role in inflammation due to cigarette smoke inhalation, by releasing lysosomal products.

Cellular and humoral immune responses play a vital part in lung defence. Lymphokines are produced by T-lymphocytes and regulate immunoglobulin synthesis. B-lymphocytes produce antibodies by transforming into plasma cells. Natural killer cells are lymphocytes that can kill bacteria without prior sensitization. IgAs in the nasopharynx bind to viruses and bacteria and facilitate microorganism agglutination. Protease-activated receptors in the pulmonary epithelium help release prostaglandin E₂, which protects epithelial cells. Alpha-1 antitrypsin inactivates proteolytic enzymes from bacteria and necrotic cells. Interferon produced by macrophages and lymphocytes has antiviral activity.

Metabolic and endocrine functions of the lungs

Surfactant produced by type 2 alveolar cells is important at birth and prevents the lungs from collapsing. As well as removing prostaglandins from circulation, the lungs also synthesize and release prostaglandins, histamine, and kallikrein into blood. Angiotensin-converting enzyme located on the pulmonary capillary endothelial cells is responsible for converting inactive angiotensin I to the active hormone angiotensin II in the pulmonary circulation. Lungs also play a role in removing vasoactive substances such as serotonin and norepinephrine.

126 Diagnosis in suspected respiratory disease

James Bonnington

Introduction

When there is suspicion of respiratory pathology, the clinician's role is to obtain a diagnosis accurately and, where possible, swiftly while subjecting the patient to the minimum of anxiety and invasive or potentially harmful tests. It is not only in rapidly progressive disease and malignancy where speed is of the essence. Potentially reversible airways disease often becomes irreversible once established and conditions that erode into lung reserve lead to increasing levels of disability if unchecked. Furthermore, in the case of respiratory-borne infections, there may be a public health risk.

A pertinent question always to be asked is whether the patient's respiratory symptoms are a consequence of lung pathology or whether the problem lies elsewhere. Shortness of breath is a common presenting symptom in left ventricular failure. Chronic cough may be the sole presenting symptom in a number of extrapulmonary conditions, in particular postnasal drip syndrome (41%) and gastroesophageal reflux (21%). If the patient's history and examination findings continue to point towards a problem within the respiratory system, this should be considered in some detail. Successful ventilation requires a number of factors. The thoracic cage should be intact and appropriately shaped and orientated. In turn, it must be moved by muscles of adequate strength and assisted by a competent diaphragm. Airways, both large and small, should be of appropriate calibre and elasticity and supported by the lung interstitium without compression from abnormal lymphatics or masses. If ventilation is successful, it needs to be paired with adequate perfusion, requiring the flow of blood laden with functional haemoglobin through pulmonary vessels free of thrombus and unimpeded by increased vascular resistance. The innocuously simple complaint of dyspnoea may be caused by a problem in any one of these! It is the physician's challenge to identify which component is compromised. This can only be achieved by taking a full clinical history, performing a thorough physical examination, and following this with targeted investigations.

The respiratory history

It is widely accepted that roughly 80% of diagnoses are made on reading of a referral letter and taking a clinical history, a further 10% on performing a physical exam, and the final 10% when presented with the results of appropriate investigations. This is nowhere more true than in respiratory medicine, where, although a panoply of investigations are available to the physician, most are hampered by a wide range of normal values, and few have significant positive predictive value unless accompanied by an appropriate pretest probability.

The patient typically presents with one or two major symptoms. The nature of these should be established along with the time for which they have been present and any change in their severity. While many congenital anomalies of the lung are usually noted in the first few weeks of life, others may not be identified until later in childhood while some, such as bronchogenic cysts, may not become problematic until early adulthood. Diagnoses of asthma in young adults are five times more likely in those who experienced symptoms of bronchial hyper-responsiveness in childhood. A range of respiratory disease may first present in middle age, including bronchiectasis as a consequence of childhood infection, pulmonary manifestations of systemic disease, fibrotic lung disease, and malignancy. From the sixth decade onwards, the effects of chronic smoking often manifest themselves,

and patients with indolent forms of usual interstitial pneumonitis may first seek medical attention.

Associated symptoms should be identified and any constitutional symptoms noted. Weight loss may accompany malignancy, but may also be seen in chronic inflammatory conditions, where the work of breathing exceeds calorific intake and where breathlessness precludes good dietary intake.

Wherever possible, a trigger for symptom worsening should be identified which may be either a patient factor or an environmental factor. Patient factors could be a change in smoking habit or an insidious increase in weight. Environmental factors hint at allergen-related disease and may include changes to home life: moving near an active farm, or the acquisition of a new pet. Changes to the working environment need to be elicited (and documented) if a diagnosis of occupational asthma is suspected. A diurnal variation in cough or wheeze hints at a diagnosis of asthma, while profuse early morning expectoration is common in bronchiectasis.

Without quantifying symptom severity, it may be difficult to identify disease progression or response to treatment. For the dyspnoeic patient, the MRC breathlessness scale correlates well with lung function measurements and is useful for stratifying interventions in COPD (Table 126.1). Few will measure their exercise tolerance in absolute terms so a guide to their functional impairment can be sought. Many hospitals provide an exercise load in terms of a remote car park or a sloped corridor: although non-standard, such tests are at least reproducible on a visit-by-visit basis! Patients should be encouraged to describe their sputum production in terms of volume, colour, and viscosity. Cough can be hard to quantify, as patient perception and reporting varies, but validated questionnaires are available.

A synopsis of the patient's past medical history and drugs prescribed may identify an atopic individual, one with multisystem disease, or a patient at risk from pulmonary fibrosis (as a consequence of previous chemotherapy, radiotherapy where the lung was included in the radiation field, or other drugs with recognized pulmonary toxicity). Up to 15% of patients commencing ACE-inhibitor therapy develop dry cough, which is normally relieved by cessation of treatment but may take several months to resolve fully (and may persist in a small minority).

A smoking history, quantified in pack years, should be documented along with any recreational drug abuse. Inhalation of freebase

Table 126.1 The MRC scale of breathlessness

Grade	Degree of breathlessness related to activities
1	Not troubled by breathlessness except on strenuous exercise
2	Short of breath when hurrying or walking up a slight hill
3	Walks slower than contemporaries on level ground because of breathlessness, or has to stop for breath when walking at own pace
4	Stops for breath after walking 100 m or after a few minutes on level ground
5	Too breathless to leave the house, or breathless when dressing or undressing

cocaine, particularly when mixed with impurities, is associated with significant respiratory pathology ('crack lung'). A family history of respiratory disease may identify inherited disease or shared exposure to an environmental factor such as asbestos in prefabricated housing. It is important to be familiar with local disease patterns and associated socio-economic factors. The UK incidence of TB is modest (12/100 000 in 2014) and the clinician should be aware of the local situation: immigration patterns, uptake of BCG vaccination, and any local resistance patterns. Local industry, current and past, has a profound effect on the patterns of respiratory disease seen, including the incidence of occupational asthma and pneumoconioses.

The respiratory examination

Although much of the diagnosis will have been made from the clinical history, a thorough physical examination is essential. It may seem contrary to note that the most useful information is to be gained away from the chest. On arrival at clinic, all patients should have a height and weight recorded and a BMI calculated. Any significant deviation away from the normal range (19.0–24.9 kg/m²) is to be discussed with the patient to identify rapid or relentless changes. This should be accompanied by measurements of heart rate, blood pressure, and arterial oxygen saturation. Patients noted to be hypoxic should be questioned as to whether this represents arterial oxygen saturation at rest or after exercise (e.g. walking to the clinic) An increased respiratory rate is a non-specific sign, although the clinician should be alert to the presence of Cheyne–Stokes breathing, which is seen in encephalopathy, severe congestive heart failure, and CNS damage at the cerebral level.

Examination of the hands may reveal evidence of cyanosis, anaemia, or occult cigarette smoking, but also signs of systemic disease such as rheumatoid arthritis or scleroderma. Finger clubbing is a non-specific sign and may be found in cases of malignancy, lung abscess, bronchiectasis, and lung fibrosis, along with various extra-pulmonary diseases. Palpation of the peripheral lymph nodes is essential and may provide evidence of an on-going inflammatory process, TB, or disseminated malignancy. Inspection of the chest wall identifies mechanical factors likely to impede ventilation, including central obesity and deformities of the spine, such as kyphosis and scoliosis. Percussion may reveal areas of dullness as a consequence of either fluid accumulation or consolidation (which can be differentiated by vocal resonance, tactile vocal fremitus, or whispering pectoriloquy). Auscultation will detect areas of reduced air entry and the presence or absence of any crackles or wheeze.

Respiratory investigations

Having taken a full history and performed a thorough examination, the clinician should be in a position to offer a diagnosis or, at the least, a short differential. This leaves the role of respiratory investigations as:

- narrowing the differential to a definitive diagnosis
- excluding important diagnoses
- staging disease
- guiding therapy

In a minority of cases, the diagnosis remains uncertain even after extensive investigation and then a trial of therapy may be appropriate. A range of investigations is available and so, by asking which question is being tackled, the clinician can identify which investigations are most suitable.

Lung function tests can be both a source of revelation and consternation and, as such, need to be interpreted with caution. Seldom diagnostic, the patterns of abnormality often fit with a fairly small group of diseases. Patients may be referred following grossly abnormal spirometry results in a number of situations. A typical scenario is the patient who was predicted to have an obstructive defect but not to the extent of that revealed by spirometry. In this instance, it can be educational to simply repeat the test in the clinic room. This often reveals a patient who lacks enthusiasm in expiration and can be encouraged towards a normal FEV₁/FVC ratio. Likewise, patients who stop expiring prematurely before reaching FVC may be erroneously found to have a restrictive defect. This is particularly a problem

with computerized spirometers, which terminate the test after a few seconds. A volume–time trace that is still sloping upwards at the end of the test hints towards this scenario. Caution should also be exercised when faced with the presumption that a restrictive spirometry pattern in the presence of breathlessness must indicate fibrotic lung disease. Increasingly, the restriction (and cause of the breathlessness) is found to be extra-thoracic in origin: a consequence of central obesity. Sensitive questioning, calculation of the BMI, and advice may be all that is required in such situations but, if further reassurance is necessary, lung volumes and gas transfer may be established. In intra-thoracic restriction, both the transfer factor for carbon monoxide and the carbon monoxide transfer coefficient may be reduced; when the restriction is extra-thoracic, the latter will be preserved or elevated.

Gas transfer is a sensitive test of lung function and often one of the first abnormalities when pathology develops in the alveoli. In patients with a history suggestive of a dynamic airway problem, a single spirometry recording is largely unhelpful, and thought should be given to peak flow diaries, tests of reversibility, and provocation tests. Where a diagnosis of airway obstruction is considered, the possibility of a reversible element to the disease must be pursued thoroughly. As understanding of asthma improves, it becomes apparent that patients labelled as having 'irreversible' airway obstruction may in fact have 'poorly characterized' or even 'significantly under-treated' disease. This presents the potential opportunity to render patients virtually symptom-free, or at least significantly improve their quality of life. Asthma can be associated with the progression of symptoms and the development of irreversible airflow obstruction. Such airway remodelling may be limited with appropriate treatment.

Cardiopulmonary exercise testing allows the response of the cardiovascular and respiratory systems to a known exercise stress to be measured concomitantly. This is particularly useful where a patient is thought to have elements of both respiratory and cardiac disease and the relative contributions to their symptoms are difficult to quantify. In the area of sleep medicine, many centres will have access to overnight oximetry recording. In conjunction with the clinical scoring systems, this provides a reasonable screening tool, facilitating referral to more specialist units.

A standard chest radiograph is indicated in most patients, if only to guide the choice of more definitive imaging. The effective radiation dose of a posterior–anterior projection is 0.1 mSv. Other views (lateral, oblique, lateral decubitus, etc.) have largely fallen from favour with the increasing availability of CT. Improvements in CT have considerably increased its usefulness in respiratory medicine, and a number of imaging protocols have been developed. In order to perform the most appropriate investigation, it is imperative that the radiologist is provided with thorough clinical details along with the diagnostic thought processes.

Direct examination of the airways by bronchoscopy should only follow appropriate imaging, as a targeted examination has considerably higher yield, both for infection and for identifying malignancy.

Sputum culture is of relatively little value in the diagnosis of community-acquired pneumonia, but may be helpful in those chronically colonized. When considering tuberculosis, the yield is higher when early morning samples are examined (patients should be instructed to provide these via a deep cough shortly after waking). The yield of any single specimen is low (36%–63%) and is insufficient to exclude a diagnosis of active tuberculosis. Sputum cultures positive for *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Pseudomonas aeruginosa* raise the possibility of bronchiectasis, although the pathogens may also be found in patients with chronic bronchitis. Sputum may be induced safely by inhaling 3% saline, and the yield is improved. Characterizing the inflammatory profile of induced sputum is becoming an increasingly useful step in the management of a variety of airway diseases, including asthma, COPD, and chronic cough.

The choice of venous blood tests should be guided by the likely underlying pathology. Both anaemia and marked polycythaemia may cause breathlessness. Renal and liver dysfunction may suggest systemic disease. Total immunoglobulin levels can be appropriate; raised IgE is suggestive of an allergic process, while depressed IgG levels may be seen in bronchiectasis. Raised IgE against *Aspergillus fumigatus* is required for a diagnosis of allergic bronchopulmonary aspergillosis,

while low IgG titres against encapsulated organisms provide a treatment target in bronchiectasis.

Although not always necessary, tissue diagnosis remains the gold standard for a number of conditions where treatment is potentially long or likely to put the patient at significant risk of complications or side effects (e.g. sarcoidosis). While there remains a limited role for blind pleural biopsy in cases of suspected tuberculosis, in all other cases prior imaging should be considered essential. Available sampling techniques include CT-guided needle biopsy, advanced bronchoscopic techniques, thoracoscopy, and open lung biopsy. In general, the choice of technique should be decided in discussion with the reporting radiologist or, where appropriate, in a multidisciplinary meeting. Physical examination and imaging may reveal involvement of peripheral lymph nodes or other organs (e.g. liver) that may provide safer biopsy targets than the lung tissue itself. Note also that, with recent advance in tissue-sampling techniques, some patients may have been empirically initiated on long-term treatment many years ago for conditions that are now amenable to more rigorous investigation.

Diagnosis is continually reviewed against expected clinical progress and response to treatment. If these are not as predicted, thought must be given to both unusual presentations of disease and the presence of uncommon disease.

Conclusion

Faced with a patient with suspected respiratory disease, the problem is far from a lack of diagnostic tools; rather, it is choosing those most fit for purpose. Any investigation is only as good as its interpretation and this in turn will depend upon the context in which it is used. Perform a thorough clinical history and physical examination; being alert to the cardinal symptoms and signs should lead to a logical route of investigation. Together, these approaches should culminate in an appropriate diagnosis and a way forwards for physician and patient.

127 Investigation in respiratory disease

Pranabashis Haldar

Introduction

Investigation in respiratory disease may be broadly classified as:

- tests that aid diagnosis
- tests that assess disease severity; these are usually measures of respiratory function and inform prognosis
- tests that assess disease activity; these are usually non-invasive biomarkers, enabling serial measurement, and may inform therapy

One of the challenges of respiratory medicine is the limited spectrum of clinical expression associated with a diverse spectrum of pathologies. Clinical symptoms in respiratory medicine are often of poor specificity for securing a diagnosis or assessing disease severity. Investigations, therefore, necessarily form a critical part of assessment.

The most appropriate choice of investigation is an important component of clinical decision-making that affects patient care and may be influenced by a number of different questions that the clinician will need to consider. These include:

- what am I trying to find out?
- how will this affect my patient's management?
- what are the investigations available to me?
- which investigation is most likely to give me the information I need with the least discomfort or risk to my patient?
- is my patient in agreement with my assessment and are they aware of the alternatives that may exist?

Of course, more than one investigation may be appropriate and, in such circumstances, the decision may ultimately depend on cost and availability. In practice, investigations are guided by clinical suspicion (from history and examination) and undertaken in a stepwise manner. Easily accessible, low-cost, non-invasive tests are usually

performed first and most often serve a screening function, directing further, more specific tests.

This chapter will provide a systematic overview of important tests commonly performed in the investigation of respiratory illness, and the clinical principles that govern their use in practice. More detailed discussion of specific investigations will be presented in Chapters 128–145, which address particular conditions.

Principles of investigating the respiratory system

The respiratory system may be viewed as comprising several related anatomical compartments:

- extra-pulmonary tissues, including the pleural space, the chest wall, and the diaphragm
- pulmonary parenchyma, including terminal airways, alveoli, and the interstitium
- lower airways
- pulmonary vasculature

The relationship of structure with function is shown in Figure 127.1.

The alveolar membrane is the interface for gas exchange between the atmosphere and circulation, and comprises several layers (Figure 127.1). Gas exchange occurs by simple diffusion along a concentration gradient across this membrane. The two principle factors affecting diffusion, and therefore partial pressure of gases in the pulmonary capillaries are:

- the concentration gradient for diffusion; this is primarily determined by the partial pressure of gases in the alveoli; these pressures, in turn, are determined by alveolar ventilation
- the diffusion capacity of the alveolar membrane; this is related directly to the total surface area for exchange and inversely to the thickness of the membrane; it should be noted that the surface

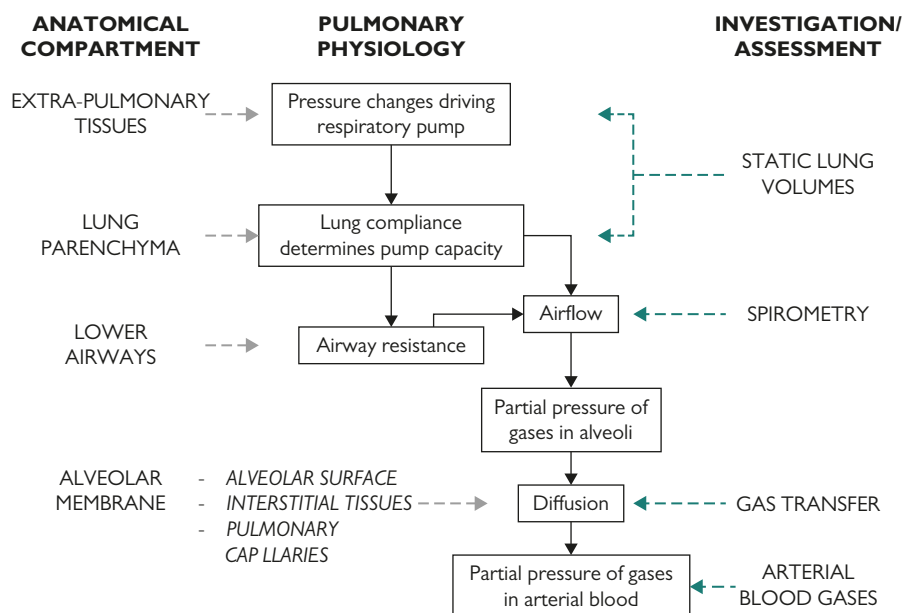

Figure 127.1 The anatomic sites that different respiratory tests evaluate.

area available for gas exchange is not the same as the anatomical surface area provided by the alveoli, but includes only the proportion of this area that is accompanied by blood flow (ventilation–perfusion matching)

Information about each component of these processes can be obtained from specific investigations of pulmonary function (see Figure 127.1), as will be discussed in this chapter.

Arterial blood gases and respiratory failure

Failure of the respiratory system is defined by abnormalities identified in the arterial blood gases (ABGs), that is, the partial pressures of O_2 (PaO_2) and CO_2 ($PaCO_2$) in arterial blood. These represent the final common pathway in respiratory function (Figure 127.1). Resting tachypnoea is often the first sign of respiratory failure, and respiratory rate should always be noted in the assessment of respiratory disease. Respiratory failure is divided into two types:

- type 1 respiratory failure, defined by a low PaO_2 and a low or normal $PaCO_2$
- type 2 respiratory failure, defined by a low PaO_2 and a raised $PaCO_2$.

This distinction has an important physiological basis. The solubility and therefore diffusion capacity of $PaCO_2$ is 20-fold greater than for O_2 . This has two implications. First, pathology affecting gas exchange rarely disturbs CO_2 homeostasis; second, pathology leading to a raised $PaCO_2$ will always be associated with hypoxia. The only determinant of arterial $PaCO_2$ is the alveolar $PaCO_2$, which is a function of alveolar ventilation. Thus, type 1 respiratory failure indicates a problem of gas exchange, while type 2 respiratory failure implies insufficient ventilation.

The interpretation of ABGs and, in particular, type 1 respiratory failure is entirely dependent upon the inspired fraction of oxygen (FiO_2). The FiO_2 of room air at atmospheric pressure is 0.21, and this defines the normal range for PaO_2 . For this reason, ABG sampling at room air is always preferred, when possible.

Interpreting the PaO_2 at higher FiO_2 requires knowledge of the alveolar PaO_2 (PAO_2), which is calculated from the alveolar gas equation. A simplified form of the equation at sea level is

$$PAO_2 = (95 \times FiO_2) - (1.2 \times PaCO_2),$$

where PAO_2 is in kilopascals. To determine whether a problem of gas exchange exists, the difference between PAO_2 and measured PaO_2 is calculated. This is known as the alveolar–arterial gradient and is normally less than 2 kPa.

ABG is an unusual example of a test that is both an easily accessible screening tool (to determine that a problem of respiratory function exists) and a clinical gold standard (for identifying and characterizing respiratory failure). It should be remembered that ABG sampling has important limitations. First, it is invasive and may be associated with complications (haematoma, infection, distal ischaemia, damage to adjacent structures such as the median nerve in the wrist), particularly when the procedure is technically challenging (low volume pulse, joint deformity, anomalous vascular anatomy, obesity) or performed by inexperienced operators. It is also of limited value prior to the onset of frank respiratory failure and unnecessary for monitoring type 1 respiratory failure. For the latter, measurement of arterial oxygen saturation (SaO_2) with a finger probe provides sufficient information to monitor progress and guide therapy. Subclinical type 1 respiratory failure may be precipitated with controlled exercise.

Investigations of pulmonary function

There are three types of pulmonary function tests:

- spirometry, which is used to measure airflow
- static lung volume, which determines pump capacity
- diffusing capacity, which measures gas transfer across the alveolar membrane

Of these, spirometry is routinely available and easily performed at the bedside. Although primarily used to test airway function, spirometry

is also frequently used as a screening test of pulmonary function to guide further investigation.

Spirometry and testing airway function

The lower airways refer to the trachea and all divisions that follow. The primary role of the airways is the conduction of air to and from the gas exchange surface of the lungs. Pathology affecting the airways, therefore, manifests in disordered airflow that is measurable with spirometry. Differences exist in the effects of pathology on airflow at different levels of the bronchial tree and in the different phases of the respiratory cycle (Table 127.1). A basic understanding of these factors will help with interpretation of spirometry.

Airway anatomy

Structurally, large bronchi repeatedly divide into progressively smaller bronchioles that end in terminal respiratory bronchioles and alveoli. Approximately 23 divisions of the bronchial tree (airway generations) are recognized. It is useful to think of the smaller and larger airways as two separate compartments. Larger airways constitute the first four to six generations and are structurally characterized by the presence of supporting cartilage to maintain airway patency. In contrast, smooth muscle that encircles the entire bronchial tree alone maintains structural integrity of smaller airways. The basic anatomy of the airways is dynamic and propagated by changes in pressure and volume during inspiration and expiration. The effects are greatest in the smaller, floppier airways that lack cartilaginous support.

Effects of the respiratory cycle

During inspiration, intra-thoracic pressure falls below atmospheric pressure as the chest wall and the diaphragm expand. This negative pressure applies a force to the airways and pulls them open. Outside the thoracic cavity, a pressure gradient between the atmosphere, and negative pressure within the airway (i.e. the larynx and the trachea), will promote airway collapse, but this is normally prevented by the existing cartilaginous support. Inspiration, therefore, improves airflow in the intra-thoracic airways, but has the opposite effect on the extra-thoracic portion of the lower airway.

During expiration, positive pressure has a compressive effect on intra-thoracic airways, promoting narrowing proximally and closure distally in the smaller airways with no supporting cartilage. In contrast, positive pressure within the extra-thoracic airway acts as a pneumatic splint to improve patency.

Pathology affecting the intra-thoracic airway is, therefore, more apparent in expiration and, for the extra-thoracic airway, is more apparent during inspiration. Clinically, the contrast is usefully made in the distinction between expiratory wheeze (implies narrowing of proximal intra-thoracic airways) and inspiratory stridor (implies pathology affecting either the larynx or the trachea). Despite their size, the smaller airways collectively contribute only a small proportion of total airway resistance because of their large number and arrangement in parallel. Pathology of the small airways will lead to premature closure during expiration, and gas trapping that will be clinically evident as hyperinflation and reduced air entry (Table 127.2).

Interpreting outputs of spirometry

Spirometry provides both quantitative and graphical information. Graphically, there are two outputs that provide related but complementary information:

The volume–time (V–T) curve: This displays the cumulative volume of air that is expired as a function of time (see Figure 127.2A1), and examines expiration only.

The flow–volume (F–V) loop: This displays the flow of air as a function of lung volume during both inspiration and expiration (see Figure 127.2B). The F–V loop is therefore needed to investigate pathology affecting the extra-thoracic airway; most often, the pathology will be evident as flattening of the inspiratory limb.

Basic spirometry requires the patient to take a maximal breath in followed by a forced and complete expiration into the spirometer. The most common indices recorded are:

Table 127.1 Suggested investigations to further evaluate respiratory symptoms

		Extra-pulmonary pathology						Airways pathology			Pulmonary tissues pathology	Pulmonary vasculature pathology	
		Chest wall	Pleural space	Diaphragm	Mediastinum	Proximal/larger airways	Distal/small airways						
Clinical symptoms	Screening and further investigation	Chest pain Breathlessness Orthopnoea	Pleuritic pain Breathlessness	Breathlessness Orthopnoea	Usually asymptomatic	Wheeze Productive cough Breathlessness	Dry cough Breathlessness	Dry cough Breathlessness					
	Investigations	CXR CT/MRI (for detailed characterization of soft tissues)	CXR USS CT	CXR	CXR CT/MRI	CXR Spirometry Static lung volumes	CXR Spirometry Static lung volumes	CXR Spirometry Static lung volumes					
	Diagnostic	Biopsy EMG/nerve conduction studies	Diagnostic aspiration Pleural biopsy (CT guided or thoracoscopy)	USS	EBUS-TBNA Surgical mediastinoscopy	CT (for diagnosing bronchiectasis) Methacholine PC20 (for diagnosing asthma) Sputum induction Bronchoscopy/BAL	CT Bronchoscopy/ BAL Transbronchial biopsy	CT Transbronchial biopsy Lung biopsy (CT guided or surgical)					

Abbreviations: ABG, arterial blood gas; BAL, bronchoalveolar lavage; CT, computed tomography; CTPA, CT pulmonary angiography; CXR, chest radiography; EBUS-TBNA, endobronchial ultrasound-guided transbronchial needle aspiration; ECG, electrocardiography; Echo, echocardiography; EMG, electromyography; MRA, magnetic resonance angiography; MRI, magnetic resonance imaging; SaO₂, arterial oxygen saturation; USS, ultrasound scan.

Investigation	Description	Use	Positives	Negatives
Spirometry	Straightforward test to measure FEV ₁ , and FVC	Quick assessment on ward or GP surgery to distinguish between obstructive and restrictive pathologies Determine severity of COPD (GOLD criteria) Serial measurements can track decline in COPD/asthma	Simple Quick Inexpensive Rapidly narrows differential diagnosis	Technique cannot always be mastered; this limits usefulness of results
Pulmonary function test	A 45-minute test to measure FEV ₁ , FVC, TLC, residual volume, KCO, and TLCO	To diagnose and quantify severity of restrictive pathology Serial measurements can monitor decline of interstitial lung disease	Narrows differential diagnosis Reasonably simple to perform	Technique cannot always be mastered Measuring TLCO and KCO requires a 10-second breath hold Requires some sophisticated apparatus not routinely available. Tests cannot be performed in Primary Care
Reversibility	Spirometry is carried out before and after 200 µg (two puffs) salbutamol is administered via inhaler	Improvement in FEV ₁ by 20% and >200 ml is indicative of reversible airways disease	Asthma can be diagnosed COPD/asthma can be characterized as reversible or fixed Effectiveness of inhaled bronchodilator therapy can be assessed	Lack of significant reversibility does not always correlate with a lack of improvement in patient's symptoms
Methacholine PC ₂₀ challenge	Nebulized methacholine, which causes bronchospasm in hyper-reactive airways, is given in incremental doses; the amount required to cause FEV ₁ to fall by >20% is called the 'PC ₂₀ '	A positive test (<8 mg/ml) indicates airway hyper-responsiveness and probable asthma or reactive airway dysfunction syndrome; normal values are >16 mg/ml	Helpful confirmatory test for the diagnosis of asthma	Not widely available Causes bronchoconstriction Contraindicated in patients with baseline FEV ₁ <50% Specificity falls with reducing baseline FEV ₁ False-negative tests commonly occur in patients who have continued with regular asthma medication or antihistamine therapy prior to testing
Exhaled nitric oxide	Nitric oxide, which is released by inflamed bronchial cells, is measured via a breath test; an elevated result indicates airway inflammation	Assessing treatment effectiveness in asthma May help with assessment of compliance with inhaled corticosteroids	Equipment is inexpensive and can easily be used in smaller hospitals/peripheral clinics	Not widely available Elevated result is not specific to asthma
Induced sputum	Sputum is induced by nebulized hypertonic saline after the teeth are cleaned and inhaled salbutamol is given; it is then mixed with 0.1% dithiothreitol and saline, and the cells in it are filtered out and centrifuged	Characterizing inflammation as neutrophilic or eosinophilic, to target corticosteroid treatment Assessing treatment effectiveness in asthma Serial measurement is used to titrate corticosteroid and immunosuppressive therapy in specialist centres Diagnosing TB and PCP	May make it possible to avoid the need for bronchoscopy in suspected TB and PCP	Available in specialized laboratories only Care required with pulmonary infections
Plethysmography	The patient sits in an air-tight chamber and undergoes pulmonary function tests; a sensitive method of determining absolute lung volumes	Helpful in assessing whether lung volume reduction surgery will be beneficial	True volume of lung and gas trapping can be calculated	Not widely available

Abbreviations: FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; GOLD, Global Initiative for Chronic Obstructive Lung Disease; GP, general practitioner; KCO, carbon monoxide transfer coefficient; PCP, pneumocystis pneumonia; TB, tuberculosis; TLC, total lung capacity; TLCO, transfer factor for carbon monoxide.

- forced expiratory volume in 1 second (FEV₁); this is the volume of air forcefully exhaled in the first second
- forced vital capacity (FVC); this is the maximum volume of air forcefully exhaled from the point of maximum inspiration

Between 75% and 80% of the total expired volume is normally expelled in the first second during forced expiration. Airflow

obstruction is defined by an FEV₁/FVC ratio of <70% or 0.7. If airflow obstruction is identified, reversibility testing should be performed. This involves inhalation of 200–400 µg salbutamol through a spacer, followed by repeated spirometry after 20 minutes. Severity of obstruction is defined by the reduction in post-bronchodilator FEV₁ (as per cent predicted) and not by the ratio. There are a number of common pitfalls to be aware of:

Figure 127.2 (A1) Volume–time curve; (A2) lung volumes in respiratory disease; (B) flow–volume loop; FEV₁, forced expiratory volume in 1 second; FRC, functional residual capacity; IC, inspiratory capacity; RV, residual volume; TLC, total lung capacity; VC, vital capacity; V_T , tidal volume; $\dot{V}_E \text{ max}$, maximum airflow on expiration; $\dot{V}_I \text{ max}$, maximum airflow on inhalation.

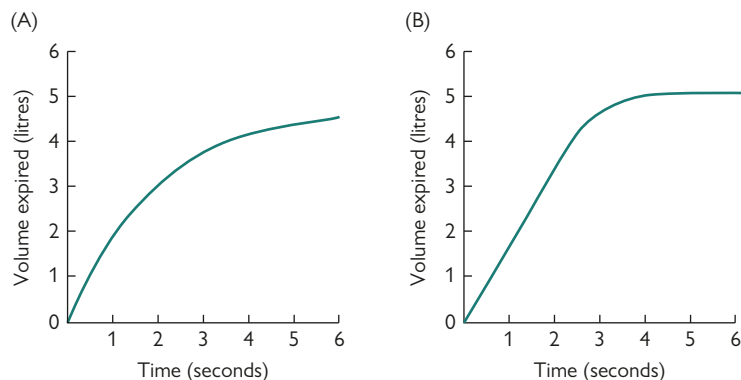

Figure 127.3 (A) An algorithm for interpreting spirometry; (B) an algorithm for interpreting static lung volume measurements; EP, extra-pulmonary; FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; RV, residual volume; TLC, total lung capacity.

- The FEV₁/FVC ratio falls in the ageing lung. This is physiological senescence, and caution must be exercised when interpreting spirometry in people beyond the age of 70 years, as normal values are not well validated for this group.
- A low FEV₁/FVC ratio may be accompanied by a 'normal' FEV₁ in young and fit individuals, as defined by the reference range. However, the true FEV₁ may be considerably higher in this group, and the measured FEV₁ may therefore represent a significant fall from baseline and can be difficult to quantify.
- The FEV₁/FVC ratio may improve and even normalize with increasing severity of airflow obstruction, due to a fall in the FVC. This occurs as increasing involvement of the smaller airways leads to air trapping that is exacerbated by forced expiration. For advanced airways disease, a more accurate measure of FVC (and therefore underlying obstruction) may be obtained by performing a slow vital capacity test. In this test, the patient exhales slowly from peak inspiration for as long as possible. The lower intrathoracic pressures generated reduce the extent of small airway collapse and gas trapping that occurs.

An algorithm for interpreting spirometry is presented in Figure 127.3A.

Measuring static lung volumes

The measurement of static lung volume involves calculation of the residual volume. This is the volume of air that remains in the lungs at the end of a full expiration. This measurement cannot be performed with spirometry and is essential to calculate total lung capacity (TLC; TLC = vital capacity + residual volume). Static lung volume measurements provide information that helps with the assessment of disordered physiology at two levels:

To determine and assess the severity of a restrictive lung deficit: A restrictive deficit is diagnosed by a demonstration of TLC <80% predicted. The severity of the restriction is determined by the size of the reduction in TLC. However, the presence of a reduction does not indicate whether the restriction is due to pulmonary pathology or extra-pulmonary pathology. Determining this requires further investigation (Figure 127.4), which is often done by examining the carbon monoxide-transferring ability of the lung.

To identify gas trapping as evidence for small airways disease: This is determined by measuring the ratio of the residual volume to the TLC ratio. This should be below 40% but is increased with gas trapping seen in small airways disease (increased residual volume, normal TLC) or emphysema (increased residual volume and increased TLC). A raised ratio is not diagnostic of gas trapping as it may also be increased with thoracic neuromuscular weakness (increased residual volume and reduced TLC).

There are two principal techniques used for the measurement of static lung volumes:

Helium dilution: This is the simpler technique and requires patients to gently breathe air containing a known volume of helium (which does not diffuse across the alveolar membrane) until the partial pressure of the gas reaches equilibrium. Total lung volume can

be calculated by knowing the change in partial pressure of helium from baseline. This technique is limited by the assumption that the helium distributes evenly and completely in both lungs. For patients with airways disease, the distribution of gas may be inhomogeneous and incomplete, leading to significant underestimation of the total lung volume.

Body plethysmography: This is considered the gold-standard diagnostic test for respiratory disease, but is limited by technical difficulty and limited availability. Patients also find this investigation less tolerable. The patient is required to sit in a sealed chamber and breathe through a mouthpiece. At the end of a normal breath, a shutter occludes the mouthpiece, and the patient is asked to continue making gentle respiratory efforts against the shutter. By measuring the pressure changes at the mouthpiece (alveolar pressure) and within the chamber, it is possible to derive the volume of gas in the lungs.

An algorithm for interpreting static lung volume measurements is presented in Figure 127.3B.

Measuring diffusion capacity

The diffusion capacity of the alveolar membrane is investigated by measuring the rate of diffusion of a known volume of inspired CO. CO is highly soluble and diffuses rapidly into the blood stream, and is retained there after binding with haemoglobin. Therefore, no back diffusion occurs and the rate at which the measured partial pressure of CO falls with time can be used to determine diffusion.

Diffusion across the alveolar membrane is influenced by numerous factors. Processes leading to thickening of the membrane reduce the rate of gas transfer. These include alveolitis; alveolar disruption as seen with emphysema, interstitial thickening due to pulmonary oedema, mitral stenosis, or lymphangitis; and thickening of the pulmonary capillaries due to vasculitis or primary pulmonary hypertension. In addition, as CO transfer is in part regulated by binding with haemoglobin, it is reduced with anaemia and increased with polycythaemia. Lung function reports can provide a correction for this, but the laboratory needs to be informed of an abnormal haemoglobin level. Finally, the rate of delivery of blood to ventilated lung will also influence gas transfer. Diffusion will be accelerated in high-output states and reduced when blood flow is sluggish (e.g. during cardiac failure or hypovolaemia) or absent (e.g. during ventilation-perfusion mismatching).

Gas transfer is expressed in two variables:

- TLCO, the transfer factor for CO, quantifies the diffusion capacity of the respiratory system
- KCO, the diffusion coefficient for CO, quantifies the diffusion capacity per unit volume of lung

KCO corrects for lung volume changes that may confound the interpretation of TLCO. An important example of when KCO is used is when distinguishing between pulmonary and extra-pulmonary restriction. In both types of restriction, a reduction in lung volume leads to a fall in TLCO. However, with pulmonary restriction, which will be associated with impaired gas transfer across a thickened alveolar membrane, KCO will be reduced as well; in contrast, KCO remains normal with extra-pulmonary restriction.

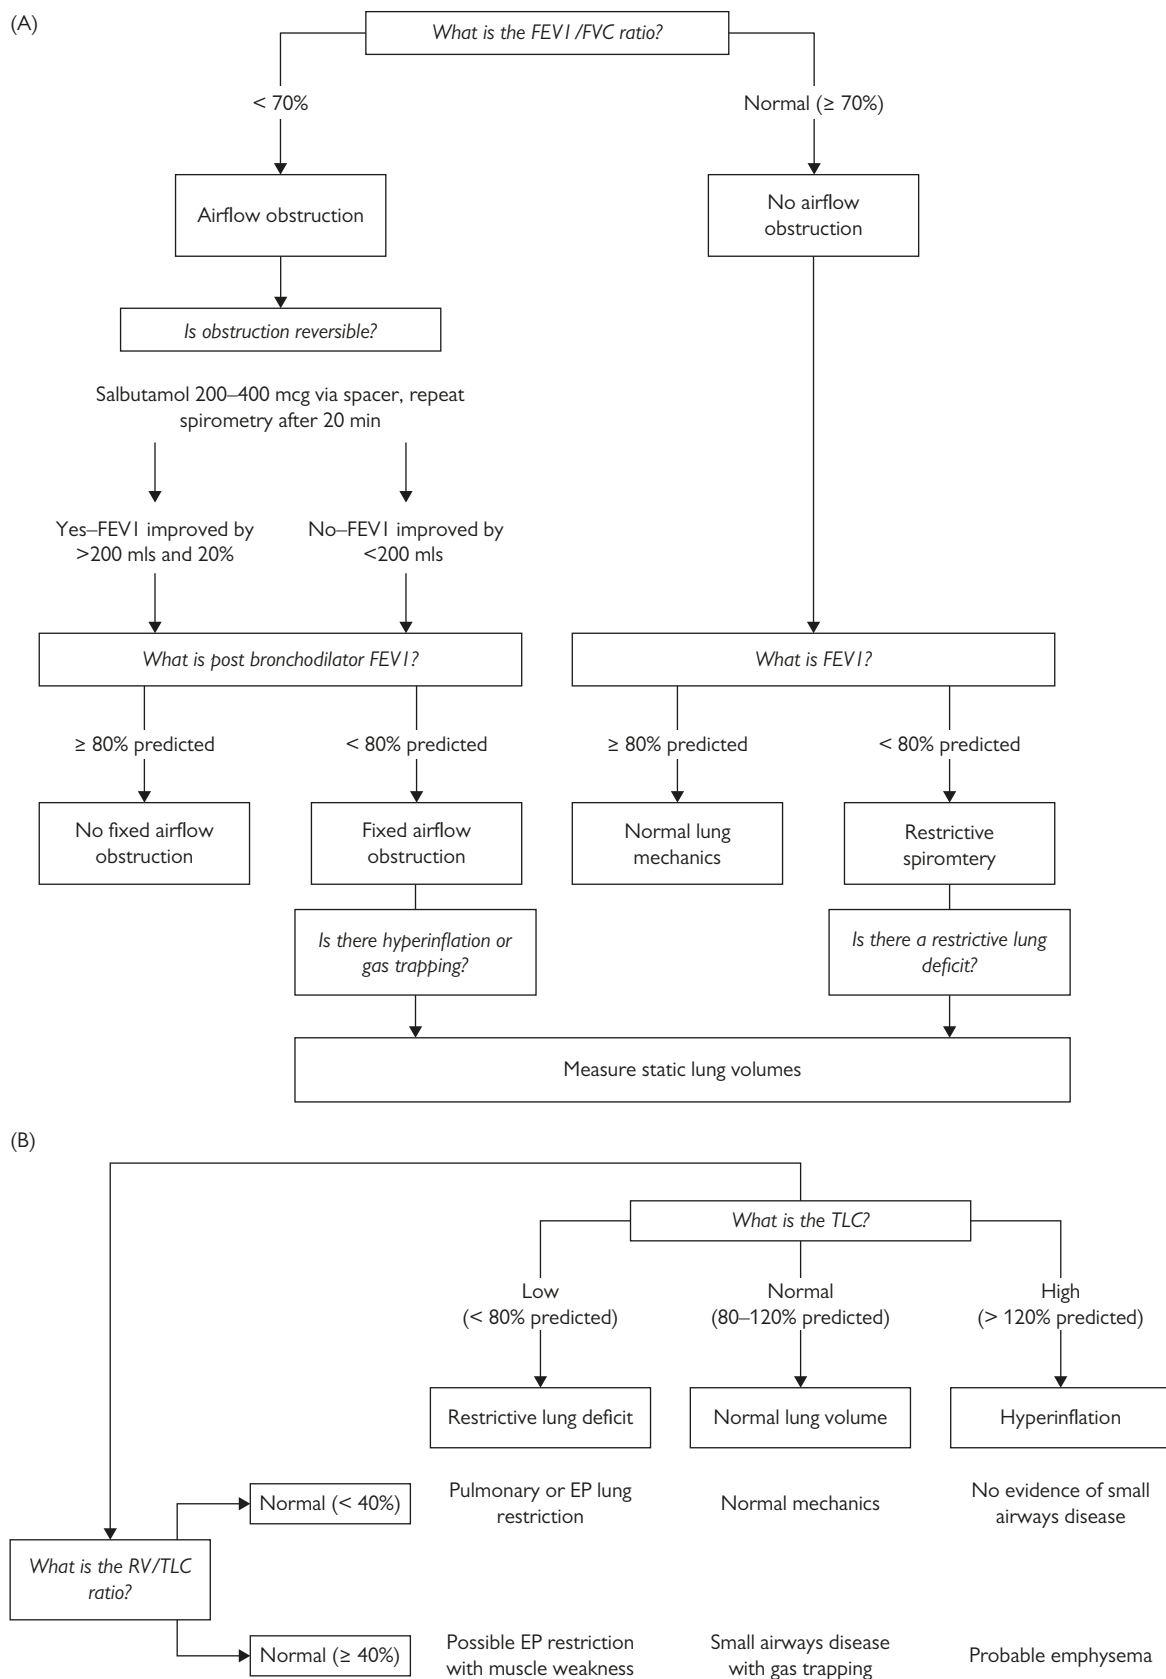

Figure 127.4 Schematic spirometers of two patients with airway obstruction and similar values for the forced expiratory volume in 1 second (FEV₁). (A) Diffuse intra-thoracic airway narrowing (COPD or asthma). Note that forced expiration is continuing after 6 s. (B) Upper airway narrowing with a 'straight' spirogram which corresponds to the plateau of flow in the earlier part of the expiration.

Table 127.3 Radiological investigations in respiratory disease

Investigation	Description	Use	Positives	Negatives
Staging CT	CT scan of the lower neck, chest, and abdomen, usually with contrast; 5 mm slices taken at 5 mm intervals, with image reconstruction, so the whole lung is scanned	Staging of cancer	Whole lung is scanned	High radiation dose (equivalent to 150 chest X-rays) Poorer resolution than ordinary CT
High-resolution CT	CT of 1.25 mm slices at 10 mm intervals of the lung, usually with contrast	Visualization of lung parenchyma and nodules	Diagnosis of most lung diseases Monitor progression of interstitial lung disease Can provide limited information without contrast	Radiation dose Scanning protocol skips segments of lung and therefore small nodules can be missed
CT pulmonary angiogram	CT of 2 mm slices at 2 mm intervals, with contrast timed to visualize pulmonary arteries	Diagnosis of acute and chronic pulmonary embolism Diagnosis of arteriovenous malformations	High sensitivity and specificity, particularly for clots in the proximal third of the vascular tree	Cannot be performed if there is renal impairment or contrast/iodine allergy Loses sensitivity for small, subsegmental emboli (but the clinical importance of these is unknown)
Ventilation/perfusion scan	IV radiolabelled albumin is injected and cannot be filtered by the lungs; areas where there are perfusion defects show as a mismatch in perfusion/ventilation scans; results are divided into low/intermediate/high probability	Diagnosis of pulmonary embolism in patients who have a normal chest X-ray	Lower dose of radiation than with CT pulmonary angiogram Can be used in people who are allergic to the contrast agent	Alternative diagnosis for the symptoms cannot be made if the scan is negative Loses specificity and therefore is of limited value in persons with other chronic or acute lung pathology Patients remain radioactive after the scan (difficult in nursing mothers) Patients with intermediate probability require a CT pulmonary angiogram
Ultrasound thorax	Fluid is a good acoustic window, and ultrasound is a non-invasive method for identifying the site and size of pleural effusions	Can differentiate amongst consolidation, air, and fluid Accurate marking of a safe site for pleural aspiration and biopsy Loculated effusions can be diagnosed	No radiation involved Safe site for pleural aspiration can be marked by the bedside Improved rate of successful pleural aspiration without complications	Users are required to be Level 1 competent
PET-CT	Radiolabelled glucose is administered, and areas with high metabolic activity have high uptake and show up strongly on the image	Accurate cancer staging	Cancer staging is more accurate than with CT alone	Cannot differentiate between infections (particularly TB) and cancer Malignant areas under 10 mm can be missed, so of limited value for assessment of small nodules Bowel has a lot of physiological uptake and there are a high number of false positives in this area
CT-guided biopsy	The site of the tumour is identified on CT, and a fine needle is passed to obtain a cellular aspirate; usual sites of investigation include the lungs, cervical nodes, and the chest wall	Diagnosis, usually in suspected cancer when histology for biomarkers is not required	Diagnosis can be made with safe sampling without general anaesthetic Well tolerated	Fin-needle aspirates provide small samples, so sufficient material for measuring biomarkers such as EGFR may not be obtained Cannot be used for suspected lymphoma, as it provides insufficient material for immunohistochemistry 10% risk of pneumothorax

An isolated reduction in KCO and TLCO in patients that have normal lung volumes and spirometry is seen with pulmonary vascular disease and may also be seen with early interstitial lung disease.

Approach to utilizing investigations in respiratory diagnosis

Pathological processes affecting the respiratory system may be broadly divided into three groups:

- primary diseases of the lung

- diseases that are part of a multisystem disease process (e.g. connective tissue disorders, other immunopathological syndromes)
- secondary physiological manifestations of disease in another organ system; most commonly, pulmonary manifestations of cardiac disease (e.g. pulmonary oedema) or neurological disease (e.g. weakness of the thoracic muscles)

Whatever the cause, the pathway to diagnosis is systematic and seeks to address three questions (see Figure 127.1):

- What is the physiological disturbance causing symptoms?
- What is the site of this disturbance?
- What is the underlying pathology?

Table 127.4 Endoscopic investigations in respiratory disease

Investigation	Description	Use	Positives	Negatives
<i>Bronchoscopic procedures</i>				
Bronchoscopy	A fibre-optic camera is passed into the lungs via the nose or mouth, under local anaesthetic and sometimes sedation; images are then seen on a screen	Visualization of obstructing lesions Targeted wash when infection suspected Bronchoscopy of bronchial and lung tissues can diagnose sarcoidosis	Quick Usually well tolerated Tissue diagnosis usually possible	Possible failure to get a diagnosis Typical complications include sore throat, sore nose, and haemoptysis; large-volume haemoptysis can be settled with ice-cold water and a 1:10 000 adrenaline solution
Bronchoalveolar lavage	The bronchoscope is wedged into an airway of the affected area; 50–100 ml saline is used to wash the area and is then aspirated back; the fluid is then sent to specialized laboratories for analysis	Diagnosis of pulmonary infections and parenchymal diseases such as ILD	Can allow the diagnosis of parenchymal lung diseases based on the cell population that predominates; infection can also be diagnosed, although a wash alone is usually insufficient for this	Hypoxia proportional to the volume of fluid used can occur
Transbronchial biopsy	Parenchymal tissue sampled by pushing the biopsy forceps down a bronchiole until resistance is met; clopidogrel should be omitted for 7 days preprocedure	Diagnosis of parenchymal lung diseases, particularly sarcoidosis	Usually well tolerated	There is a 10% risk of pneumothorax Surgical-wedge biopsy is preferable in ILD, suspected bronchoalveolar carcinoma, and organizing pneumonia
TBNA	Blind biopsy of large lymph nodes around the carina at the time of a bronchoscopy; a CT scan is required to determine the site of the nodes.	Diagnosis and staging of cancer (sensitivity 78%, specificity 99%) Diagnosing TB Diagnosing sarcoidosis	Diagnosis and staging possible in centres without EBUS-TBNA so delays to treatment are avoided Cheaper than EBUS-TBNA	Success is operator dependant Diagnostic rate less than EBUS-TBNA Complications include pneumothorax, pneumomediastinum, perforation of adjacent structures, and bleeding
EBUS-TBNA	An ultrasound probe is incorporated into a bronchoscope to allow for detection of enlarged lymph nodes and fine-needle aspiration biopsy under vision	The procedure of choice for investigation of mediastinal lymphadenopathy Diagnosis and staging of cancer (sensitivity 82%–94%, specificity close to 100%) Diagnosing TB Diagnosing sarcoidosis (diagnostic in 88%–93%)	Makes it possible to avoid the need for a mediastinoscopy under general anaesthetic Can be used to stage cancer	Risks include bleeding, puncture of adjacent structures, infection, and pneumomediastinum Not widely available Mediastinoscopy for histology may still be required for non-diagnostic samples and for lymphoma
Autofluorescent bronchoscopy	Blue light is used during bronchoscopy; when viewed through a specialized bronchoscope, normal and abnormal tissues appear to be different colours	Diagnosis of carcinoma in situ and dysplasia Allows for targeted biopsies	Cancer can be detected and treated at a very early stage Clearance at surgical resection sites can be checked	Progression from dysplasia and tumours in situ to invasive cancer is unclear, so the usefulness of the procedure in improving prognosis is unknown Only available in a few centres around the country
<i>Pleural procedures</i>				
LAVAT	Procedure performed under local anaesthetic and conscious sedation by physicians to diagnose the cause of a pleural effusion; the pleural cavity is visualized, and targeted biopsies taken; the effusion can be drained and pleurodesis carried out	Investigation of choice for exudative effusions where aspiration is inconclusive and malignancy is suspected Diagnostic sensitivity for malignancy is 92.6%	Greater yield for TB pleuritis than blind biopsy Pleurodesis is successful in 80%–90%	Complications (2.3%) include pneumonia, empyema, and bleeding Not available at every centre
Diagnostic pleural aspiration	Removal of 50 ml of pleural fluid, under ultrasound guidance, using a green needle and local anaesthetic, in order to diagnose the cause of the effusion; fluid should be sent for pH, protein, LDH, MC&S, AAFB, and cytology	The effusion can quickly be categorized into transudate or exudate Empyema and malignancy can be diagnosed	Quick and simple to perform Well tolerated	Ultrasound guidance should be used to confirm effusion and reduce the complication rate from iatrogenic pneumothorax and organ puncture
Abram's needle pleural biopsy	Blind biopsy of the pleura performed under local anaesthetic and ultrasound guidance	Diagnosis of TB pleural effusions (however, 47% sensitivity vs 87% in CT-guided group); the use of Abram's needle is now limited to investigation of suspected TB only	Can be used in centres where CT-guided pleural biopsy is not available	Risk of pneumothorax and progression to chest drain Risk of bleeding High non-diagnostic rate

Abbreviations: AAFB, acid- and alcohol-fast bacteria; CT, computed tomography; EBUS-TBNA, endobronchial ultrasound-guided transbronchial needle aspiration; ILD, interstitial lung disease; LAVAT, local anaesthetic video-assisted thoracoscopy; LDH, lactate dehydrogenase; MC&S, microscopy, culture, and sensitivities; TB, tuberculosis; TBNA, transbronchial needle aspiration.

Clinical assessment

Investigations are always preceded by clinical history and examination. Although respiratory symptoms are non-specific, they provide clues to the underlying site of pathology. A detailed respiratory history should elicit the rapidity of symptom onset, whether additional associated symptoms exist, whether symptoms are progressive or intermittent, and, if intermittent, whether there are identifiable triggers (Table 127.1).

Cough and wheeze indicate disorders of the airways. Cough that is productive of sputum indicates airway inflammation and usually involvement of larger airways. Breathlessness indicates increased work of breathing and is a ubiquitous indicator of respiratory compromise. Chest pain associated with the respiratory system is usually sharp and localized and indicates either injury to the chest wall or, if pleuritic in character, inflammation of the pleural surface.

Screening tests

Three screening tests, providing complementary information, are most often performed in an outpatient setting:

- SaO₂ (screening of respiratory failure)
- spirometry (screening of respiratory physiology)
- chest radiography (CXR; screening of respiratory anatomy)

In combination with detailed clinical assessment, these tests usually provide sufficient information to formulate a short differential diagnosis and direct further investigation.

What is the physiological disturbance causing symptoms?

The principles of investigating respiratory physiology have already been discussed and should inform the likely site of pathology.

What is the site of pathology?

CXR

The site of pathology is frequently evident on the screening CXR, which is useful for revealing structural abnormalities in extra-pulmonary tissues (e.g. skeletal deformities of the thoracic cage, rib fractures, diaphragmatic weakness), pleural pathology (pneumothorax, effusion), and gross changes of the pulmonary parenchyma (interstitial lung disease, consolidation, pulmonary oedema, soft tissue growth).

The CXR is often not helpful for characterizing pathology of the airways, subtle pathology of the lung parenchyma, and pathology of the pulmonary vasculature. Although pathology at these sites may be suspected from the clinical assessment and other screening investigations, the absence of abnormal findings on the CXR can also help alert the clinician to consider these sites more carefully.

CT scan

Continuing advances in scanning technology and computer analysis has put CT scanning at the forefront of detailed imaging for the respiratory system. A number of different scanning protocols are used to optimize imaging of different sites (Table 127.3). Not just a screening test, CT scanning should be regarded as a tool for detailed characterization of suspected pathology. Furthermore, 'low-dose' protocols of targeted imaging are available that significantly lower the radiation dose to patients and permit longitudinal evaluation of abnormalities, most notably pulmonary nodules.

PET-CT

CT scanning combined with positron emission tomography (PET-CT) is now performed routinely for staging of lung cancer (Table 127.3). An expanded future clinical role for PET-CT is likely, as research is presently being undertaken to evaluate its utility in the characterization of interstitial lung diseases, sarcoidosis, and pulmonary infections.

Ultrasound scan

Ultrasound scanning is useful for investigating pleural pathology. It is used routinely to guide appropriate and safe insertion of needles for thoracentesis or for insertion of intercostal drains. Indeed, recently updated British Thoracic Society guidelines recommend all such pleural interventions should be performed with ultrasound guidance.

MRI

The role of MRI is presently limited for respiratory disease, although this is likely to change. MRI is useful for characterizing abnormalities of the mediastinum and can provide detailed images of the pulmonary vasculature (via magnetic resonance angiography), using software for 3D reconstruction. It is used for the evaluation of pulmonary vascular disease and assessment of the mediastinum in women of childbearing age, when radiation to the breasts is avoided, if possible.

What is the underlying pathology?

A definitive diagnosis may be achieved in a number of different ways. Structural abnormalities may be diagnosed with imaging alone. These include musculoskeletal deformity, bronchiectasis, and pulmonary embolism. Detailed characterization of interstitial lung disease with CT scanning can be diagnostic for subgroups with usual interstitial pneumonitis and asbestosis.

COPD and asthma are diagnosed using physiological criteria. For most other conditions, a sample of tissue is required for cytological, histological, or microbiological analysis. Different strategies exist for obtaining samples from the different anatomical compartments. These are summarized in Table 127.4.

Finally, investigation beyond the respiratory system will be needed for diagnosing systemic pathology that presents with respiratory manifestations. These will be guided by clinical suspicion and from results of preliminary investigations.

Conclusions

In summary, the breadth and scope of investigation of the respiratory system is considerable. The challenge to clinicians is to understand the choices available and organize a strategy for investigation that delivers the necessary information in a patient-centred and cost-effective way.

128 Upper respiratory tract infections, including influenza

Pippa Newton

Definition of the disease

Infections of the nasal cavity, sinuses, pharynx, epiglottis, and larynx are termed upper respiratory tract infections (URTIs). These include acute coryza, pertussis, sinusitis, pharyngitis, tonsillitis, epiglottitis, laryngitis, laryngotracheobronchitis, and influenza.

Aetiology of the disease

Rhinoviruses and coronaviruses account for the majority of acute coryzal illnesses. Other causes include human parainfluenza viruses (HPIVs), respiratory syncytial virus (RSV), enteroviruses, adenoviruses, and influenza. Acute coryzal symptoms may be an early manifestation of pertussis.

Acute sinusitis (<4 weeks duration) is usually viral in origin, with rhinoviruses, HPIVs, and influenza responsible for most cases. Approximately 2% of cases are complicated by bacterial infections such as *Haemophilus influenzae*, *Streptococcus pyogenes* (Group A streptococcus; GAS), *Streptococcus pneumoniae*, *Moraxella catarrhalis*, *Staphylococcus aureus*, Gram negative bacteria, and anaerobic bacteria. Chronic sinusitis (>12 weeks duration) can also be caused by *Pseudomonas aeruginosa*, *Bacteroides* spp., and fungal infections.

About 70% of pharyngitis and tonsillitis cases are viral in aetiology. The viruses involved include rhinoviruses, coronaviruses, adenoviruses, enteroviruses, HPIVs, influenza, herpes simplex virus (HSV), EBV, CMV, and HIV. GAS is the commonest bacterial cause, with Group C and G Streptococci, *Corynebacterium diphtheriae*, *Borrelia vincentii* (Vincent's angina), *Neisseria gonorrhoea*, *Treponema pallidum*, and *Fusobacterium* spp. less frequent causes.

Haemophilus influenzae type B is responsible for most cases of epiglottitis. Other causes include *Streptococcus pneumoniae*, other Streptococci, and *Staphylococcus aureus*.

Acute laryngitis and laryngotracheobronchitis are usually caused by HPIVs. Other causes include RSV, adenoviruses, influenza, GAS, *Corynebacterium diphtheriae*, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, and *Haemophilus influenzae*.

Typical symptoms of the disease and less common symptoms

Acute coryza has prominent nasal symptoms associated with mild systemic symptoms. Clinical features include sneezing, nasal congestion, a profuse watery nasal discharge, sore throat, conjunctivitis, earache, sinus discomfort, and a cough. Systemic features include a mild fever, headache, myalgia, lethargy, and anorexia.

Pertussis has an insidious onset with an initial catarrhal stage followed by a paroxysmal cough. Initial symptoms last about 2 weeks and include sneezing, rhinorrhoea, conjunctivitis, and a mild dry cough. The cough worsens and becomes productive and paroxysmal in nature. It can be triggered by several stimuli, including laughing, yawning, and eating. Towards the end of the paroxysm, there is an inspiratory gasp of air, termed the inspiratory whoop. This may be absent in young infants. Paroxysms can be associated with cyanosis, subconjunctival haemorrhages, and vomiting. This stage lasts several weeks.

In young children, acute sinusitis often presents with persistent rhinorrhoea, a cough, and fever. Less commonly, facial swelling and tenderness occur. Older children and adults usually present with

nasal blockage, purulent rhinorrhoea, facial pressure/pain over the involved sinus (if frontal or maxillary), and headaches. The headache is often unilateral and severe. Fevers are usually absent. Chronic sinusitis presents with a persistent cough, nasal blockage, purulent rhinorrhoea, facial pain/tenderness, and headaches. Both forms of sinusitis may be associated with nausea, lethargy, and a reduced sense of smell and taste.

Pharyngitis and tonsillitis are often associated with a prodromal illness including fever, malaise, headache, and myalgia. Acute coryzal symptoms often accompany the onset of a sore throat. Other clinical features may include gingivostomatitis (HSV), mouth ulcers (enteroviruses, HSV), soft palate petechiae (EBV), conjunctivitis (adenoviruses), cervical lymphadenopathy (HSV, EBV, CMV, HIV), a maculopapular rash (HIV), jaundice (EBV, CMV), lymphocytosis/atypical lymphocytes (EBV, CMV), and splenomegaly (EBV). Bacterial pharyngitis and tonsillitis are often present with a high fever, painful cervical lymphadenopathy, and soft palate/tonsillar exudates. In children, abdominal pain secondary to mesenteric adenitis may occur. The presence of an erythematous rash and a strawberry tongue suggests a diagnosis of scarlet fever (GAS). A greyish pseudomembrane at the back of the throat raises the possibility of diphtheria (*Corynebacterium diphtheriae*). Ulcerative tonsillitis with associated tissue necrosis is suggestive of Vincent's angina (*Borrelia vincentii*).

Epiglottitis typically presents with a fever, sore throat, difficulty swallowing, and breathing. Stridor may be present. Laryngitis and laryngotracheobronchitis may mimic epiglottitis in young children. Other features include a hoarse voice and barking cough. Older children and adults present with a fever, sore throat, and hoarse voice. Cervical lymphadenopathy may be present.

Influenza has an abrupt onset. Clinical features include high fever, headache, myalgia, arthralgia, anorexia, nasal congestion, rhinorrhoea, a sore throat, dry cough, and diarrhoea. The systemic features last a few days, but the cough, sore throat, and lethargy may persist several weeks. In children, influenza often presents with fever, cervical lymphadenopathy, nausea, and vomiting.

Demographics of the disease

URTIs are the commonest infections seen in the general population. Their incidence decreases with age. In temperate and cold climates, the majority of viral infections occur in the winter/spring months and some tend to occur in mini-epidemics (RSV, HPIVs, influenza). Influenza A and B may cause epidemics, and influenza A has caused several pandemics.

Pertussis, epiglottitis, and GAS infections primarily affect young children. Pertussis is endemic in most populations, with epidemics occurring every 2–5 years in late winter/early spring. GAS infections are commoner during the winter.

Natural history and complications of the disease

The majority of URTIs are short-lived illnesses that resolve spontaneously.

Acute coryzal illnesses usually last less than 10 days but can persist for several weeks. Their complications include otitis media, sinusitis, and secondary bacterial infections. They cause exacerbations of asthma and COPD.

Pertussis tends to last several weeks. Its complications include cerebral anoxia, seizures, encephalopathy, pneumonia, otitis media, and bronchiectasis.

Acute sinusitis of viral aetiology usually settles spontaneously. If symptoms persist over a week or there is an associated purulent rhinorrhoea with facial tenderness and a fever, then bacterial infection should be considered. Periorbital oedema, orbital cellulitis, intra-orbital abscess, cavernous sinus thrombosis, meningitis, osteomyelitis, and a cerebral abscess are known complications.

The majority of cases of viral pharyngitis and tonsillitis last a few days. Complications include secondary bacterial infections, thrombocytopenia, haemolytic anaemia, pneumonitis, encephalitis, and myocarditis. GAS pharyngitis and tonsillitis may be complicated by a peritonsillar abscess, otitis media, sinusitis, and scarlet fever. Late complications (several weeks later) include rheumatic fever and acute glomerulonephritis. Tonsillitis secondary to *Fusobacterium* infection can result in thrombophlebitis of the internal jugular vein, causing carotid thrombosis (Lemierre's syndrome). Complications of diphtheria include respiratory obstruction, myocarditis, and cranial/peripheral nerve paralysis.

Epiglottitis may be complicated by a bacteraemia and severe air-flow obstruction. Examination of the epiglottis should not be performed until the airway is secured. Most cases of laryngitis settle spontaneously. Complications include respiratory obstruction and bacterial tracheitis.

Influenza is usually a self-limiting illness which lasts a few days. The associated malaise may persist for longer. Complications include pneumonia (viral, secondary bacterial), sinusitis, otitis media, myocarditis, encephalitis, and rhabdomyolysis. In children, Reye's syndrome may occur.

Approach to diagnosing the disease

History and examination play an important role in determining the likely diagnosis and differential diagnosis. The age, vaccination history, prominent clinical features, and associated clinical manifestations all provide important clues. Unusual clinical symptoms, signs, or laboratory results often provide additional information. For example, a young child presenting with coryzal symptoms, a cough, and a very high peripheral lymphocyte count is likely to have pertussis.

As most URTIs are viral in origin, it is important to assess whether the patient is likely to have a bacterial infection (primary or secondary). Knowledge of the usual pathogens and the proportion of infections that they cause often aids the assessment; for example, pharyngitis and tonsillitis in young children are most frequently caused by GAS infections, whilst in adults GAS accounts for only about 10% of cases. Bacterial infections should be suspected in patients with tachycardia, hypotension, a neutrophilia, and a high C-reactive protein result.

Other diagnoses that should be considered

These include otitis media, allergic rhinitis/sinusitis, vasculitis, retropharyngeal abscess, meningitis, and lower respiratory tract infections.

'Gold-standard' diagnostic test

For bacterial infections, the gold-standard diagnostic test remains culture. This also enables antibiotic sensitivities to be determined. Viral

culture is now rarely used and viral polymerase chain reaction technologies are often now the preferred diagnostic test. The collection of appropriate clinical specimens for microbiological testing remains of paramount importance.

Acceptable diagnostic alternatives to the gold standard

These include immunofluorescence to detect viral antigens (RSV), the Paul-Bunnell test (EBV), and specific antibody responses.

Other relevant investigations

Routine bloods including a full blood count, renal and liver function tests, and inflammatory markers. CT imaging of sinuses may be required for suspected sinusitis.

Prognosis and how to estimate it

Most URTIs settle spontaneously without complications. The mortality associated with pertussis, diphtheria, and *Haemophilus influenzae* infections has greatly reduced following the introduction of vaccination programmes.

Treatment and its effectiveness

The majority of URTIs are viral in origin and require no specific treatment apart from symptomatic relief. Oseltamivir and zanamivir can reduce the duration of influenza symptoms and have a role in prophylaxis. Specific CMV treatment (ganciclovir, foscarnet) is primarily used in immunocompromised individuals. Antibiotic therapy should be directed against the likely causative bacterial pathogen.

Bacterial sinusitis may require antibiotics, although studies have shown limited benefit in uncomplicated cases. Typically, a 2-week course of amoxicillin, co-amoxiclav, cefixime, or macrolides is given and failure to respond to therapy necessitates ENT referral.

Bacterial pharyngitis and tonsillitis due to GAS is treated with a 10-day course of amoxicillin, erythromycin, or clindamycin to prevent complications and reduce carriage.

Diphtheria and epiglottitis require urgent airway protection. Antitoxin is given in suspected diphtheria cases and antibiotics including penicillin or erythromycin are used. For epiglottitis parenteral ceftriaxone or amoxicillin for 10 days is recommended.

Pertussis is treated with erythromycin for at least two weeks. It reduces infectivity and may also reduce the severity and duration of the illness. Erythromycin is also used in prophylaxis.

Summary

URTIs are common and usually self-limiting illnesses. The clinical history, examination, and associated clinical manifestations often provide important clues as to the likely diagnosis and differential diagnosis. Assessment of the likelihood of a bacterial infection should help to determine whether antibiotic therapy is indicated.

129 Pneumonia

Pippa Newton

Definition of the disease

Pneumonia is defined as acute infection of the pulmonary parenchyma, presenting with consistent symptoms and signs and associated with new radiographic shadowing. It may be acute or chronic in onset and involve either one area of a lung (e.g. lobar pneumonia) or be multifocal in nature. It may be community-acquired or hospital-acquired.

Community-acquired pneumonia (CAP) is defined as pneumonia occurring in an individual with no recent contact with a healthcare setting, or in a patient admitted to hospital with development of symptoms and/or signs of pneumonia within 48 hours of admission. Hospital-acquired pneumonia (HAP) or nosocomial pneumonia (NP) occurs when a patient develops symptoms or signs of pneumonia after 48 hours of admission to a healthcare setting or in the context of a long-term nursing home resident. A subtype of NP is ventilator-associated pneumonia (VAP), defined as pneumonia occurring at least 48–72 hours post intubation.

Aetiology of the disease

The majority of cases of CAP are bacterial in origin and include both typical (e.g. *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Klebsiella pneumoniae*, and *Staphylococcus aureus*) and atypical (e.g. *Mycoplasma pneumoniae*, *Legionella pneumophila*, *Chlamydia pneumoniae/psittaci*, and *Coxiella burnetii*) organisms. The latter are classified as atypical because they replicate within cells and respond to agents that are concentrated intracellularly, such as macrolides, tetracyclines, and quinolones. They are characteristically resistant to beta-lactams.

Viruses such as influenza, parainfluenza, respiratory syncytial virus (RSV), and adenovirus account for almost all of the remaining cases where an etiological agent is found. In some studies, the causative agent remains unclear in up to a third of cases. Rarer viral causes of CAP include metapneumovirus, measles, and varicella zoster. Primary viral pneumonias may be complicated by bacterial infections such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus aureus*. Rare causes of CAP include other bacterial infections (e.g. *Salmonella typhoid/paratyphoid* infections; *Bordetella pertussis*, *Leptospira* spp., *Brucella* spp., and *Listeria monocytogenes*) fungal infections (e.g. *Histoplasmosis*, *Aspergillus fumigatus* infection), and parasitic infections (e.g. with migrating helminths).

Viral infections are the commonest cause of CAP in children under the age of 2. RSV, parainfluenza, influenza, and adenoviruses are the commonest pathogens. Mixed viral and bacterial infections also frequently occur. The predominant bacterial cause in neonates is Group B *Streptococci*, with other causes including *Chlamydia trachomatis* and *Listeria monocytogenes*. In slightly older infants, *Streptococcus pneumoniae* and *Haemophilus influenzae* are more common causes. In children over 2 years old, the frequency of viral, bacterial, and mixed bacterial and viral infections is similar. The viral pathogens seen are similar to those described in younger infants. The main bacterial pathogens in this age group include *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Mycoplasma pneumoniae*, and *Staphylococcus aureus*.

In adults, the commonest bacterial causes of CAP are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Mycoplasma pneumoniae*. In patients with underlying lung disease such as bronchiectasis and COPD, *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Pseudomonas aeruginosa*, and *Moraxella catarrhalis* are common pathogens. About 20% of cases of CAP in adults are viral in aetiology. Influenza, parainfluenza, RSV, and adenovirus are the most frequent causes.

Immunocompromised individuals may develop CAP with the same organisms as seen in immunocompetent individuals. However,

CAP tends to be more severe in these patients. Some immunocompromised patients have an increased susceptibility to *Streptococcus pneumoniae* infections (e.g. HIV infection and hyposplenism/splenectomy). Immunocompromised patients are also susceptible to opportunistic infections with microbes of low pathogenicity that rarely cause significant disease in immunocompetent individuals. These pathogens include *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*), cytomegalovirus (CMV), *Cryptococcus neoformans*, *Aspergillus fumigatus*, *Nocardia* spp., and atypical mycobacteria.

The pathogens that cause HAP are usually different from those that cause CAP, except when HAP occurs within 5 days of admission. In that instance, the most commonly isolated organisms are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus aureus*. As the length of inpatient stay increases, enteric Gram-negative bacteria such as *Escherichia coli*, *Enterobacter* spp., *Proteus* spp., *Klebsiella* spp., and *Serratia marcescens* become more prominent. In late-onset HAP (after 5 days of admission) other pathogens, including MRSA and multidrug-resistant (MDR) strains such *Pseudomonas aeruginosa*, *Enterobacter* spp., *Klebsiella* spp., and *Acinetobacter* spp., should be considered, and polymicrobial infection may occur. VAP is most frequently caused by enteric Gram-negative bacteria, including MDR strains, followed by *Streptococcus pneumoniae* and *Staphylococcus aureus*. Less common causes of HAP include anaerobes, *Legionella* spp., and viral causes such as influenza, parainfluenza, RSV, and adenovirus.

Typical symptoms of the disease, and less common symptoms

The clinical presentation of pneumonia may be acute or insidious in onset and will vary depending upon the causative organism and the immune status of the individual. It may follow an upper respiratory tract infection. Both constitutional and respiratory symptoms may be present and, in some cases, the constitutional symptoms may be more prominent. The constitutional symptoms include lethargy and fatigue, fever and rigors, anorexia, myalgia, arthralgia, and headache. Respiratory symptoms include cough (dry or productive), haemoptysis, breathlessness, and pleuritic chest pain. In some cases, where lower lobe pneumonia is present, the patient may describe abdominal pain.

Historically, CAP was divided into typical and atypical presentations, but studies have failed to accurately match the etiological agent to clinical presentation and these terms are no longer advocated.

Extra-pulmonary manifestations are less common and include rashes (e.g. erythema multiforme or nodosum), gastrointestinal symptoms (e.g. vomiting and diarrhoea), jaundice, meningitis, meningoencephalitis, encephalitis, myocarditis, pericarditis and delirium.

Elderly patients more frequently present with non-specific symptoms, especially delirium, and are less likely to have fever than younger patients.

Immunocompromised patients are susceptible to the commonly implicated organisms as well to opportunistic pathogens, and presentation will depend on aetiology. For example, *Pneumocystis jirovecii* pneumonia has an insidious onset, typically of several weeks duration. It often presents with a high fever and night sweats, weight loss, a dry cough, and increasing breathlessness associated with a progressive exertional dyspnoea and chest discomfort. Haemoptysis and extra-pulmonary manifestations, such as lymphadenopathy, are rare.

HAP can be difficult to detect. Patients may present with typical features of pneumonia, but more often their illness is non-specific. Sometimes, the only new feature is a fever. It should be suspected

in any patient with a fever who has a recent history of reduced consciousness or known swallowing difficulties. In this instance, aspiration pneumonia should be suspected. VAP tends to occur in the intensive care setting, often in unconscious patients, but can occur in patients invasively ventilated via a tracheostomy. Such patients may develop increased respiratory secretions and worsening breathlessness in addition to fever and chest pain.

Demographics of the disease

CAP occurs worldwide with various incidence rates reported. These range from 1 to 36 cases per 1000 of the population. The highest incidence rates tend to be seen in small children (<5 years old) and in the elderly. The majority of cases of CAP occur during the winter/spring months in temperate and cold climates. This is when some of the causative agents, such as influenza, parainfluenza (type 1 and 2), and RSV, are most prevalent and may also occur in mini-epidemics. As *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus aureus* may complicate influenza, it is not surprising that these bacterial pathogens cause the majority of CAPs during the winter months.

There are several respiratory pathogens that are more prevalent during later spring or summer. These include *Coxiella burnetii*, enteroviruses, and parainfluenza type 3 infections. *Mycoplasma pneumoniae* most frequently occurs in later summer and autumn in the northern hemisphere and typically affects young adults. Every few years there is a worldwide epidemic. Infections with *Legionella* spp. also tend to occur in the summer months and, as these bacteria are spread by contaminated aerosols, cases may be sporadic in nature or be part of a localized outbreak.

Several potential opportunistic pathogens have a variable worldwide distribution (e.g. *Histoplasma* spp., *Cryptococcus gattii*, and atypical mycobacterial species). Others, such as *Pneumocystis jirovecii*, are often under-reported in some developing countries due to a lack of specific diagnostic tests.

HAP is the second commonest nosocomial infection and is most commonly seen in elderly patients. It is estimated that it extends an inpatient stay of a survivor by between 5 and 9 days on average, resulting in a huge cost burden to the healthcare provider. VAP is very common in the intensive care setting; the risk of a patient developing a VAP is of the order of 1%–3% for each day on a ventilator.

The few studies that have looked into age predilection have found that most pathogens affect the young and old in similar frequency. Having said that, *Mycoplasma pneumoniae* and *Legionella* spp. were isolated less frequently in the elderly, who were more prone to have aspiration pneumonia and infections of unknown aetiology.

Natural history, and complications of the disease

As most cases of pneumonia are bacterial in origin, the patient is at risk of clinical deterioration without appropriate treatment. Immunocompromised patients often present with more severe illness and have a higher risk of deterioration. For viral causes of pneumonia, the majority will settle spontaneously without specific treatment, provided the pneumonia is not complicated by a secondary bacterial infection.

The common complications of pneumonia include severe sepsis/septicaemia in cases of associated bacteraemia (e.g. *Streptococcus pneumoniae*) and pleural collections, which can be either parapneumonic effusion or empyema. Others include bradycardia (e.g. in infection with *Coxiella burnetii*, *Legionella* spp., *Leptospira* spp., *Salmonella typhi*/paratyphi), lung abscess, metastatic infection (e.g. infection with *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Klebsiella* spp., anaerobes), necrotizing pneumonia (e.g. Panton–Valentine leukocidin *Staphylococcus aureus*), respiratory failure, acute respiratory distress syndrome, and death. In cases of pneumonia due to atypical pathogens, in addition to pulmonary complications, there may be complications associated with the extra-pulmonary manifestations of the disease, such as neurological complications from meningitis, or bleeding from an associated thrombocytopenia. *Pneumocystis jirovecii* pneumonia can be associated with the development of a pneumatocele, which may rupture, causing a pneumothorax. As opportunistic

infections are often associated with disseminated disease, there may also be complications related to the systemic infection. For example, disseminated CMV infection may cause a hepatitis, oesophageal ulceration, colitis, adrenal failure, and a retinitis. Additional complications may arise for patients with VAP. They may be difficult to wean off a ventilator and, after prolonged ventilation, have an increased risk of herpes simplex virus pneumonitis and *Candida* infections.

Recurrent episodes of pneumonia may be associated with underlying bronchiectasis or an obstructing bronchial lesion. They should also alert the physician to the possibility of underlying lung disease, malignancy, or immunosuppression.

Approach to diagnosing the disease

The history, examination, and initial investigations, including the radiological findings, play an important role in determining the diagnosis and differential diagnosis. The age of the patient, the vaccination history (e.g. Pneumococcal and *Haemophilus influenzae* vaccines), underlying respiratory diseases (e.g. COPD, bronchiectasis, bronchial obstruction secondary to a tumour), smoking history (increases risk of invasive Streptococcal pneumonia), alcohol excess (e.g. *Klebsiella* spp., *Mycobacterium tuberculosis*), immune status (e.g. immunodeficiency, transplant, immunomodulatory drugs), any neurological illness (e.g. risk of aspiration), travel history, pets (especially birds) and animal contacts, and their clinical presentation all provide useful clues as to the likely diagnosis. Questions relating to recent contact with healthcare settings will help differentiate CAP from HAP.

For CAP, additional questions relating to the prominence of both systemic symptoms and extra-pulmonary manifestations may help to differentiate between typical and atypical pathogens. In the case of immunosuppressed individuals, the nature of the immune defect and the severity may make it easier to ascertain the likely cause. For example, HIV-positive patients are at risk of *Pneumocystis jirovecii* pneumonia once their CD4 count is less than 200 per cubic millimetre or 11% of their total lymphocytes. In the transplant setting, the timing of the infection post transplant often gives a clue to the likely pathogen. The presence of latent infections (e.g. CMV infection) may also be relevant.

Table 129.1 summarizes the different clinical features that may provide important clues to the likely pathogen in CAP. It also describes some of the clinical presentations that may occur in immunocompromised patients with opportunistic infections. For HAPs, the likely pathogens isolated depend upon the timing of the infection. In early onset HAP (between 48 and 120 hours post admission), the pathogen isolated is often similar to that found in CAP (e.g. *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus aureus*) but, as the inpatient stay lengthens, enteric Gram-negative bacteria become the predominant pathogens, and the risk of developing an infection with a multidrug-resistant pathogen increases, especially following repeated courses of antibiotics. A high index of clinical suspicion is needed to consider this infection, as often patients have limited clinical symptoms and signs. This is particularly important in the setting of VAPs.

Other diagnoses that should be considered

These include mycobacterial infections, cryptogenic organizing pneumonia, pulmonary emboli, alveolitis, pulmonary oedema, primary and metastatic lung malignancies, vasculitis, and pulmonary eosinophilia. Other infections such as typhoid, paratyphoid, brucellosis, and leptospirosis may present with symptoms and signs of pneumonia, often as a minor feature of the overall systemic illness.

Several illnesses such as ischaemic heart disease, peptic ulcer disease, pancreatitis, and liver or subphrenic abscesses can mimic the clinical presentation of pneumonia and must be considered in the differential diagnosis.

'Gold-standard' diagnostic test

As pneumonia is defined as inflammation of the lower respiratory tract, in association with radiological evidence of lung parenchymal involvement, the gold-standard diagnostic test for pneumonia is really

Table 129.1 Clinical features that may provide clues to the underlying causative pathogen in different types of pneumonia

Clinical feature	Likely pathogen
History	
Rusty sputum	<i>Streptococcus pneumoniae</i>
Exertional dyspnoea	<i>Pneumocystis jirovecii</i>
Prodromal flu-like illness or initial upper respiratory tract infection then lower respiratory tract symptoms	<i>Mycoplasma pneumoniae</i> , <i>Chlamydia</i> spp., <i>Legionella</i> spp., <i>Coxiella burnetii</i> , influenza, parainfluenza, RSV, adenovirus
Extra-pulmonary manifestations, e.g. diarrhoea	<i>Legionella</i> spp., <i>Streptococcus pneumoniae</i> , <i>Mycoplasma pneumoniae</i> , <i>Coxiella burnetii</i> , influenza, adenovirus, CMV
COPD or bronchiectasis	<i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Pseudomonas aeruginosa</i> , <i>Moraxella catarrhalis</i>
Alcoholism	<i>Streptococcus pneumoniae</i> , <i>Klebsiella pneumoniae</i> , <i>Staphylococcus aureus</i> , anaerobes, <i>Mycobacterium tuberculosis</i>
Immunocompromise	<i>Pneumocystis jirovecii</i> , mycobacteria, CMV, <i>Aspergillus fumigatus</i> , <i>Cryptococcus neoformans</i> , <i>Nocardia</i> spp., mycobacteria
Animal exposure	<i>Chlamydia</i> spp. (birds), <i>Leptospira</i> spp. (rats), <i>Coxiella burnetii</i> (cattle)
Examination findings	
Bullous myringitis	<i>Mycoplasma pneumoniae</i>
Rash	
Erythema multiforme	<i>Chlamydia pneumoniae</i> , <i>Mycoplasma pneumoniae</i>
Erythema nodosum	
Vesicular rash	Varicella zoster virus
Maculopapular or macular rash	Measles virus, <i>Chlamydia</i> spp.
Lymphadenopathy	<i>Mycoplasma pneumoniae</i>
Meningitis/encephalitis	<i>Legionella</i> spp., <i>Mycoplasma pneumoniae</i>
Myocarditis/pericarditis	<i>Coxiella burnetii</i> , <i>Mycoplasma pneumoniae</i>
Limited chest signs	<i>Pneumocystis jirovecii</i>
Radiological findings	
Lobar pneumonia	<i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i>
Multilobar pneumonia	<i>Legionella</i> spp., <i>Mycoplasma pneumoniae</i>
Multiple pulmonary abscesses	<i>Staphylococcus aureus</i> (including PVL strains), <i>Streptococcus pneumoniae</i> , <i>Klebsiella pneumoniae</i>
Interstitial shadowing	<i>Pneumocystis jirovecii</i> (often perihilar), CMV
Nodular lesions	<i>Aspergillus fumigatus</i> , Mycobacteria
Laboratory findings	
Normal white blood cell count	<i>Mycoplasma pneumoniae</i>
Lymphopenia	<i>Legionella</i> spp.; <i>Pneumocystis jirovecii</i> and other opportunistic agents
Atypical lymphocytes	CMV
Hepatitis	<i>Legionella</i> spp., <i>Leptospira</i> spp., CMV
Renal failure	<i>Legionella</i> spp., <i>Leptospira</i> spp.

Hyponatraemia	<i>Legionella</i> spp.

Abbreviations: CMV, cytomegalovirus; PVL, Pantón–Valentine leukocidin; RSV, respiratory syncytial virus.

a combination of clinical features of pneumonia in the presence of appropriate radiological findings. However, it is important to note that the radiological features of pneumonia can lag behind the clinical presentation, and therefore it is possible that patients with symptoms of lower respiratory tract infections may not initially have radiological

evidence of lung parenchymal involvement, but may develop it a few days later.

The gold-standard diagnostic test for bacterial and fungal infections remains culture. This enables antimicrobial sensitivities to be determined. For *Pneumocystis jirovecii* pneumonia, the demonstration of cysts or trophozoites in bronchoalveolar lavage (BAL) or lung tissue by methenamine silver staining is the standard diagnostic test, although polymerase chain reaction (PCR) is often now the preferred diagnostic test. Viral culture is now rarely used, and PCR is the usual diagnostic tool to determine the viral pathogen.

The appropriate collection of microbiological samples for culture, prior to commencement of antimicrobial therapy, remains very important, as the culture yield decreases significantly following antimicrobial therapy.

Acceptable diagnostic alternative to the gold standard

These include urinary antigens (for *Streptococcus pneumoniae*, *Legionella* spp.), blood cultures (in cases of bacteraemia), direct immunofluorescence on respiratory samples (e.g. *Pneumocystis jirovecii*, *Chlamydia* spp.), fungal antigens in blood (e.g. Beta D glucan for *Pneumocystis jirovecii*, galactomannan for *Aspergillus* spp.) or sputum (e.g. for *Aspergillus* spp.), cold agglutinins (e.g. for *Mycoplasma pneumoniae*), and the presence of a specific antibody response (e.g. to *Mycoplasma pneumoniae*, *Coxiella burnetii*, *Chlamydia* spp.).

Other relevant investigations

BAL samples are collected in cases of suspected VAP and may be required in some patients presenting with a non-productive cough. All patients should have routine blood tests, including a full blood count and differential white cell count, renal and liver function tests, and tests for inflammatory markers. Although CT imaging of the chest may provide useful information regarding the likely aetiology, it has no routine role in the investigation of pneumonia. It would be useful when diagnosis is in doubt or to investigate possible complications, such as lung abscess. Patients with associated pleural effusion should have diagnostic thoracentesis under ultrasound guidance with pH testing to exclude an empyema and samples sent for culture.

Prognosis and how to estimate it

CAP tends to have a better prognosis than HAP. In CAP there are several different methods to assess clinical severity and prognosis. For example, the British Thoracic Society (BTS) guidelines use the CURB-65 score, which uses several clinical parameters (new onset **confusion**, a **urea** above 7 mmol/l, a **respiratory** rate of 30 or more breaths per minute, a systolic **blood pressure** less than 90 mm Hg, or a diastolic blood pressure less than 60 mm Hg and an age of **65** or over) to estimate mortality. Each factor scores 1, and combining the scores gives an overall estimate of mortality. A total score of 1 or less is associated with a mortality of less than 3%, while a score of 3–5 has an estimated mortality of 15–40% (see Figure 129.1).

The prognosis of early early-onset HAP is better than that of late-onset disease, presumably due to the reduced prevalence of multidrug-resistant organisms causing the illness. The crude mortality rate for HAP has been estimated to be as high as 70% in some studies, although this is likely to be an overestimate, as several factors may have contributed to death. It is probably responsible for between a third and a half of deaths in patients with HAP. Severity scores for HAP are less well developed than in CAP. Several factors known to increase mortality have been identified. These include evidence of sepsis (systolic blood pressure less than 90 mm Hg or diastolic blood pressure less than 60 mm Hg; greater than 4 hours of vasopressor usage; poor urine output (less than 80 ml in 4 hours), or need for renal support), respiratory failure (mechanical ventilation; requirement of over 35% oxygen to keep oxygen saturations over 90%), multifocal disease, and admission to intensive care.

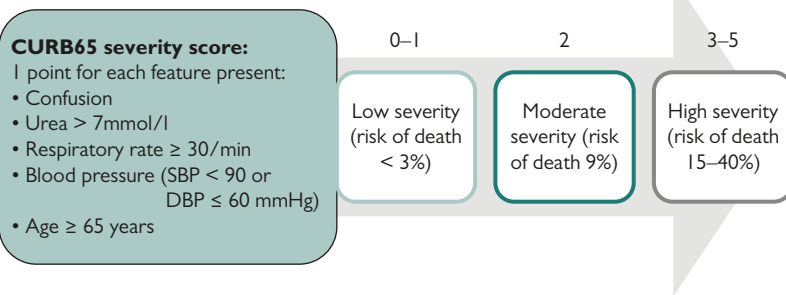

Figure 129.1 CURB-65 severity score; DBP, diastolic blood pressure; SBP, systolic blood pressure.

Reproduced from Lim WS et al. Defining community acquired pneumonia severity on presentation to hospital: an international derivation and validation study, *Thorax*, volume 58, pp 377, copyright 2003 with permission from BMJ Publishing Group Ltd.

Other factors associated with a higher mortality include underlying pulmonary disease, cardiac disease, immunosuppression, multifocal disease, and treatment delay.

Treatment and its effectiveness

As the majority of cases of pneumonia are bacterial in origin, it is important to start prompt antibiotic therapy for suspected bacterial cases. Treatment is aimed at reducing the severity of the illness, and potential complications. Empirical treatment is usually started, as the causative organism is often unknown at presentation, but treatment should be modified when microbiological results become available. Reviewing previously isolated organisms in the sputum of chronic respiratory patients may also provide useful information on any colonizing organisms and their susceptibility. Viral pneumonias may not require specific treatment but, for infections such as influenza, specific antiviral agents (zanamivir, oseltamivir) may reduce the duration of the illness.

In order to start appropriate empirical treatment, it is important to ascertain whether the patient has a CAP or HAP and whether they are immunosuppressed. Several treatment guidelines are available for the management of CAP, including the BTS guidelines, which provide advice of when, on clinical judgement, it should be safe to manage the patient in the community (CURB65 score of 0) and when admission to hospital may be needed (CURB65 score of 1 to 2) or advised (CURB65 score of 3 and above). For patients treated at home, the preferred antibiotic regimen is amoxicillin 500 mg to 1 g three times per day orally or, in penicillin-allergic individuals, erythromycin 500 mg four times per day or clarithromycin 500 mg twice per day orally. The same treatment regimen can be used in hospital for non-severe cases of CAP when treatment was not started in the community. More commonly, these cases are treated with a combination of amoxicillin and macrolide, either IV or oral, and, for penicillin-allergic individuals, levofloxacin 500 mg once daily or doxycycline, with a 200 mg loading dose and then 100 mg once daily. For patients presenting with severe CAP, the guidelines recommend IV co-amoxiclav 1.2 g three times per day or cefuroxime 1.5 g three times per day plus an IV macrolide (plus rifampicin if suspected *Legionella* infection); in penicillin-allergic individuals, IV levofloxacin 500 mg twice per day is advised. The exact duration of treatment is dependent upon the clinic response, but it is usually around 7–10 days in duration for the more severe forms of the illness. The treatment of specific respiratory pathogens, once identified, is also discussed in the BTS guidelines.

Each opportunistic infection requires specific treatment. It is advisable to obtain specialist advice on the most appropriate

treatment. For example, *Pneumocystis jirovecii* pneumonia is treated with high-dose co-trimoxazole (120 mg/kg day⁻¹ IV in two to four divided doses) for 21 days, and steroids (methylprednisolone, followed by a reducing course of prednisolone) given to patients with moderate to severe disease. Following treatment, secondary prophylaxis with daily co-trimoxazole is given. For CMV infection, ganciclovir or foscarnet may be indicated.

The empirical treatment of HAP is dependent upon whether the infection is of early or late onset, whether there are features of disease severity, and whether there are risk factors for multidrug resistance. If the HAP is of early onset with no other associated features, then IV co-amoxiclav 1.2 g three times per day or IV ceftriaxone 2 g per day would be appropriate; in penicillin-allergic individuals, levofloxacin 500 mg twice per day would be recommended. In late-onset disease, where the risk of multidrug resistance is higher, empirical dual antimicrobial therapy is often indicated. Treatment regimens may include IV ceftazidime 2 g three times per day, IV meropenem 1 g three times per day, or IV tazobactam with piperacillin 4.5 g three times per day plus an aminoglycoside such as gentamicin or tobramycin. For penicillin-allergic individuals, IV levofloxacin and/or an aminoglycoside may be indicated.

Summary

Both CAP and HAP pneumonia are common medical presentations, and the majority are bacterial in origin. The clinical history, examination findings, and initial investigations often provide useful clues to the likely pathogen. Clinical severity scores help guide the initial empirical treatment of suspected bacterial infections, and treatment should be modified once appropriate microbiology results are available.

130 Tuberculosis

Pranabashis Haldar

Definition

Tuberculosis (TB) is an infectious disease caused by the bacterial organism *Mycobacterium tuberculosis*. In this context, reference to the word **disease** is important, as TB implies *Mycobacterium tuberculosis* infection that is associated with symptoms. Approximately 10% of *Mycobacterium tuberculosis* infection is manifest as disease. In the large majority, *Mycobacterium tuberculosis* infection is latent and defined by evidence of a measurable and significant cell-mediated immune response to mycobacterial antigens in the absence of clinical or radiological evidence of disease. TB may be clinically classified further according to the site of disease. Miliary TB refers to systemic disease that may affect multiple organs.

Aetiology

Mycobacterium tuberculosis is one of four species (*Mycobacterium bovis*, *Mycobacterium africanum*, and *Mycobacterium microti* are the others) belonging to the *Mycobacterium* genus of the Mycobacteriaceae family. Collectively, these species share a close genotypic relationship and comprise the *Mycobacterium tuberculosis* complex. The microbiological properties of these organisms are unusual and of clinicopathological relevance. *Mycobacterium tuberculosis* is an obligate aerobe that resides intracellularly within cells of the monocyte–macrophage lineage in vivo. This adaptation is a form of immune sequestration. Structurally, the bacillus has a cell wall with a high lipid content that provides an effective barrier to immune and drug-mediated cytolytic processes. One consequence of the lipid cell wall is a comparatively slow rate of bacterial replication. In vitro, *Mycobacterium tuberculosis* can only be cultured using special media, and this may take up to 6 weeks. ‘Acid-fastness’ refers to the high retention of dye in the mycobacterial cell wall after washing with dilute acid during staining procedures and is a further consequence of its high lipid content. However, this is not unique to mycobacteria, and therefore identification of acid-fast bacilli at microscopy should not be considered synonymous with mycobacterial infection.

A number of other species from the Mycobacteriaceae family may infect humans and cause disease that may clinically resemble TB. Typically, infections with so-called non-tuberculous mycobacteria are more frequently seen in patients that are immunosuppressed or have chronic lung disease.

Typical symptoms of the disease, and less common symptoms

Symptoms in TB may be broadly categorized as systemic or organ specific (Box 130.1). The lungs are involved most frequently and comprise 75% of all TB cases. Extra-pulmonary TB may include any organ system, but most commonly involves intra- or extra-thoracic lymph nodes, bones, the gastrointestinal tract, and the genitourinary tract. Involvement of the CNS is uncommon (approximately 5% of non-pulmonary TB) but of disproportionate importance due to significant associated morbidity and mortality. Extra-pulmonary TB occurs more frequently in ethnic minorities and the immunocompromised. For the latter, miliary TB is significantly more common, and involvement of multiple extra-pulmonary sites should be considered.

Primary TB (see ‘Natural history, and complications’) is associated with some specific clinical presentations arising from hypersensitivity reactions. These include:

- erythema nodosum: reddish and painful raised lesions, most frequently seen on the anterior surface of the lower legs

Box 130.1 Symptoms of TB

Systemic

- fever
- night sweats
- weight loss
- anorexia

Organ/system specific

Pulmonary

- cough
- haemoptysis
- chest pain
- breathlessness

Lymphatic

- lymph node enlargement (cold abscess)*

Gastrointestinal

- non-specific abdominal pain
- ascites
- terminal ileitis†

Genitourinary

- haematuria
- dysuria with sterile pyuria
- prostatitis
- infertility

Musculoskeletal

- chronic osteomyelitis with focal bone pain
- chronic back pain (vertebral osteomyelitis)
- chronic discharging sinus
- psoas abscess, presenting with hip and buttock pain

CNS

- non-specific headache
- symptoms of meningitis
- cranial nerve palsies (single or multiple)
- hemiparesis (tuberculoma)

* Lymphadenopathy is most commonly cervical and confined to a single anatomical group. Enlargement is commonly painless to begin with but may become uncomfortable with increasing size.

† Involvement of the terminal ileum may clinically resemble Crohn’s disease or appendicitis.

- dactylitis: pain and swelling of fingers and/or toes
- phlyctenular conjunctivitis: characterized by itching and soreness of the eye, with excessive tear production; usually, symptoms are monocular, and small grey nodules may be visualized at the conjunctival periphery; the condition most often affects young girls and is self-limiting

Systemic symptoms may accompany any form of TB and include intermittent fever, night sweats, weight loss, anorexia, and cachexia. Systemic symptoms can often dominate presentation and this raises diagnostic challenges; TB should be high on the differential diagnosis of all patients with an unexplained fever or weight loss, particularly if they are foreign-born and from ethnic minorities with a high TB prevalence in their country of origin (see ‘Demographics of the disease’).

Box 130.2 Risk factors for TB**Prior latent infection**

- previous TB
- recent TB contact
- residence in country with high TB prevalence
- increasing age

Immunodeficiency

- HIV infection
- alcoholism
- chronic malnutrition*
- chronic kidney disease[†]
- diabetes mellitus
- immunosuppressant therapies[‡]
- haematological disease

* Malabsorption syndromes are considered to be in this category; jejunioleal bypass is associated with a higher risk of TB.

[†] Increasing TB risk with Stages 4 and 5 of chronic kidney disease; patients requiring dialysis are at the highest risk in this group.

[‡] Notably, anti-tumour necrosis factor agents; consider increased TB risk in patients requiring this therapy for comorbid conditions; profound immunosuppression following organ transplant.

Demographics of the disease

The risk of TB is a function of two factors that reflect demographic characteristics of the disease (see Box 130.2):

- probability of prior latent *Mycobacterium tuberculosis* infection
- level of immunocompetence

There were 5,664 notified cases of TB in England in 2016 (10 per 100,000 population). The rising trend in this figure over the past 20 years is primarily attributable to immigration. Foreign-born UK residents comprise 80% of all cases, and limited data suggest that approximately half of these occur within 5 years of UK entry. Amongst foreign-born persons, the case rate is comparable with the reported rate for their country of origin, suggesting that TB in this setting is due to reactivation of imported latent infection (see 'Natural history, and complications'). Amongst UK-born Caucasians, the case rate is 4 per 100 000. Immunodeficiency is the single most important risk factor for disease in this population (see Box 130.2).

Worldwide, there are approximately 9 million new cases of TB and 1.5 million deaths due to TB each year. Co-infection with HIV

is seen in approximately 15% of all cases for which testing has been performed and recorded. HIV co-infection is most prevalent in countries of sub-Saharan Africa (50%–90%), where the incidence of TB is also highest.

Natural history, and complications

Mycobacterium tuberculosis is transmitted almost exclusively by aerosol. Individuals acquire infection by inhaling droplets which are released by pulmonary TB patients when they cough, sneeze, or talk. Infectious droplets are typically 1–5 µm in diameter. Within this range, droplets are small enough to allow suspension in the air for several hours, increasing the likelihood of inhalation, and large enough to deposit in the small airways and alveoli.

Once deposited in the alveoli, *Mycobacterium tuberculosis* is internalized by resident alveolar macrophages. However, the development of infection and disease progression thereafter is variable and determined by a complex interaction between the organism and host immune response; this interaction is poorly understood (see Figure 130.1). The organism replicates within alveolar macrophages, leading to the death of the infected macrophages, and recruitment of further macrophages. An adaptive immune response develops in response to antigen presentation by dendritic cells at regional lymph nodes. Adaptive immunity is a Th1-driven, cell-mediated response that is measurable clinically 6 weeks after infection. Adaptive immunity may prevent disease progression in two ways:

- by *clearance* of the infection, via cytotoxic responses that effectively destroy infecting bacilli
- by *containment* of the infection, via a chronic inflammatory response that ensues after a failed cytotoxic response and leads to the formation of granulomas that localize the infection

In most cases, this 'primary' phase of infection is subclinical and leads to the production of Ghon foci, which are small, rounded, calcified lesions visible at chest radiography in the peripheral lung fields. They represent old granulomas and indicate previous primary *Mycobacterium tuberculosis* infection. The term 'Ghon complex' refers to a Ghon focus associated with ipsilateral hilar adenopathy.

Between 5% and 10% of primary *Mycobacterium tuberculosis* infection is associated with disease. Primary TB occurs most often in young children with immature immune systems that are unable to clear or contain the organism effectively. The tubercle bacillus may spread within the body by passing through the lymphatic system or the bloodstream. Dissemination of the infection via the lymphatic system most common and is typically associated with local or more generalized lymphadenopathy. Passage of *Mycobacterium tuberculosis* in the bloodstream likely occurs by direct invasion of the alveolar

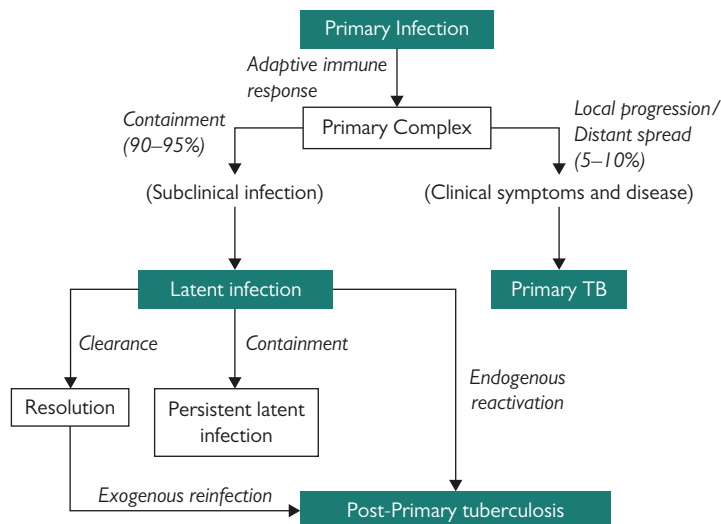

Figure 130.1 Natural history of infection with *Mycobacterium tuberculosis*.

Table 130.1 Disease-related complications of TB

Body system		Complication
Respiratory	Lung	Pulmonary fibrosis, bronchiectasis, extensive cavitation with bullous disease, aspergilloma, accelerated lung function decline, COPD
	Pleura	Secondary pneumothorax arising from bronchopleural fistula, chronic tuberculous empyema with pleural calcification and pulmonary restriction
Cardiovascular	Pericardium	Constrictive pericarditis
	Myocardium	Conduction defects, risk of ventricular arrhythmia
Abdominal	Gastrointestinal system	Bowel strictures, peritoneal adhesions, protein-losing enteropathy with intestinal lymphangiectasia secondary to mesenteric TB lymphadenitis
	Renal system	Hypercalcaemia and secondary nephrolithiasis, renal papillary necrosis, tubulointerstitial nephritis, ureteric strictures
	Adrenal system	Primary adrenal insufficiency
Pelvic	Female reproductive tract	Infertility, ectopic pregnancy
	Male reproductive tract	Infertility
Musculoskeletal	Spine	Pronounced kyphoscoliosis (Pott's disease)
	Other bones and joints	Destructive arthropathy, pathological fractures
CNS	Meninges	Multiple cranial nerve palsies, neurological disability
	Tuberculoma	Secondary epilepsy, neurological disability
	Retina	Visual loss

microvasculature and implies miliary TB; in this form of the disease, lymphadenopathy may be absent. Primary pulmonary TB is notable for involving more often the mid and lower zones of the lungs; involvement of the upper lobes and apical segments of the lower lobes is typical of post-primary TB.

The term 'post-primary TB' (or 'secondary TB') refers to disease in individuals with previous *Mycobacterium tuberculosis* infection. In these cases, the duration of infection that is latent or subclinical is undefined and may be a few weeks or many years. Progression to disease in this setting is uncertain but likely to be heterogeneous. In some cases, disease will occur with disruption of the equilibrium between host immunity and viable bacilli (reactivation); in others, particularly older adults, disease may represent new infection (reinfection).

The complications of TB may be broadly categorized as those arising from specific organ involvement, and those arising from treatment (see 'Treatment and its effectiveness' and Table 130.1). Organ-specific complications are a consequence of chronic granulomatous inflammation that leads to tissue destruction, space-occupying effects, and fibrotic tissue repair (Table 130.1).

Approach to diagnosis

The diagnosis of TB can be challenging, particularly in cases of extra-pulmonary disease. The diagnosis is **suspected** from the history (see 'Typical symptoms of the disease, and less common symptoms' and Box 130.1). Appropriate radiological imaging may identify abnormalities that **support** this suspicion. The diagnosis is ideally **confirmed** by demonstration of tubercle bacilli in tissue samples obtained from the affected organ at microscopy (smear positive) or after culture.

Smear-positive TB is most common with pulmonary disease that is radiologically extensive and cavitating. For suspected pulmonary TB, three or more sputum samples are collected, preferably on waking. It is recommended that the samples are collected prior to or within 7 days of starting antituberculous chemotherapy. In patients unable to provide spontaneous sputum, samples may be induced with nebulized saline or bronchoscopy and washings performed to obtain samples. Children are likely to swallow sputum, and gastric lavage is often useful in this age group and often performed prior to considering bronchoscopy.

Culture confirmation is achieved in approximately 80% of cases with pulmonary TB. However, the yield from other sites may be considerably lower; for example, a positive culture is obtained in less than 50% of samples taken from extra-thoracic lymph nodes. For culture-negative TB, a hierarchy of other findings are considered appropriate for arriving at the diagnosis (see 'Other diagnoses that should be considered').

PCR-based molecular methods have been developed that offer more rapid microbiological confirmation of the diagnosis. Molecular methods are increasingly used in routine practice, and in some low resource settings, replacing culture based methods for the diagnosis of TB. The most well known commercial platform GeneXpert MTB/RIF (Cepheid Inc.) has near 100% specificity for *Mtb*. While not as sensitive as culture, a recent enhancement of the assay (Xpert ULTRA) offers sensitivity that is approaching culture and more robust detection of drug resistance genes. Results from molecular testing are available within hours, facilitating rapid diagnosis to guide immediate management.

Interferon gamma release assays (IGRAs) are enzyme-linked immunosorbent assays (ELISAs) that detect the production and release of interferon gamma by T-cells reacting to specific *Mycobacterium tuberculosis* antigens. Studies indicate that, while these assays are useful for informing *Mycobacterium tuberculosis* specific cell-mediated immunity, they are unable to distinguish between latent infection and active disease. IGRAs may therefore provide useful supporting evidence in the diagnostic evaluation of TB.

Other diagnoses that should be considered

The differential diagnosis in TB is broad and will depend upon the organ system that is affected. Most commonly, the differential diagnosis includes lymphoproliferative disease, other malignant disease, and granulomatous disorders, such as sarcoidosis and the granulomatous vasculitides.

'Gold-standard' diagnostic test

The gold-standard diagnostic test for TB is microbiological confirmation, with culture of *Mycobacterium tuberculosis*.

Acceptable diagnostic alternatives to the gold standard

A hierarchy exists for grades of evidence used in the diagnosis of TB. For patients that are culture negative with a clinical suspicion of TB, the hierarchy, in order of credibility, is:

- tissue microscopy revealing acid fast bacilli. Note that subjects with partially or completely treated TB may expel dead organisms that are visible at microscopy and in some instances the microscopic appearances are not sufficiently specific to be diagnostic. In treatment naive subjects, positive smear microscopy that is supported by positive rapid PCR testing is equivalent to positive culture for a diagnosis of TB
- histological evidence of tissue necrosis, lymphocytosis, and granulomatous inflammation
- radiological features of TB, with evidence of clinical and radiological improvement after treatment

Other relevant investigations

Chest X-ray

While routinely performed for suspected pulmonary TB, a chest X-ray should also be performed for patients with extra-pulmonary TB, as concomitant pulmonary TB often exists.

Bronchoscopy

Bronchoscopy is useful for obtaining samples from the lower airways in patients who are suspected of having pulmonary TB but do not have a productive cough. In patients with suspected miliary disease, a bronchoscopy with transbronchial biopsy may be performed to obtain samples of lung parenchyma that may reveal acid-fast bacilli at microscopy.

Evaluation of CNS involvement

While uncommon, CNS involvement should be considered in all TB patients, as this will determine the duration of antituberculous therapy. High-risk groups are those with miliary disease, children, and patients with concomitant immunodeficiency. For all patients with miliary TB, a CT or MRI scan of the brain is recommended and should be followed by lumbar puncture if appearances are not diagnostic but there is clinical concern.

HIV testing

UK policy recommends screening for HIV infection in all patients diagnosed with TB.

Vitamin D levels in plasma

There is in vitro evidence that supports a role for vitamin D in cell-mediated immunity to TB. In practice, TB patients identified with vitamin D deficiency may benefit from replacement therapy, although this remains to be clinically proven.

Contact screening

Recent close contacts of a patient with TB (usually other household members) should be screened for disease (via direct questioning about symptoms, and a chest X-ray). In the absence of evidence for active TB, current UK guidelines recommend screening of contacts under 35 years for latent infection with *Mycobacterium tuberculosis* (LTBI). This is diagnosed by demonstrating a positive reaction with tuberculin skin testing and/or a positive IGRA. Recent contacts under 35 years with

LTBI are offered a prophylactic regimen of antituberculous chemotherapy that reduces the risk of TB for 2 years after contact by up to 90%.

Treatment and its effectiveness

Overview

In common with other chronic diseases, the care of patients with TB is best managed in a specialist, multidisciplinary TB clinic.

Current UK guidance recommends routine treatment of TB for 6 months. Treatment is divided into an early phase (Months 1 and 2) and continuation phase (Months 3 to 6). Early phase treatment is with four antibiotics: rifampicin, isoniazid, pyrazinamide, and ethambutol. In the continuation phase, rifampicin and isoniazid are continued. Dosing is weight dependent, and medication is available as combination tablets that may help to minimize prescription errors and improve treatment adherence.

Patient information

All of the drugs used for treating TB have significant side effects, and information about these should be provided to all patients before commencing therapy (Table 130.2). Ideally, this should be in the form of an information leaflet that is kept for reference. Although uncommon, side effects carry a risk of significant morbidity and may be potentially life-threatening. Patients are advised to report possible drug-related symptoms early to minimize risk.

Adherence to therapy

A crucial component of patient education is the importance of being adherent to therapy. This can be difficult for a regimen of many tablets over a long period, and the message may require reinforcement at multiple time points during the treatment course. Poor adherence is associated with an incomplete treatment response, and risks development of drug resistance.

Directly observed therapy (DOT) refers to observation of the patient to confirm that treatment is being taken, by a health professional or designated member of family. DOT is recommended for

Table 130.2 Antituberculous chemotherapy in clinical practice

Drug	Mechanism of action	Treatment independent and adverse effects	Monitoring	Patient information and other comments
Rifampicin	Inhibits mRNA transcription and translation Both bactericidal and bacteriostatic function	Hepatitis Rash Nausea, vomiting, diarrhoea, abdominal cramps Flu-like symptoms Inducer of cytochrome P450 enzymes	Liver function tests every 6–8 weeks	Patient should be alert to RUQ pain, pruritus, or jaundice Red/orange colouration of body fluids, particularly urine; this is harmless Accelerated metabolism of drugs may require altered dosing for warfarin and glucocorticoids Accelerated metabolism of OCP; additional contraception should be used Reduced absorption by up to 50% when taken with food; treatment should be taken at least 30 minutes before food
Isoniazid	Inhibits cell-wall formation by blocking fatty acid synthesis Both bactericidal and bacteriostatic function	Hepatitis Rash Peripheral neuropathy Metabolic acidosis (high anion gap) Sideroblastic anaemia Drug interactions may elevate drug levels of some drugs Epilepsy	Liver function tests every 6 to 8 weeks	Patient should be alert to RUQ pain, pruritus, or jaundice Patient should be alert to peripheral paraesthesiae or numbness, which can occur due to vitamin B6 depletion, which is the basis for pyridoxine supplementation Care with use in patients with epilepsy
Pyrazinamide	Inhibits cell-wall formation by blocking fatty acid synthesis Both bactericidal and bacteriostatic function	Hepatitis Rash Arthralgia Nausea, vomiting, diarrhoea, and abdominal cramps Hyperuricaemia Sideroblastic anaemia	Liver function tests every 6 to 8 weeks	Patient should be alert to RUQ pain, pruritus, or jaundice Arthralgia is the commonest side effect and is managed with simple analgesia; it is rarely of clinical concern May exacerbate gout
Ethambutol	Impaired cell-wall synthesis Primarily bacteriostatic	Optic neuritis Red–green colour blindness Peripheral neuropathy Arthralgia Hyperuricaemia	Visual acuity testing performed prior to commencement of therapy; repeated if visual symptoms are reported	Patient should be alert to any visual symptoms May exacerbate gout

Abbreviations: OCP, oral contraceptive pill; RUQ, right upper quadrant.

patients at high risk of treatment non-adherence (e.g. patients with no fixed abode); patients with serious mental illness; for disease with multiple drug resistance; and also for patients with disease recurrence after completing a course of therapy. For convenience, DOT regimens are intermittent (usually three times per week).

Drug-resistant TB

Fortunately, most cases of TB in the UK are fully sensitive to the standard regimen. Drug resistance may be to a single or multiple agents. Single drug resistance is most commonly to isoniazid and is covered by the quadruple regimen described. Multidrug-resistant TB (MDR-TB) is encountered most often in Eastern Europe and South Africa. Treatment for MDR-TB is usually prolonged and should be managed by a doctor with specialist experience. In the UK, a national internet-based forum exists for clinical discussion and advice of MDR-TB cases.

Extended treatment regimens

Antituberculous therapy should be continued beyond 6 months in:

- patients with a slow but continued response to therapy
- patients with CNS disease (treatment should be continued for 12–24 months)
- patients with MDR-TB

Additional treatments

Pyridoxine

Pyridoxine is usually prescribed with antituberculous chemotherapy to minimize the risk of peripheral neuropathy with isoniazid. A dose of 10 mg/day is routinely prescribed, but may be escalated in groups at higher risk of neuropathy. These include patients with malnutrition (who are likely to be vitamin deficient), alcohol dependence, diabetes mellitus, and HIV.

Glucocorticoids

Glucocorticoids have a dual role in TB therapy: as anti-inflammatory agents, and for cortisol replacement. Specific indications for the use of glucocorticoids are:

- TB adrenalitis with adrenal insufficiency
- gross cachexia
- TB meningitis (as glucocorticoid use reduces the risk of long-term neurological sequelae)

- TB pericarditis (as glucocorticoid use reduces the risk of constrictive pericarditis)

Prognosis and how to estimate it

The majority of TB cases are treated successfully with antibiotic chemotherapy. Prognosis is determined by the effectiveness of the treatment; the site and type of disease; coexistent illness; and the age of the patient.

Treatment effectiveness is a function of both the drug sensitivity of the infecting organism, and the site of disease. Sequestration of the organism in immune-privileged sites, such as the CNS and within cavities, will impair drug efficacy. In practice, a common cause for a slow or partial treatment response is poor adherence to the medication regimen.

In the pre-chemotherapy era, untreated tuberculosis had a mortality rate of 50%. While debated, it is likely that both effective chemotherapy and advances in social well-being have contributed to the decline in mortality and TB prevalence over the past 50 years. In the UK, current TB-related mortality is estimated to be 3%; however, this figure is age dependent and increases rapidly with age above 65 years.

Long-term TB-related morbidity is more likely in patients with prolonged disease, due to a significant delay in commencing treatment (either through delayed presentation or diagnosis), leading to extensive tissue destruction.

131 Pneumothorax

Saifudin Khalid, Rowland J. Bright-Thomas, and Seamus Grundy

Definition of the disease

Pneumothorax is defined as the presence of air within the pleural space. Pneumothoraces are divided into spontaneous and traumatic categories, depending on the presence or absence of preceding trauma. Spontaneous pneumothoraces are subclassified as primary or secondary: a primary spontaneous pneumothorax (PSP) occurs in a person without underlying lung disease, whereas a secondary spontaneous pneumothorax (SSP) takes place in a person who has an underlying lung condition, such as COPD or asthma. Tension pneumothorax is a medical emergency where air entering the pleural space on inspiration is unable to escape on expiration, causing mediastinal shift and cardiovascular compromise.

Aetiology of the disease

The aetiology of spontaneous pneumothoraces depends on their subtype. PSPs are believed to arise from the rupture of an apical subpleural bleb, which can often be seen during thoracoscopy. The exact pathogenesis of these blebs is unclear but smoking increases the risk of developing PSP, in a dose-dependent manner (the risk of pneumothorax is 12% in smokers compared with 0.1% in non-smokers), while cannabis use further increases the risk. Taller subjects appear to be at greater risk of developing PSP and this may be because the fall in intra-pleural pressure with the increase in vertical height contributes to the formation of apical blebs.

Many underlying lung diseases are associated with SSP, the commonest being COPD, which is responsible for over 50% of cases. Other common underlying diagnoses are asthma, interstitial lung disease, bronchial carcinoma, pulmonary infection (especially *Pneumocystis jirovecii* infection), tuberculosis, cystic fibrosis, and Langerhans cell histiocytosis. Catamenial pneumothorax is pneumothorax occurring at the time of menstruation.

Iatrogenic pneumothorax may occur during central line insertion, pleural procedures, or transbronchial lung biopsy, or in ventilated patients in the ICU.

Typical symptoms of the disease, and less common symptoms

A high proportion of patients with PSP with normal pulmonary reserve may be relatively asymptomatic initially and may not seek immediate medical attention. Symptoms tend to be more severe in patients with SSP, due to reduced respiratory reserve.

Common symptoms at presentation are chest pain and dyspnoea. The chest pain is usually sudden in onset and ipsilateral. Patients with SSP usually complain of worsening of their breathlessness.

On physical examination, signs of pneumothorax include tachycardia and, on the affected side, there may be reduced movement of the chest wall; a hyper-resonant percussion note; reduced breath sounds; and vocal resonance. In large pneumothoraces, tachycardia may be marked, and a pulse rate of more than 140, together with hypotension, may suggest the presence of tension pneumothorax. Cyanosis may be present in large primary pneumothoraces or in patients with underlying lung disease.

Clinical examination findings are often unreliable in indicating the size of the pneumothorax—many patients with PSP appear well even when they have a large underlying pneumothorax. Patients with SSP can be extremely unwell with relatively small pneumothoraces and it may be more difficult to interpret clinical signs due to the presence of underlying disease.

Demographics of the disease

The incidence of PSP is estimated to be around 18–28/100 000 in males, and 1.2–6/100 000 in females. The peak age of PSP is in the 20s, and the condition becomes rare after the age of 40. Patients with SSP tend to be older, with a peak age of 75 years. It tends to be more common in tall, thin males.

Natural history, and complications of the disease

A pneumothorax without a persistent air leak will resolve at a rate of approximately 2% of the volume of the hemithorax each day. Thus, a small apical pneumothorax can resolve completely within a few days, whereas a large pneumothorax may take many weeks. The likelihood of recurrence after a first PSP is approximately 30%, with most recurrences occurring within 2 years. After a second or third event, the risk of recurrence increases to 62% or 83%, respectively. The risk of recurrence for SSP is higher, with independent risk factors including age, ongoing smoking, and height.

Approach to diagnosing the disease

The diagnosis in cases of both PSP and SSP is often suggested by the clinical history and the physical examination and is confirmed by a chest radiograph demonstrating a pleural line. A standard postero-anterior chest X-ray is normally adequate to diagnose a pneumothorax. However, CT imaging is much more accurate at estimating the volume of pneumothorax and can clearly discern between large emphysematous bullae and pneumothorax, a distinction which isn't always possible with a plain X-ray. The absence of lung sliding on ultrasound is sensitive for diagnosing pneumothorax, although its use is primarily limited to trauma cases.

Pneumothorax size is usually estimated as either 'small' or 'large', depending on whether the rim of air around the lung is <2 cm or >2 cm, respectively. This approach is preferred by the British Thoracic Society and helps in formulating a management plan. Another method of estimating the size of pneumothorax is based on an equation known as the Light index, where the size of the pneumothorax is expressed as a percentage: $Pneumothorax = 100(1 - Lung^3 / Hemithorax^3)$.

Other diagnoses that should be considered

Moderate-to-large pneumothoraces are normally easily recognized with an X-ray. However, in the presence of large emphysematous bullae, pneumothorax can be misdiagnosed. It can be catastrophic to insert a drain into a bulla and so, if there is any doubt, a CT scan must be performed prior to any intervention.

'Gold-standard' diagnostic test

Although, in most cases, the diagnosis can be made on a postero-anterior chest X-ray, in cases of doubt, a lateral decubitus X-ray may be performed, as its sensitivity is superior to that of a standard chest X-ray. A CT scan is rarely necessary but is regarded as highly accurate. Where there is confusion about the presence of a pneumothorax or a bulla, the two can be differentiated by the shape of the pleural line—a convex-outward line suggests pneumothorax, and a concave-outward appearance suggests a bulla.

Acceptable diagnostic alternatives to the gold standard

If the diagnosis is unclear or if there is complex underlying lung disease, a CT thorax may be requested to delineate the pneumothorax and extent of underlying lung disease.

Prognosis and how to estimate it

In making decisions regarding the management of pneumothorax, it is important to consider the likelihood of spontaneous resolution and the risk and potential consequences of future recurrence. Hence, an asymptomatic, small, first, primary spontaneous pneumothorax can be managed on an outpatient basis, with simple observation, whereas a recurrent, secondary spontaneous pneumothorax causing significant symptoms will require early intervention and consideration of how to prevent future recurrences.

After a first presentation with a PSP, around 30% of patients will have an ipsilateral recurrence within a year, and the risk of a contralateral pneumothorax in such patients is 15%. The risk is greatest within the first year and is increased if smoking is continued. After a recurrence, the risk of a subsequent pneumothorax goes up to 50%. The risk of recurrence in SSP is greater and, after first presentation, around 45% of patients have a recurrence within 3–5 years.

Treatment and its effectiveness

The treatment of spontaneous pneumothorax differs depending on whether it is primary or secondary, the size of the pneumothorax, and the presence or severity of symptoms (see Figure 131.1). Management options available include observation alone, simple aspiration, chest drain insertion, and chemical and surgical pleurodesis.

Management

Observation alone

In the absence of an ongoing air leak, air within the pleural space gradually gets reabsorbed and, for patients with PSP who have a small (<2 cm) pneumothorax and are asymptomatic, it is sufficient to simply observe and repeat a chest X-ray at early outpatient follow-up. It must, however, be explained to these patients that, if they develop worsening breathlessness, they must immediately return to the hospital. Patients with SSP should be admitted to hospital. If such patients have a very small (<1 cm) or isolated apical pneumothorax and few symptoms, observation alone may be considered, if the patient is stable, with close chest X-ray monitoring.

Supplemental oxygen

Supplemental high-flow oxygen should be given to all patients, except those who have a history of CO₂ retention, as these should be admitted to hospital. Supplemental oxygen accelerates the resolution of pneumothorax fourfold by reducing the partial pressure of nitrogen in the blood, encouraging air removal from the pleural space.

Simple aspiration

Simple aspiration in PSP

Simple aspiration in PSP is relatively painless and is successful in up to 60% of patients. While opinion differs among chest physicians, simple aspiration is currently the recommended first procedure in

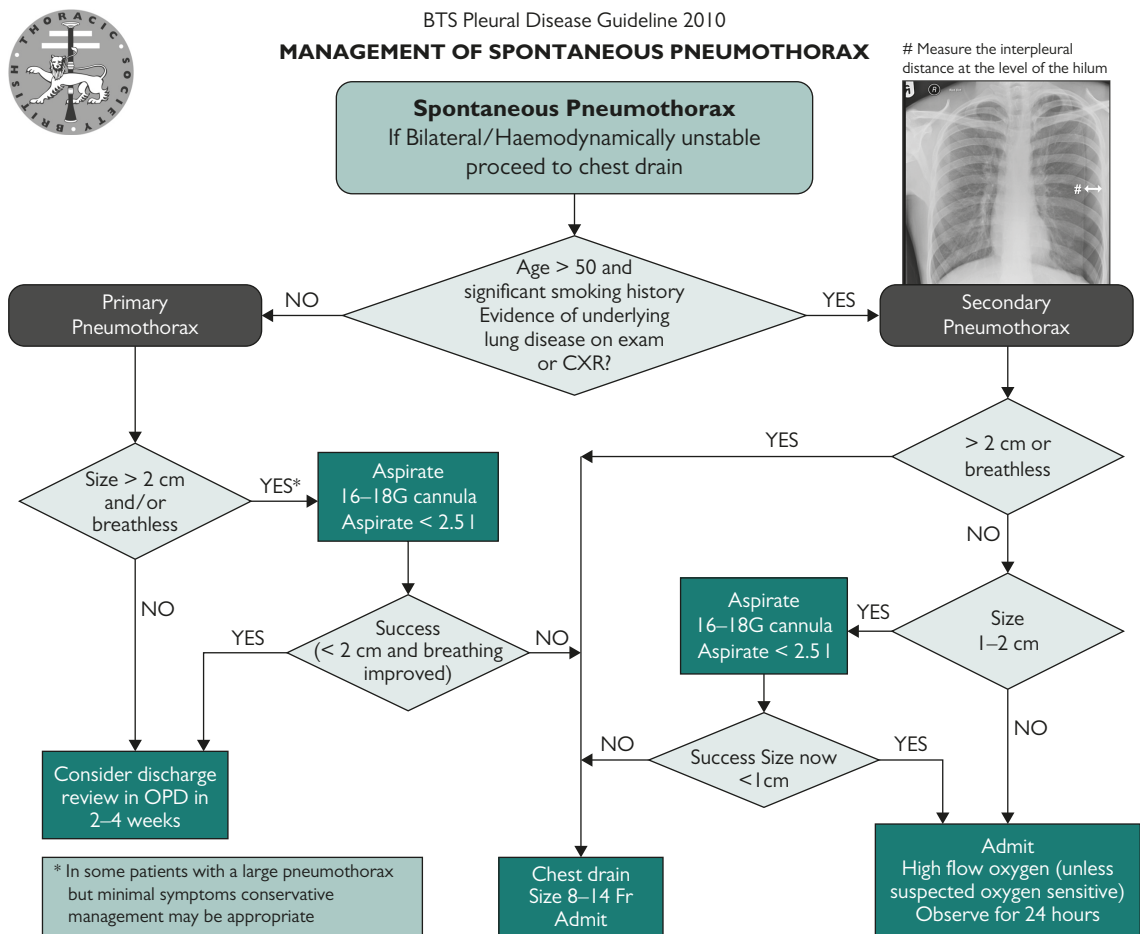

Figure 131.1 Management of spontaneous pneumothorax; BTS, British Thoracic Society; CXR, chest X-ray; OPD, outpatient department.

Management of spontaneous pneumothorax: British Thoracic Society pleural disease guideline 2010. *Thorax* 2010;65(Suppl 2):ii18-ii31. Available online at: <http://www.brit-thoracic.org.uk/clinical-information/pleural-disease.aspx>

PSP patients if they are symptomatic or have a pneumothorax >2 cm in size. The risk of recurrence after simple aspiration appears to be similar to that after chest drain insertion. Simple aspiration can be repeated once if there is unsatisfactory improvement after the first attempt but, if a repeat attempt is also unsuccessful, then the next procedure should be the insertion of a chest drain.

Simple aspiration in SSP

Simple aspiration in SSP is much less likely to be successful than simple aspiration in PSP and should only be carried out if the patient has minimal dyspnoea, is less than 50 years old, and has a pneumothorax <2 cm. If aspiration fails, a chest drain should be inserted before clinical deterioration takes place.

Intercostal chest tube drainage

Intercostal chest tube drainage is indicated for PSP patients who have failed simple aspiration, and for all SSP patients who have a large (>2 cm) pneumothorax, are symptomatic, or are more than 50 years old. Patients with tension pneumothorax require urgent insertion of a large-bore cannula into the appropriate intercostal space and, immediately afterwards, insertion of a chest drain. While traditional practice has been to place the cannula in the second intercostal space in the case of tension pneumothorax, a standard cannula may be of insufficient length to reach the pleural space, due to the thickness of the chest wall in this area. Consequently, if this first approach fails, the cannula or chest drain may be inserted in the safe triangle laterally. Most patients with traumatic pneumothorax require an intercostal drain.

In most cases, the initial chest drain should be a small-calibre drain, which is usually as effective as a large-bore chest drain and is more comfortable for the patient. Drains should be attached to an underwater-seal bottle. A swinging drain indicates that the drain is in the pleural space, while bubbling indicates an ongoing air leak. If the drain does not swing, it is blocked, clamped, or not in the correct position. A bubbling chest drain should never be clamped, as this can result in tension pneumothorax.

When a chest drain produces cessation of air leak and full re-expansion of the lung, it is usually removed after a further 24 hours. If the chest drain insertion fails to improve the pneumothorax, after around 48 hours, then low-pressure, high-volume suction should be considered. If this does not resolve the pneumothorax, a surgical opinion should be sought.

Chemical pleurodesis

Chemical pleurodesis with talc or other sclerosing agents such as tetracycline can be employed in patients who are not suitable to undergo surgery, due to their comorbid conditions, or are unwilling to undergo the procedure. Although the risk of recurrence with this technique is reduced, it is still higher than the risk after surgery.

Indications for surgical intervention

The common indications for surgical intervention include failure of re-expansion of lung 5 days after chest drain insertion; second ipsilateral or first contralateral pneumothorax; spontaneous haemopneumothorax; bilateral spontaneous pneumothoraces; and patients working in professions at risk (e.g. scuba divers, pilots). It can also be considered in patients with a first episode of SSP and who are at risk of serious complications from a recurrence.

Video-assisted thoracoscopic surgery (VATS) has generally replaced open thoracotomy, as it is less invasive. In PSP patients, VATS allows apical bullectomy, stapling, and pleurectomy. If pleurodesis is to be performed, this is usually achieved by mechanical pleural abrasion. In SSP with significant underlying lung disease, trauma to the lung may cause a persistent air leak, and simple pleurodesis with talc poudrage is most commonly used.

132 Cystic fibrosis

Rowland J. Bright-Thomas and Andrew M. Jones

Definition of the disease

Cystic fibrosis is the most common lethal autosomal recessive disorder in Caucasians. There is no known survival advantage of the heterozygote carrier state. Chronic progressive pulmonary infection and bronchiectasis are the major causes of morbidity and mortality. The disease affects all ductal systems where the basic defect is manifest, including the pancreas, gastrointestinal tract, sinuses, hepatobiliary system, and male reproductive system, and has significant effects on nutrition and growth.

Aetiology of the disease

The abnormal gene responsible for cystic fibrosis is found on the long arm of Chromosome 7 and encodes a protein called the cystic fibrosis transmembrane conductance regulator (CFTR). CFTR is a cAMP-regulated anion channel responsible for chloride transport in the apical membranes of epithelial cells. To date, more than 2000 mutations affecting the CFTR gene have been detected, although only about 200 have been shown to be disease-causing, with the commonest one in the UK being Phe508del, found in 70% of patients with cystic fibrosis. Defects in CFTR affect ion and water transport properties across epithelia throughout the body. In the airway epithelium, the CFTR defect gives rise to viscid secretions which promote airway obstruction, bacterial infection, and chronic inflammation. The inflammatory process is characterized by infiltration of massive numbers of neutrophils into the airways. These release an arsenal of oxidants and proteases which damage the architecture of the lung and further enhance bacterial adhesion. The main bacterial pathogens in early childhood are *Staphylococcus aureus* and *Haemophilus influenzae*. In late childhood and adult life, *Pseudomonas aeruginosa* predominates.

Typical symptoms of the disease, and less common symptoms

Although cystic fibrosis is a multisystem disorder, it is respiratory disease that accounts for the majority of the associated morbidity and mortality. Classically, patients have upper lobe bronchiectasis initially, which later becomes widespread. Typical symptoms are dyspnoea, malaise, chronic cough, haemoptysis, and excess purulent sputum production, although sputum retention may occur. The clinical course is punctuated by repeated infective exacerbations.

Demographics of the disease

In the UK Caucasian population, approximately 1 in 25 individuals is a carrier of a cystic fibrosis gene, and the disease frequency is about 1 in 2500 live births. There are currently >10 000 patients in the UK with cystic fibrosis, and adult patients now outnumber paediatric patients. Cystic fibrosis cases occur in all races, and cystic fibrosis genes are present worldwide but incidence estimates are not available for most non-Caucasian populations.

Natural history, and complications of the disease

The natural history of untreated cystic fibrosis lung disease is one of inexorable decline until death or double-lung transplantation. With expert care delivered at cystic fibrosis centres, this decline is extremely attenuated, albeit often with a high treatment burden.

Non-pulmonary complications relate to CFTR-mediated epithelial dysfunction (e.g. pancreatic, gastrointestinal, hepatobiliary, and sweat gland manifestations), systemic consequences of chronic infection (e.g. vasculitis and arthropathy), or a combination of these processes (e.g. poor nutrition and growth, and osteoporosis).

Pancreatic and gastrointestinal disease

Approximately 90% of cystic fibrosis patients have exocrine pancreatic insufficiency (PI), with clinical effects including malabsorption, steatorrhoea, malnutrition, deficiencies of fat soluble vitamins, and growth failure. PI patients need lifelong oral pancreatic enzyme supplementation. Exocrine pancreatic sufficient patients have an improved nutritional status and prognosis but a high incidence of acute and chronic pancreatitis.

Gastrointestinal dysmotility is common and may manifest as gastro-oesophageal reflux disease, delayed gastric emptying, reduced small intestinal transit, and reduced large bowel motility. Constipation is a frequent occurrence and may become chronic. Meconium ileus in infancy, and distal intestinal obstruction syndrome in older patients, are characteristic of cystic fibrosis presenting as small bowel obstruction secondary to the build-up of abnormally viscid material.

Hepatobiliary disease in cystic fibrosis

CFTR is present on the apical membrane of intra-hepatic bile duct cells. Abnormal bile salt composition causes cholelithiasis, which is present in approximately 15% of the adult population. Plugging of intra-hepatic bile ducts, with subsequent cirrhosis, portal hypertension, hypersplenism, and risk of variceal bleeding occurs in 2%–5% of patients.

Nutrition, growth, and bones

The poor nutritional state of many cystic fibrosis patients reflects intestinal malabsorption, the increased energy demands resulting from continual respiratory infection, and other factors such as cystic fibrosis-related diabetes and liver disease. Although growth has historically been poor in cystic fibrosis patients, with modern standards of care there is the expectation for normal growth in the vast majority of cystic fibrosis patients. The prevalence of low bone-mineral density is high.

Cystic fibrosis-related diabetes

Loss of beta cell mass, due to pancreatic destruction, end-organ insulin resistance and delayed absorption causes postprandial hypoglycaemia, impaired glucose tolerance, and overt diabetes mellitus. Approximately 25% of patients over 10 years have cystic fibrosis-related diabetes, and the incidence rises with age.

Sinus disease

The sinuses are affected in more than 90% of patients, and nasal polyps and nasal obstruction are extremely common. Medical treatment usually meets with limited success, and surgery is often required.

Arthropathy and vasculitis

Vasculitic rashes and polyarthropathy occur in cystic fibrosis adults with chronic bronchial infection and have been linked with circulating immune complexes.

Fertility in cystic fibrosis

Males with cystic fibrosis are infertile due to the absence or maldevelopment of the vas deferens. Assisted reproduction techniques

such as sperm retrieval and intra-cytoplasmic sperm injection now allow males to father their own genetic offspring. Females with cystic fibrosis probably have near normal fertility but pregnancy can risk a deterioration in clinical status.

Approach to diagnosing the disease

Cystic fibrosis can present at any age but is usually diagnosed in infancy. Newborns may present with meconium ileus. In early life, failure to thrive, often with malabsorptive symptoms and recurrent chest infections, is common. Some patients are diagnosed in adulthood, with features including bronchiectasis, pancreatitis, nasal polyps, and male infertility, or on screening following the identification of a family member with cystic fibrosis.

Newborn screening programmes have been introduced in the UK and are estimated to identify >90% of newborn patients with cystic fibrosis. The test measures immunoreactive trypsin on a blood spot from newborns—those with a positive result go on to have a second test and genetic screening.

Other diagnoses that should be considered

In children who present with failure to thrive and pancreatic insufficiency, the diagnosis, once considered, is usually clear. Shwachman–Diamond syndrome, a rare autosomal recessive disorder characterized by exocrine pancreatic insufficiency, bone marrow dysfunction, and skeletal and growth abnormalities, needs to be considered. In adults presenting with bronchiectasis or chronic respiratory infection, the differential includes tuberculosis, non-tuberculous mycobacterial infection, primary ciliary dyskinesia, allergic bronchopulmonary aspergillosis, and immune deficiency states.

‘Gold-standard’ diagnostic test

Cystic fibrosis is a clinical diagnosis requiring appropriate clinical features. The sweat test is the gold-standard diagnostic test: a sweat chloride of >60 mmol/l is consistent with a diagnosis of cystic fibrosis. However, sweat chlorides as low as 30 mmol/l are seen in some patients, results can be unreliable in adulthood, expertise is required to accurately perform the test, and contamination can occur.

Acceptable diagnostic alternatives to the gold standard

With the advent of genetic screening, cystic fibrosis is often diagnosed on the basis of two disease-causing mutations. However, >2000 cystic fibrosis mutations have been described but not all are disease causing and the presence of two mutations does not signify clinical cystic fibrosis; the diagnosis requires characteristic phenotypic features and/or an abnormal sweat test. Whether healthy men with a congenital bilateral absence of the vas deferens, and two CFTR gene mutations, should be classified as having cystic fibrosis is an ethical dilemma.

Other relevant investigations

Nasal potential difference recordings may be useful in patients with a high clinical suspicion but with a non-diagnostic sweat test or without two identified cystic fibrosis-causing gene mutations.

Prognosis and how to estimate it

With aggressive modern treatment regimens and the multidisciplinary care afforded to cystic fibrosis patients, survival of cystic fibrosis cohorts continues to improve. The current median survival of cystic fibrosis patients is 40 years but extrapolation of the survival curve for babies born in 2000 suggests median survival may be >50 years.

Treatment and its effectiveness

Many cystic fibrosis patients have an enormous treatment burden, and care is best delivered at cystic fibrosis centres, where multidisciplinary

teams of staff, including physicians, nurses, physiotherapists, dieticians, pharmacists, social workers, and psychologists, work together to manage the multisystem nature of the disease and achieve best outcomes. The cystic fibrosis team should also have close links with other specialist services such as interventional radiology, diabetes, ENT, obstetric and gastroenterology teams.

Pulmonary treatment

Chest treatment aimed at controlling airway infection, reducing airway obstruction, and improving nutritional status is the cornerstone of successful management of cystic fibrosis. Chest physiotherapy combined with adjuncts providing positive expiratory pressure and/or oscillation forms the major airway clearance strategy. Nebulized mucolytics and expectorants such as dornase alfa and hypertonic (7%) sodium chloride help clear respiratory secretions. Exercise improves prognosis and quality of life.

Oral antibiotics are used continuously, to control the burden of infection, or intermittently, to treat pulmonary exacerbations. A combination of a beta-lactam and an aminoglycoside are usually given intravenously to treat *Pseudomonas aeruginosa* infection. Patients with cystic fibrosis bronchiectasis typically require high doses and a long duration of antibiotic therapy. Nebulized antibiotics are predominantly used in patients infected with *Pseudomonas aeruginosa* to eradicate early infection, and to reduce the number of pulmonary exacerbations and improve lung function in those patients with chronic infection. Inhaled and oral corticosteroids are frequently prescribed in cystic fibrosis but evidence is lacking on their long-term benefit.

Double-lung transplantation offers patients with end-stage lung disease prolonged survival with an improved quality of life. However, lifelong immunosuppressive therapy is required post-transplantation and the incidence of early complications and later graft rejection is high, with a median post-transplant survival of 5–10 years.

Non-pulmonary treatment

Nutritional support is essential, and improved nutritional status is associated with a better prognosis. CFRD needs to be managed closely in conjunction between cystic fibrosis and diabetic teams. PI patients require lifelong supplementation with pancreatic enzymes and the fat soluble vitamins A, D, E, and K. Low bone mineral density is treated with exercise, calcium and vitamin D supplementation. Gastro-oesophageal reflux disease is usually treated with proton-pump inhibitors, and constipation with laxatives. Liver disease and gallstones are usually treated with ursodeoxycholic acid. In severe cases, liver transplantation may be needed.

CFTR-mutation-specific therapies

Restoring CFTR function is the ultimate goal of cystic fibrosis treatment. Patients with CFTR gating mutations have shown remarkable clinical improvements following treatment with ivacaftor, a small-molecule potentiator for CFTR. Another small molecule, lumacaftor, augments the transport of CFTR to the cell surface and, combined with ivacaftor, has been approved as a treatment for patients homozygous for the Phe508del mutation.

Gene therapy and future treatments

The CFTR gene was cloned in 1989 but initial expectations that gene therapy was just around the corner have been tempered by the complex genetics of cystic fibrosis, and difficulties finding safe, effective, non-immunogenic vectors. Despite this, survival continues to improve via the use of aggressive treatment; on the horizon are new inhaled antimicrobials and CFTR-mutation-specific therapies.

133 Asthma

Andrew Jeffrey, Abdul Nasimudeen, and Joshua Agbetile

Definition of the disease

Asthma is a disorder of airway smooth muscle and airway inflammation, manifested by variable airflow limitation. This definition continues to be refined in light of developments in our understanding of asthma's pathophysiology, immunology, and treatment.

Aetiology of the disease

Asthma is genetically heterogeneous. While many genetic wide-association studies have identified common alleles associated with disease risk at all ages, its interaction with environmental factors remains very important. Identifying triggers, which include common environmental aeroallergens, exercise, and emotional factors, consequently play key roles in patient-focused management. Its presentation is correspondingly variable:

- early onset is associated with family history of atopy
- non-allergic late-onset with aspirin sensitivity (when with nasal polyposis, this is known as Samter's triad)
- occupational asthma; it is particularly important to seek occupational triggers in those presenting in adult life, as early removal from a sensitizer may lead to resolution of the asthma

Typical symptoms of the disease, and less common symptoms

Episodic breathlessness, cough, and wheeze, often with associated chest tightness, are regarded as the cardinal symptoms of asthma. Importantly, these symptoms occur at rest as well as on exertion in the vast majority. It is well recognized also that cough alone may be the sole presenting feature, known otherwise as cough variant asthma, due to airways hyper-responsiveness, the absence of which, in the presence of eosinophilic airway inflammation, is the diagnostic criterion for non-asthmatic eosinophilic bronchitis.

The inflammation in asthma is described as being present from the tip of the nose to the terminal bronchi. It is debatable if this is always true, but rhinitis is frequently found in patients with asthma. This can be diagnosed by the presence of rhinorrhoea, frequent sneezing, post-nasal drip, and an impaired sense of smell. These symptoms should be actively sought in all patients presenting with possible asthma.

Demographics of the disease

Current estimates are that around 300 million people worldwide have asthma, with a projected increase by 100 million persons in the next two decades. Asthma contributes to significant morbidity, with disability-adjusted life years lost due to asthma worldwide similar to that for diabetes, and cirrhosis of the liver. Asthma is most prevalent in Westernized societies, affecting approximately 1 in 8 children, and 1 in 20 adults in Europe.

Difficult or therapy-resistant asthma is estimated at 5%–10% of those with asthma. Clinical trials aimed at escalating treatment until control is achieved in patients with asthma have shown that less than 60% achieve total symptomatic control. The reasons for this are not clear but are almost certainly multifactorial, including behavioural as well as disease factors.

Natural history and complications of the disease

Most patients with asthma are able to achieve adequate control of their symptoms with minimal therapy. Most continue to experience

symptoms but not sufficiently to interfere with normal daily activities at a troublesome level.

Asthma does not actuarially reduce life expectancy, and the vast majority of sufferers will remain in employment until the normal retirement age. Many can undertake physically active work and athletic pursuits.

Many 'asthma scores' have been proposed to assess asthma control, but it is perhaps most easily assessed using three questions:

- In the last month/week, have you had difficulty sleeping due to your asthma (including cough symptoms)?
- Have you had your usual asthma symptoms (e.g. cough, wheeze, chest tightness, shortness of breath) during the day?
- Has your asthma interfered with your usual daily activities (e.g. school, work, housework)?

One 'yes' indicates medium morbidity, and two or three 'yes' answers indicate high morbidity.

The consequences of poor symptomatic control can lead to significant additional morbidity. Symptoms frequently unappreciated include:

- urinary stress incontinence
- disturbed sleep
- symptoms interfering with work, sports, or recreation
- side effects of therapy
- consequences of fixed airflow obstruction/airway remodelling, with frequent exacerbations requiring hospital visits

Approach to diagnosing the disease

Traditionally, the diagnosis and management of asthma has been based on patient-reported symptoms, with objective measures of airflow obstruction. More importantly, assessing the 'A to E of airway disease', that is, the factors responsible for morbidity in patients with airway disease—**A**irway hyper-responsiveness, **B**ronchitis, **C**ough reflex hypersensitivity, **D**amage to the airway and surrounding lung, and **E**xtra-pulmonary factors—both utilizes pathophysiological mechanisms and offers a more patient-centred approach, particularly in difficult cases (see Table 133.1).

Other diagnoses that should be considered

Other diagnoses that should be considered include:

- dysfunctional breathing
- vocal cord dysfunction
- Churg–Strauss syndrome
- emphysema
- bronchiectasis
- left ventricular failure (in the older patient)
- allergic bronchopulmonary aspergillosis

'Gold-standard' diagnostic test

Asthma has traditionally been regarded as a reversible airway disease with a 20% and 400 ml improvement in FEV₁ following bronchodilation with salbutamol. More advanced techniques, such as airway inflammation using induced sputum differentials, are helpful in both the diagnosis and management of difficult cases. Direct and indirect airway challenges are becoming more readily available and give useful information to airway hyper-responsiveness, which is itself often mediated through airway inflammation.

Table 133.1 The A to E of airway disease

	Clinical features	Definition	Physiology	Pathology	Mechanism	Existing treatments	Potential new treatments
Airway hyperresponsiveness	Short-term variable breathlessness, wheeze and chest tightness (i.e. over minutes or hours) Often exercise-induced and nocturnal	One or more of: methacholine PC20 <8 mg/mL; >12% improvement in FEV1 after inhaled bronchodilator; >20% within day variability in peak expiratory flow	Bronchodilator responsive airflow obstruction Exaggerated bronchoconstrictor response to constrictor stimuli Deep breath-induced bronchodilatation	Mast cell infiltration of airway smooth muscle Increased airway smooth muscle mass	Direct interaction between mast cells and airway smooth muscle involving multiple mediators, including histamine, cysteinyl-LT, PGD2 Increased airway smooth muscle contractility Altered airway smooth muscle phenotype	Short- and long-acting β_2 -agonists Anti-muscarinic agents Inhaled corticosteroids	Bronchial thermoplasty TNF- α antagonists
Bronchitis	Exacerbations, particularly when co-existing with an acute inflammatory stimulus and if A and/or D are present Cough with morning sputum May be clinically silent	Raised induced sputum eosinophil (>2%) or neutrophil (>61%) count Raised neutrophil and total inflammatory cell count may suggest infection Raised exhaled nitric oxide concentration suggests eosinophilic airway inflammation	Bronchodilator resistant corticosteroid responsive airflow obstruction (eosinophilic) Deep breath-induced bronchoconstriction	Eosinophilic or neutrophilic infiltration of mucosa Goblet cell hyperplasia	Allergic, Th2 cytokine driven (eosinophilic) or infection/innate immune response driven (neutrophilic) Airflow obstruction as a result of mucosal oedema and intraluminal impaction with mucus and cellular debris	Inhaled and oral corticosteroids for eosinophilic bronchitis; latter may be more effective for small airway disease Anti-leukotrienes Antibiotics for infective neutrophilic bronchitis	Eosinophilic: ● Omalizumab ● Mepolizumab Neutrophilic: long-term macrolide antibiotics
Cough reflex hypersensitivity	Excess dry cough with changes in temperature, fumes, talking, laughing	Capsaicin cough reflex hypersensitivity	Heightened cough response to inhaled tussive stimuli such as capsaicin and citric acid	Increased sputum neutrophil numbers in some BAL lymphocytosis Sputum and airway mucosal eosinophilia in 10–15%	Sensitization of sensory nerve endings by pro-tussive mediators such as histamine and PGE2	Removal of aggravating factors (smoking, angiotensin converting enzyme inhibitor therapy, gastroesophageal reflux, rhinitis) Inhaled and oral corticosteroids helpful in eosinophilic disease	None
Damage	Non-variable breathlessness, wheeze and chest tightness Chest deformity	Post-bronchodilator and oral corticosteroid FEV1/FVC <70% Impaired gas transfer CT criteria for emphysema and bronchiectasis	Bronchodilator resistant corticosteroid unresponsive airflow obstruction Impaired gas transfer Increased lung volumes	Emphysema Small airway fibrosis Thickening of basement membrane Increased lymphoid follicles Bronchiectasis	Likely a result of chronic airway inflammation, particularly if multiple inflammatory hits Airflow obstruction as a result of progressive small airway constriction and loss of airway support Reduction of area for gas exchange Damage induced by aspergillus sensitization and colonization	Smoking cessation	Lung volume reduction for emphysema
Extrapulmonary factors	Episodic dyspnoea and chest tightness Weight loss or gain Rhinitis Premature vascular disease	Specific to individual extrapulmonary factor	Altered vascular reactivity Muscle weakness	Increased systemic inflammation	Hyperventilation Upper airway obstruction and hypersensitivity Vocal cord dysfunction Insulin resistance Muscle wasting Loss of confidence Effect of obesity on lung function Poor adherence with therapy	Breathing retraining Nasal corticosteroids Modification of vascular risk factors Weight loss or dietary support Pulmonary rehabilitation	Anabolic agents

Factors potentially responsible for symptoms and morbidity in a patient with airway disease.

Abbreviations: BAL, bronchoalveolar lavage; FEV1, forced expiratory volume in 1 second; FVC, forced vital capacity; LT, leukotriene; PC20, the provocative concentration required to cause a 20% fall in FEV1; PG, prostaglandin; Th2, T-helper type 2. Acceptable diagnostic alternatives to the gold standard

Home peak flow monitoring, if carried out twice or three times daily, can demonstrate the classical diurnal variation of asthma. Variation should be more than 20%, with a repeated pattern each day: most commonly, the lowest reading being seen first thing in the morning. A therapeutic trial is sometimes required in cases of diagnostic uncertainty of reversible airflow obstruction with either oral prednisolone 30 mg daily for two weeks, or an inhaled corticosteroid for a month.

Other relevant investigations

Other relevant investigations include:

- historical blood eosinophil counts (>4%)
- allergy testing with skin-prick measurements against common aeroallergens such as house dust mite, cat, dog, grass, and fungi, or other specific IgE
- total IgE
- aspergillus IgE and aspergillus IgG
- CT chest
- antineutrophil cytoplasmic antibodies (ANCA)
- CT nose and sinuses (if symptoms of rhinitis are present)
- FeNO-Fractional expired Nitric Oxide as a measure of eosinophilic inflammation

Prognosis and how to estimate it

The prognosis for patients with asthma is one of ongoing symptoms with significant variability. Many, when they are between the ages of 14 and 25, experience an improvement in symptoms, with this improvement perhaps related to adolescence with its hormonal changes and the growth spurt. In later life, patients can experience periods of up to several years during which symptoms become worse or settle, apparently spontaneously.

Asthmatic patients who are likely to develop treatment-resistant disease and so are at high risk of dying include those who demonstrate:

- non-compliance with treatment or monitoring
- failure to attend appointments
- fewer GP contacts
- frequent home visits
- self-discharge from hospital
- psychosis, depression, other psychiatric illness, or deliberate self-harm
- current or recent major tranquillizer use
- denial
- alcohol or drug abuse
- obesity
- learning difficulties
- employment problems
- income problems
- social isolation
- childhood abuse
- severe domestic, marital, or legal stress

Persistent airflow obstruction has been defined as a post-bronchodilator FEV_1 :FVC ratio <0.70, or FEV_1 <80%. This is a frequent observation in therapy-resistant asthma and is thought to arise from factors including smoking, duration of disease, and fungal sensitization. Other risk factors include female gender and genetic factors (e.g. ADAM33 polymorphisms).

Treatment and its effectiveness

Treatment is summarized in Table 133.1. It can be divided into non-pharmacological of chronic asthma, pharmacological treatment of chronic asthma, and the treatment of acute exacerbations.

Non-pharmacological treatment of chronic asthma

Self-management plans

Most exacerbations of asthma have a preceding history of poor control, a fact often underappreciated by patients. Utilizing peak-flow measurements combined with an action plan allows patients to take more control of their care as well as aborting early exacerbations.

Allergen avoidance

Specific allergic triggers are more readily identified in children with asthma than in most adults. Where present, suitable avoidance strategies should be developed with the patient. Simple domestic measures such as keeping humidity levels low to discourage house dust mite proliferation, and barrier covers for bedding, can be effective. Desensitization is rarely practical, as most patients have multiple allergies but, where dominant allergens are identified, this approach can sometimes be effective in reducing overall symptoms. Similarly, removal of domestic animals to which the patient is allergic can be helpful. There is emerging data suggesting significant improvements in asthma quality of life when nocturnal temperature-controlled laminar airflow treatment, which reduces levels of inhaled allergens and other particles, is used in atopic patients.

Pulmonary rehabilitation

Pulmonary rehabilitation schemes have consistently been shown to be of significant benefit to patients with chronic pulmonary disease, most often COPD. In patients with severe asthma, similar benefits have been found, particularly in deconditioned patients.

Psychological interventions

When psychological issues (predominantly anxiety and depression) are recognized, appropriate interventions—relaxation, counselling, cognitive behavioural therapy, or more complex psychological therapies—should be considered. There is insufficient evidence to indicate routine psychological interventions for most patients.

Pharmacological treatment of chronic asthma

Upper and lower airways

If there is evidence of nasal involvement, this must be treated actively, if overall good control is to be achieved. The choice of inhaler device can be critical in ensuring that the medication reaches the appropriate part of the airway. As well as the ability of the patient to use the relevant device, device flow characteristics and particle size and mass are important in achieving this end. Systemic therapies ensure that the whole airway is treated but, in general, produce more side effects than topical treatments; hence, the latter represent the preferred option for achieving long-term control.

Stepwise incremental management

All national and international guidelines advocate a stepwise approach to the pharmacological treatment of asthma, generally having five steps, with Step 5 including oral steroids. If the patient's first presentation is with a significant episode, then treatment should be started on at least Step 3 and titrated down with improvement in symptoms. Only the mildest symptoms should be treated with the lowest dose therapy (usually bronchodilators alone) in the first instance. The key therapy at all but Step 1 is an inhaled steroid whose dose is increased before introducing long-acting bronchodilators, as separate- or single-inhaler combinations, and subsequently systemic therapies, such as leukotriene antagonists and/or theophyllines. Increasing inhaled steroid doses beyond the equivalent of 1000 µg/day is of doubtful benefit in the majority of patients.

Single-inhaler therapy

Single-inhaler, or combination inhaler, therapy is appropriate for those who do not achieve adequate control on low-dose inhaled steroids

and, as required, short-acting bronchodilators. The usual combination is of an inhaled steroid and a long-acting beta agonist. Several different preparations are available and, in general, produce similar overall benefit, the choice being made on the convenience of the device, the need for targeting specific parts of the airway (see 'Small airways targeted treatment'), and patient response to the therapy. If response is poor, an alternative combination should be tried before moving up to the next therapeutic step.

Although normally prescribed in a fixed-dosage regimen, there is evidence that single-inhaler therapies can be used in a more flexible manner during exacerbations. The data are best for the combination of formoterol and budesonide in a dry powder preparation which has been shown to be effective when taken up to six times in a day. Similar effects may exist for other combinations, but there is little published evidence to support this.

Small airways targeted treatment

The small particle size found in two beclomethasone preparations has been shown to result in a higher deposition in the smallest airways. Although there is little or no smooth muscle in these airways, symptoms resulting from their inflammation benefit from direct topical treatment. It is also believed that inflammation in one part of the airway exacerbates inflammation found at other levels (the one airway hypothesis). Although the evidence for overall better symptom control through specifically targeting small airways in all patients is not robust, it is worth considering when control is not easily achieved with large-particle drugs.

Anti-IgE therapy

Omalizumab, an anti-IgE monoclonal antibody therapy, is available for the treatment of resistant asthma. It is given as a once fortnightly or once weekly subcutaneous injection and is indicated when asthma control is poor, exacerbations frequent and potentially life-threatening, and blood IgE levels are elevated. The long-term side effects are not yet clear, but the majority of patients tolerate the injections with only minor discomfort at the injection site. Cost and the logistics of administering the drug are significant barriers to its widespread use at present, although the benefits in some individuals can be quite dramatic.

Antifungal therapy

While steroids have traditionally been the mainstay of therapy in those with allergic bronchopulmonary aspergillosis, antifungal therapy has been shown to offer additional benefits in steroid reduction. Patients with severe asthma and sensitization to fungal allergens but not fulfilling the criteria for allergic bronchopulmonary aspergillosis have also been shown to benefit from antifungal therapy, with improvements in quality of life.

Treatment of premenstrual/menstrual asthma

Most women with asthma will experience variation of their symptoms with the phase of their menstrual cycle. For the vast majority, this difference will be small and not pose an issue. For the minority in whom it is a dominant feature, treatment is indicated. These women present with monthly variations on symptoms, most commonly worst in the week before the and during the onset of their menstrual bleed. The administration of a single-depot contraceptive injection is a useful diagnostic step, as it will substantially relieve the problem with immediate effect. If shown to be helpful, either depot injections or tricycling (taking 3 months of tablets without a monthly break) oral contraceptives can be helpful.

Treatment of acute exacerbations

Exacerbations of asthma can be life-threatening and are always debilitating and frightening for the patient. Severe exacerbations resulting in hospital admission most often occur on a background of ongoing

symptomatic disease. Occasionally, severe episodes can have a very rapid onset in a normally asymptomatic patient (so-called type 1 brittle asthma). More often, the exacerbation is mild to moderate and results from an identifiable trigger such as an intercurrent viral infection, or exposure to a known allergic trigger.

Initial assessment includes confirmation of the diagnosis and early physiological assessment. This should include peak expiratory flow and oxygen saturation measurements. The history may be hard to get at presentation. Inability to complete sentences due to breathlessness, poor air entry, or any element of confusion is an indicator of a severe attack.

For mild (peak expiratory flow rate (PEFR) fall of less than 20% from usual levels) to moderate (PEFR fall of 20%–40%) attacks, nebulized bronchodilators may be required. In a mild exacerbation in a patient on Step 1 or 2, the dose of inhaled corticosteroids may be increased but, in all others in these groups, a course of oral corticosteroids should be prescribed at approximately 0.5 mg/kg. There is little good evidence to determine the ideal length of the course, but the dose should not be reduced until the symptoms have settled and the PEFR returned to normal. The dose need not be tailed off unless the course exceeds 2 weeks or there have been previous courses of oral steroids within the preceding 3 months.

In severe exacerbations, after initial therapy with nebulized bronchodilators, preferably delivered by an oxygen-driven nebulizer, intravenous steroids should be given. Close monitoring is needed and should be undertaken in a hospital setting where full resuscitation, including access to mechanical ventilation, is available. The monitoring should include close personal observation of the patient to check for signs of exhaustion. This can in itself be an indication for intubation and mechanical ventilation.

Arterial blood gas sampling is indicated only if the oxygen saturation falls below 94%, as carbon dioxide does not rise in asthma until hypoxia is established. If there is doubt about the diagnosis, particularly in an older patient, the blood gases should be measured at presentation.

Substantial improvement is often delayed for several hours, although some improvement should be noted within 10–15 minutes of use of the nebulized bronchodilator. If it is not, use of the nebulizer can be repeated several times. If no improvement occurs, other measures should be taken. Intravenous magnesium is regularly used in these circumstances, although the evidence for benefit is small. Failure to improve at all within 1 hour is an indication to consider intubation.

Labile peak flows are a normal feature in the recovery phase of acute severe asthma and do not necessarily indicate the need to increase therapy, so long as there is a good response to bronchodilators. For this reason, pre- and post-nebulizer peak flows should be measured while the patient is in the hospital.

Prior to discharge, the trigger for the exacerbation should be identified whenever possible and a self-management plan for the recovery period negotiated with the patient. Clear communication of the follow-up arrangements must occur and include appropriate use of both specialist and community services.

134 Chronic obstructive pulmonary disease

Patrick Davey, Sherif Gonem, Salman Siddiqui, and David Sprigings

Definition of the disease

The Global Initiative for Chronic Obstructive Lung Disease (GOLD) states that 'chronic obstructive pulmonary disease (COPD), a common preventable and treatable disease, is characterised by persistent airflow limitation that is usually progressive and is associated with an enhanced chronic inflammatory response in the airways and the lung to noxious particles and gases. Exacerbations and comorbidities contribute to the overall severity in individual patients.'

Aetiology of the disease

The majority of cases of COPD worldwide are caused by tobacco smoking. However, a variety of other environmental and occupational exposures may also contribute to the condition, including passive exposure to cigarette smoke, marijuana smoking, exposure to inorganic dusts, and exposure to smoke from biomass fuels used for cooking or heating. Chronic asthma is an underappreciated cause of COPD, with a significant proportion of asthmatic patients developing fixed airflow obstruction in middle age. The most well-characterized genetic abnormality causing COPD is alpha-1 antitrypsin deficiency, although this accounts for only a small proportion of cases. Nevertheless, family studies suggest a significant genetic component to COPD in the general population, and a number of candidate genes have been identified.

Airflow obstruction in COPD is caused by two distinct processes, either of which may be more prominent in a given patient. The first is small airway disease (bronchiolitis), which results in airway wall thickening and luminal obstruction. The second is lung parenchymal destruction (emphysema), which results in both loss of lung elastic recoil and disruption of the alveolar attachments that anchor the airways to the lung parenchyma, thus causing dynamic expiratory airway collapse.

Typical symptoms of the disease, and less common symptoms

The main symptoms of COPD are:

- shortness of breath; this characteristically occurs on exertion and is progressive over a number of years, eventually culminating in shortness of breath at rest in end-stage disease; orthopnoea is relatively common, even in the absence of coexistent congestive cardiac failure
- chronic cough; this is usually dry, or productive of small to moderate quantities of sputum; copious sputum production should raise the suspicion of coexistent bronchiectasis
- wheeze or chest tightness

Other common symptoms of COPD are related to its systemic manifestations. These include:

- oedema; this is a sign of right heart failure (cor pulmonale) or coexistent congestive cardiac failure
- weight loss and muscle wasting; this is not completely understood, but is a poor prognostic indicator
- low mood; depression commonly coexists with COPD and should be actively screened for

Demographics of the disease

COPD is the fourth leading cause of death worldwide and imposes a significant burden in terms of individual morbidity and disability.

The prevalence is difficult to estimate due to variations in diagnostic criteria used in different studies. Most national surveys report prevalence rates of approximately 6%, although it is likely that a significant proportion of patients remain undiagnosed. COPD increases in prevalence with age, being uncommon under the age of 40 years, and most common among those over the age of 60. Although previously more common in men, changing patterns of cigarette smoking have resulted in an approximately equal female prevalence. Some studies have suggested that women may be more susceptible than men to the effects of cigarette smoke, and COPD mortality among women has now surpassed that of men.

Natural history, and complications of the disease

In normal individuals, lung function, measured using the forced expiratory volume in 1 second (FEV₁), increases during childhood and peaks in early adulthood, before gradually declining. The natural history of COPD mirrors this, except that, at a certain point, usually during middle age, a level of lung function is reached that causes functional limitation and symptoms. This can occur either because the expected peak lung function is not achieved, due to early life events, or because the decline in lung function after the peak is accelerated. It has been shown that lung function measured shortly after birth tracks through to young adulthood and that maternal smoking is an important determinant of postnatal lung function. Moreover, a positive correlation has been found between birth weight and FEV₁ in middle age. Childhood asthma and lower respiratory tract infections are associated with lower lung function in adult life, but it is not known whether these events cause loss of lung function, or are themselves a consequence of preexisting diminished lung function during childhood. The most important factor causing accelerated lung function decline during adulthood is tobacco smoking. Moreover, it has been shown that cessation of smoking may result in a return to non-smoking rates of lung function decline, albeit starting from a lower baseline.

In many patients, the natural history of COPD is punctuated by periodic exacerbations of the condition, characterized by an acute onset of worsening shortness of breath and cough, often with increasing sputum quantity or purulence. It is thought that most acute exacerbations of COPD are caused by viral or bacterial infections. Exacerbations of COPD are a major cause of morbidity, mortality, and healthcare utilization associated with the condition. Moreover, there is evidence that patients with frequent exacerbations have a faster rate of lung function decline than those who do not. Other than acute exacerbations of the condition, respiratory complications of COPD include pneumonia, pneumothorax, and respiratory failure. Moreover, it is increasingly recognized that COPD is a systemic disease and that attention should be directed to its extra-pulmonary manifestations. Chief among these are the cardiovascular effects of COPD: It has been shown that reduced FEV₁ is an independent risk factor for cardiovascular disease, including ischaemic heart disease and stroke, even after controlling for smoking history, and much of the morbidity and mortality associated with COPD is due to cardiovascular rather than respiratory complications. Chronic hypoxaemia may also result in pulmonary hypertension and right heart failure. Other important extra-pulmonary manifestations of COPD include skeletal muscle atrophy, weight loss, depression, and osteoporosis.

Approach to diagnosing the disease

The diagnosis of COPD should be considered in people over the age of 40 years who present with progressive exertional dyspnoea or chronic cough, with or without sputum production, in the presence of one or more risk factors for the condition, such as tobacco smoking.

Important features of the clinical assessment

History

Important features to note when taking the history are:

- time course of symptoms: this is usually insidious, often with a lag period of months or years between the onset of symptoms and presentation to medical services
- smoking history: current smoking status and pack year history should be noted
- occupation and other relevant exposures: this includes exposure to inorganic dusts, biomass fuel smoke, and tobacco smoke

Examination

General inspection

Signs of severe COPD include dyspnoea at rest or on minimal exertion, use of accessory muscles of respiration, pursed lip breathing, cyanosis, and muscle wasting. Nicotine staining of the fingers indicates continued cigarette smoking. Clubbing is not a sign of COPD, and suggests an alternative diagnosis.

Examination of the chest

Hyperinflation may be evidenced by a 'barrel-shaped' chest, with an increased postero-anterior diameter. Quiet breath sounds on auscultation are suggestive of emphysema, while wheeze is an indication

of expiratory airflow limitation. Crackles are not a usual feature of COPD, and suggest an alternative or additional diagnosis, such as bronchiectasis or interstitial lung disease.

Other diagnoses that should be considered

A number of conditions should be considered in the differential diagnosis of stable COPD, or may occur in conjunction with it, thus altering the required management. These are shown in Table 134.1, together with the clinical features and investigation results that may suggest these alternative diagnoses. Similarly, acute exacerbation of COPD is a diagnosis of exclusion, and a number of other pathologies should be considered in a patient with COPD who presents with worsening shortness of breath or cough, as listed in Table 134.2.

'Gold-standard' diagnostic test and acceptable diagnostic alternatives

Spirometry is the gold standard for the diagnosis of COPD, as well as its classification into categories of severity. Diagnosis is made on the basis of a compatible clinical picture in conjunction with an FEV₁ to forced vital capacity (FVC) ratio of less than 70% following administration of a bronchodilator. However, there is some concern that this spirometric criterion may result in over-diagnosis of COPD in the elderly, and it may be preferable to define the lower limit of normal in terms of the lower fifth percentile value in an age, sex, and height-matched population. The spirometric classification of COPD is shown in Table 134.3. While the gold-standard diagnostic test is spirometry performed in an accredited pulmonary function laboratory by a qualified respiratory physiologist, it is acceptable and indeed encouraged for spirometry to be available in a community setting. Training is available to enable a wide variety of practitioners to perform spirometry, including practice nurses, general practitioners, and hospital doctors. However, in order to ensure accurate and consistent results across centres, it is important that spirometers are calibrated regularly, that personnel performing spirometry are trained to an appropriate standard, and that spirometry is performed according to

Table 134.1 Differential diagnoses of stable COPD

Condition	Supportive clinical features
Asthma	Young age of onset Minimal or no smoking history History of atopy/allergy Family history of asthma Mainly episodic or nocturnal symptoms Diurnal variability in peak expiratory flow Normal spirometry in the stable state Significant bronchodilator reversibility Reduced methacholine PC ₂₀
Bronchiectasis	Copious daily sputum production Coarse crackles audible on auscultation Chronic bacterial colonization in sputum (esp. with <i>Pseudomonas aeruginosa</i>) Bronchial dilatation visible on chest radiograph or CT scan
Interstitial lung disease	Fine crackles audible on auscultation Restrictive pattern on spirometry Reduced lung volumes Interstitial shadowing visible on chest radiograph or CT scan
Bronchiolitis	History of connective tissue disease, toxic fume inhalation, or previous lung or bone marrow transplant (obliterative bronchiolitis) History of sinusitis, and East Asian origin (diffuse panbronchiolitis)
Obesity hypoventilation syndrome	Obesity Restrictive pattern on spirometry and reduced lung volumes, but with normal or supra-normal carbon monoxide transfer coefficient
Congestive cardiac failure	History of ischaemic heart disease Peripheral oedema and orthopnoea out of proportion to other symptoms; paroxysmal nocturnal dyspnoea Fine basal crackles on auscultation; gallop rhythm Cardiomegaly and evidence of pulmonary oedema on chest radiograph Left ventricular failure on echocardiogram

Table 134.2 Differential diagnosis of acute exacerbation of COPD

Condition	Supportive clinical features
Pneumonia	History of pleuritic chest pain Fever and other features of the systemic inflammatory response syndrome (e.g. shock) Bronchial breathing or localized coarse crackles on auscultation Pulmonary infiltrate or lobar collapse on chest radiograph
Pneumothorax	History of pleuritic chest pain Sudden onset of symptoms Pneumothorax visible on chest radiograph
Pulmonary embolism	History of pleuritic chest pain or haemoptysis Personal or family history of venous thromboembolism Recent surgery or immobility Absence of wheeze or other abnormalities on auscultation Shortness of breath out of proportion to clinical signs Lack of response to COPD treatment New right-heart strain pattern on electrocardiogram Raised D-dimers
Silent myocardial infarction	History of ischaemic heart disease Absence of hypoxia or abnormalities on chest auscultation Ischaemic changes on electrocardiogram Raised cardiac enzymes
Congestive cardiac failure	History of ischaemic heart disease Peripheral oedema and orthopnoea out of proportion to other symptoms; paroxysmal nocturnal dyspnoea Fine basal crackles on auscultation; gallop rhythm Cardiomegaly and evidence of pulmonary oedema on chest radiograph Left ventricular failure on echocardiogram

Severity	Postbronchodilator FEV ₁ /FVC	FEV ₁ % pred.
At risk*	>0.7	≥80
Mild COPD	≤0.7	≥80
Moderate COPD	≤0.7	50–80
Severe COPD	≤0.7	30–50
Very severe COPD	≤0.7	<30

*Patients who smoke or have exposure to pollutants and have cough, sputum, or dyspnoea.

Abbreviations: FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; pred., predicted.

standard guidelines, such as those published jointly by the American Thoracic Society and the European Respiratory Society.

Other relevant investigations

Further investigations that may be required for the investigation of stable COPD include the following:

Pulmonary function tests: Carbon monoxide uptake in the lung is often reduced, and body plethysmography may show evidence of air trapping, with a raised residual volume/total lung capacity ratio.

Exercise testing: Validated exercise tests include the 6-minute walk test and the incremental shuttle walk test. These may be used to assess the level of disability, as well as providing an objective measure of the effectiveness of interventions such as pulmonary rehabilitation or lung volume reduction surgery.

Pulse oximetry: This, with or without arterial blood gas, is used to assess suitability for long-term oxygen therapy.

Chest radiograph: This may show evidence of hyperinflation or emphysematous bullae.

CT scan: This shows the extent and distribution of emphysema, as well as the presence of bullae. Associated bronchiectasis or interstitial lung disease may be visualized.

Echocardiogram: This allows right-heart function and pulmonary artery pressures to be assessed non-invasively.

Alpha-1 antitrypsin levels: Levels below 15%–20% of normal are suggestive of homozygous alpha-1 antitrypsin deficiency.

Appropriate investigations in patients presenting acutely with exacerbations of COPD may include the following:

Full blood count, and C-reactive protein level: Raised inflammatory markers could indicate bacterial infection.

Chest radiograph: Complications of COPD that may be visualized on a chest radiograph include pneumonia and pneumothorax.

Arterial blood gas: This is used to distinguish between type I and type II respiratory failure, and hence guide oxygen therapy and respiratory support.

ECG: This may show evidence of right-heart strain or right atrial hypertrophy.

Prognosis and how to estimate it

Characteristics associated with a worse prognosis in patients with COPD include severely diminished FEV₁, weight loss, poor exercise tolerance, and hypoxaemia at rest. The BODE index is a composite score that is used to estimate prognosis in patients with COPD. It comprises four components:

- **B**ody mass index
- **O**bstruction (FEV₁ (% predicted))
- **D**yspnoea (modified Medical Research Council dyspnoea scale)
- **E**xercise capacity (6-minute walk test distance)

Each component is given a score ranging from 0 (best) to 3 (worst), except for body mass index, which is scored as 0 (BMI > 21 kg/m²) or 1 (BMI ≤ 21 kg/m²). The BODE index can therefore range from 0 (best prognosis) to 10 (worst prognosis).

Treatment and its effectiveness

Treatment of stable COPD

The optimal management of stable COPD requires a holistic approach in which interventions are directed not only at improving the function of the lungs, but also at addressing the systemic manifestations of the condition, in addition to psychological and social factors. The treatments available may be divided into general, pharmacological, and interventional categories.

General management

Smoking cessation

Smoking cessation is the only intervention that has been proven to favourably alter the natural history of COPD. All patients with COPD who still smoke should be advised to quit, and those who are motivated to do so should be referred to a smoking cessation service which can provide access to pharmacotherapy in combination with regular follow-up and support. The most commonly used pharmacological treatment is nicotine replacement therapy, which can be administered in the form of gums, lozenges, patches, nasal sprays, and inhalers. Bupropion and varenicline are alternative smoking cessation agents.

Pulmonary rehabilitation

Pulmonary rehabilitation is a comprehensive intervention that has at its core an exercise training programme specifically designed to improve muscle strength and physical endurance. Allied to this may be a number of complementary components, including self-management education, dietary advice, counselling, and occupational therapy.

Long-term oxygen therapy

Long-term oxygen therapy, administered for more than 15 hours per day, has been shown to improve mortality in patients who are chronically hypoxic. It is indicated for patients with a resting arterial oxygen tension ≤7.3 kPa, or between 7.3 kPa and 8.0 kPa with concomitant evidence of cor pulmonale or polycythaemia. Continued smoking is a relative contraindication due to the risk of facial burns, and patients should be warned not to smoke near the oxygen supply or to allow others to do so.

Nocturnal non-invasive ventilation

Nocturnal non-invasive ventilation is used in occasional patients with severe COPD and chronic hypercapnia, particularly those who manifest recurrent admissions with decompensated type II respiratory failure.

Vaccination

Vaccination against influenza and *Pneumococcus* is recommended for all patients with COPD.

Pharmacological therapy

Inhaled bronchodilators

Short-acting beta-2 agonists such as salbutamol are administered via an inhaler or a nebulizer on an as-required basis for relief of symptoms, while inhaled, long-acting beta-2 agonists such as salmeterol and formoterol are used regularly to prevent or reduce chronic symptoms. Anticholinergic agents include the short-acting ipratropium and the long-acting tiotropium.

Inhaled corticosteroids

Inhaled corticosteroids such as beclometasone, budesonide, and fluticasone may be administered singly, but combination inhalers with long-acting beta-2 agonists are preferred. Regular treatment with inhaled corticosteroids has been shown to improve symptoms, lung function, and exacerbation frequency in patients with an FEV₁ (% predicted) <60%.

Theophylline

Theophylline is not a first-line treatment for COPD but may provide some benefit as an additional therapy in some patients with poorly controlled disease. Similarly, mucolytics such as carbocysteine may benefit selected patients, particularly those who complain of difficulty expectorating tenacious sputum.

Roflumilast

Roflumilast, a phosphodiesterase-type-4 inhibitor, appears to reduce exacerbations in patients with severe or very severe COPD in combination with chronic bronchitis and a history of exacerbations. It may be considered as an add-on therapy in selected patients.

Surgical and bronchoscopic therapies**Bullectomy**

Bullectomy is the surgical removal of a large (i.e. occupying at least one-third of the hemithorax) bulla which is causing compression of the adjacent lung. The procedure may be indicated in patients with severe functional limitation despite maximal medical therapy, and its primary purpose is to reduce dyspnoea.

Lung volume reduction surgery

Lung volume reduction surgery (LVRS) is the removal of emphysematous areas of the lung that are not participating in gas exchange, in order to alleviate hyperinflation and thus allow the respiratory muscles to act at a mechanical advantage. It may be performed via open surgery or video-assisted thoracoscopic surgery. A recent large trial of LVRS has emphasized the importance of careful patient selection. Patients undergoing LVRS should have upper-lobe-predominant emphysema, with significant functional limitation due to their COPD, despite undergoing pulmonary rehabilitation. The FEV₁ and the carbon monoxide transfer factor should both be greater than 20% predicted. Contraindications include age greater than 70 years (with some exceptions); continued smoking; comorbidities which may increase surgical risk; diffuse emphysema; significant hypercapnia (i.e. the partial pressure of carbon dioxide in arterial blood (P_aCO₂) >7.3 kPa); and pulmonary hypertension. LVRS has been shown to improve lung function and symptoms in patients who fit these criteria, but with a perioperative mortality of approximately 5%.

Bronchoscopic alternatives to LVRS have recently been developed. The insertion of one-way endobronchial valves causes collapse of the distal lung segments, thus ameliorating hyperinflation. Extrapulmonary bypass, which is the insertion of stents through the bronchial wall in order to bypass the site of flow limitation, allows trapped gas to escape and reduces the resistance to airflow. Both of these techniques are still under development and not yet widely available except in a research setting.

Lung transplantation

Lung transplantation is suitable for a small proportion of patients with COPD, but carries a 1-year mortality of up to 15%. Factors favouring lung transplantation over LVRS include diffuse emphysema, hypercapnia, pulmonary hypertension, and FEV₁ <20% predicted. Patients should be relatively young (under 65 years) with an absence of cardiac or renal disease, osteoporosis, or malignancy. Bilateral lung transplantation is the preferred option, but organ availability is a limiting factor.

Treatment of acute exacerbations of COPD

Many acute exacerbations of COPD can be managed successfully in the community. However, admission is required for patients who

are hypoxic, those who manifest abnormal vital signs, and those who do not have adequate social support at home. Supported early discharge schemes may allow some patients to be discharged home 24–48 hours after admission, with treatment and follow-up provided in the community by specialist nurses. Long-term therapy should be reviewed and optimized before discharge.

The treatment of acute exacerbations of COPD incorporates the following components:

Oxygen: Oxygen should initially be administered via a Venturi mask and titrated to target saturations of 88%–92%, since excessive oxygen administration may result in hypercapnic respiratory failure in susceptible patients. If the P_aCO₂ is found to be normal and there are no other risk factors for hypercapnic respiratory failure, such as previously documented episodes requiring ventilatory support, then the target range may be increased to 94%–98%. Any increase in administered oxygen concentration should be followed by an arterial blood gas 30–45 minutes later to rule out worsening hypercapnia.

Nebulized short-acting bronchodilators: Nebulized short-acting bronchodilators such as salbutamol and ipratropium should be given regularly during the acute phase of the exacerbation.

Oral corticosteroids: Short courses (5–7 days) of oral corticosteroids are routinely given, and antibiotics are appropriate in most cases, particularly if there is an increase in sputum quantity or purulence.

Aminophylline: Intravenous aminophylline may be considered in severe exacerbations which are refractory to nebulized bronchodilator treatment. However, side effects, including cardiac arrhythmias, are not uncommon, and the evidence for benefit is inconsistent. Serum levels should be monitored regularly, and cardiac monitoring is advisable.

Ventilatory support: Invasive or non-invasive ventilatory support is indicated in patients with refractory hypoxaemia or hypercapnic respiratory failure despite maximal medical therapy, including appropriate titration of oxygen. Acute non-invasive ventilation has transformed the management of type II respiratory failure in COPD, and has been shown to reduce the need for invasive ventilation, as well as reducing mortality and length of hospital stay.

135 Respiratory failure

Matt Wise and Simon Barry

Definition of the disease

Respiratory failure is a syndrome characterized by defective gas exchange due to inadequate function of the respiratory system. There is a failure to oxygenate blood (hypoxaemia) and/or eliminate carbon dioxide (hypercapnia). Hypoxaemia is defined as an arterial blood partial pressure of oxygen (PaO_2) of <8 kPa, and hypercapnia as an arterial blood partial pressure of carbon dioxide (PaCO_2) of >6 kPa.

Respiratory failure is divided into two different types, conventionally referred to as type 1 and type 2. The distinction between these two is important because it emphasizes not only their different pathophysiological mechanisms and etiologies, but also different treatments. The preferred terminology and definitions are:

- oxygenation failure (type 1 respiratory failure): PaO_2 of <8 kPa
- ventilation failure (type 2 respiratory failure): $\text{PaCO}_2 >6$ kPa

Respiratory failure may be **acute** (onset over hours to days), or **chronic** (developing over months to years); alternatively, there may be an acute deterioration of a chronic state.

Physiology and aetiology of respiratory failure

There are only five causes of a low PaO_2 on arterial blood gas sampling:

- low inspired oxygen (altitude)
- ventilation–perfusion (VQ) mismatch
- right-to-left shunt
- diffusion limitation
- alveolar hypoventilation

The first four of these cause failure of oxygenation, while the last results in ventilation failure, as the name suggests. The alveolar gas equation is crucial to understanding why hypoventilation causes hypoxaemia. PAO_2 , the partial pressure of alveolar oxygen, is calculated as follows:

$$\text{PAO}_2 = \text{PiO}_2 - (\text{PCO}_2 / 0.8).$$

The partial pressure of inspired oxygen is calculated as follows:

$$\text{PiO}_2 = \text{FiO}_2 \times (\text{Pb} - \text{PH}_2\text{O}),$$

where

FiO_2 = fraction of inspired oxygen (0.21 if breathing room air)

Pb = barometric pressure (101 kPa at sea level)

PH_2O = water vapour pressure (6.3 kPa)

$$\text{PiO}_2 = \text{breathing room air at sea level} = 0.21 \times (101 - 6.3) = 19.9 \text{ kPa.}$$

This value, 19.9 kPa, is similar for practical clinical purposes to the percentage of oxygen inspired while breathing air, 21%. If the patient is on oxygen, then the FiO_2 is adjusted to reflect this.

Therefore, to simplify:

$$\text{PAO}_2 \sim \text{FiO}_2 (\%) - (\text{PaCO}_2 / 0.8).$$

From this equation, it is apparent that any rise in PaCO_2 results in a fall in PAO_2 and, consequently, also a reduction in PaO_2 , since there must be a gradient from the alveolus to the artery. Thus, hypoventilation causes hypoxaemia.

Knowledge of the PAO_2 also enables the difference between the alveolar and the arterial oxygen partial pressures, that is, the A–a gradient to be calculated. This describes the severity of oxygenation failure. By contrast, hypoventilation will cause hypoxaemia with a normal A–a gradient. The lungs are not perfect, and there is a degree of VQ mismatch, with normal values of the A–a gradient up to 2 kPa in most and up to 3 kPa in the elderly.

Apart from causing hypoxaemia, another important result of acute hypoventilation is the development of an acidosis. The acid–base balance is described by the Henderson–Hasselbalch equation. A simplification of this is

$$\text{pH} \sim (\text{base} / \text{acid}),$$

where HCO_3 is the base, and PaCO_2 is the acid.

From this equation, a rise in PaCO_2 results in a reduction in pH and thus leads to a respiratory acidosis. This can be corrected either by improving ventilation, perhaps with invasive or non-invasive methods, or through renal conservation of bicarbonate (compensation).

Causes of oxygenation failure

The causes of oxygenation failure are ventilation perfusion mismatch, right-to-left shunt, and diffusion limitation.

Ventilation perfusion mismatch

Ventilation perfusion mismatch is by far the most common cause of oxygenation failure. Causes of ventilation perfusion mismatch include:

- pneumonia
- pulmonary embolism
- lobar collapse
- COPD or acute severe asthma

Right-to-left shunt

A right-to-left shunt is caused by either an intra-cardiac shunt, or shunting through a pulmonary arteriovenous malformation. This can be associated with hepatic disease (hepatopulmonary syndrome).

Diffusion limitation

Diffusion limitation is caused by

- pulmonary oedema
- pulmonary fibrosis

Causes of ventilation failure

The common causes of ventilation failure are:

- COPD
- obesity
- chest wall disease
- neuromuscular disease
- depressed respiratory drive

The most helpful way to understand the mechanisms of ventilation failure is to describe the balance between the respiratory drive, the load imposed by the disease process, and the respiratory muscle capacity (see Figure 135.1). Imbalances of any of these three components can result in ventilatory failure. Impaired respiratory drive may be caused by overdoses of opiates, alcohol, or recreational drugs such as gamma-hydroxybutyric acid; alternatively, it may be caused by brainstem disease. Drive may also be reduced as a compensatory mechanism for metabolic acidosis. Increased load is commonly caused by obesity, but COPD can also impose an increased

Figure 135.1 Diagram representing the balance between the respiratory drive, the load imposed on respiratory muscles, and the respiratory muscle capacity, as causes of ventilatory failure.

load due to dynamic hyperinflation. Pulmonary fibrosis increases load by impairing lung compliance, and kyphoscoliosis impairs chest wall compliance. The main causes of reduced capacity are neuromuscular diseases encompassing a number of different conditions. These are best considered as diseases affecting nerves, the neuromuscular junction, or muscle (Box 135.1).

Typical and less common symptoms, and signs of respiratory failure

Symptoms of oxygenation failure

The clinical presentation of oxygenation failure strongly suggests the underlying cause. For example, symptoms of fever, productive cough, and dyspnoea, developing over days, with coarse lung crepitations on chest auscultation and hypoxaemia suggests pneumonia. Dyspnoea is the cardinal symptom of oxygenation failure, and careful history taking is paramount, with a particular emphasis on determining the speed of onset of dyspnoea and the severity of change when compared to the baseline. Frequently, patients have a previous history of cardiac or respiratory illness, for example pulmonary fibrosis or COPD, and significant worsening of dyspnoea may represent infection, pulmonary embolism, or another process exacerbating the existing illness.

Important signs in acute oxygenation failure include the following:

- abnormal respiratory rate (≥ 20 /min or < 8 /min)
- low oxygen saturations ($< 93\%$ on air)
- tachycardia
- hypotension
- confusion
- central cyanosis

Box 135.1 Neuromuscular causes of ventilatory failure

Nerve

- motor neuron disease
- Guillain-Barré
- phrenic nerve palsy
- polio
- high spinal cord lesions (above C3)

Neuromuscular junction

- myasthenia gravis
- botulism

Muscle

- muscular dystrophies (Duchenne, Becker's, myotonic)
- metabolic myopathies (acid maltase deficiency)
- endocrine myopathies (thyroid disease)
- mitochondrial cytopathies
- inflammatory myopathies

In most cases, oxygenation failure is rapidly diagnosed in a dyspnoeic patient with low oxygen saturations, particularly since the widespread adoption of standard nursing assessments such as Early Warning Scoring and its variants, which record observations including respiratory rate and oxygen saturations.

A cause of oxygenation failure that is less commonly identified is that due to obstructive sleep apnoea (OSA), since it occurs at night and is usually associated with normal daytime oxygen saturations. A history of sleep apnoea is easy to obtain once the diagnosis is considered, and an overnight sleep study can readily diagnose the condition.

Symptoms of ventilation failure

While oxygenation failure is rapidly recognized, the converse is true in ventilatory failure, which is frequently missed. The symptoms of ventilation failure are due to the effects of hypercapnia and include increasing drowsiness, confusion, and, eventually, coma. Usually these symptoms occur in a patient at risk of ventilatory failure, such as those with obesity or with chest wall or neuromuscular disease. In addition, COPD patients placed on high-flow oxygen, usually during transport to hospital in an ambulance, constitute another group that frequently presents with ventilatory failure.

It cannot be overemphasized that oximetry gives no information about the state of ventilation, and a blood gas is necessary to make the diagnosis. Clinical signs that support ventilatory failure include:

- confusion, drowsiness, and an altered conscious state
- bounding pulse
- vasodilation
- flapping tremor
- papilloedema

Demographics of the disease

There are numerous causes of respiratory failure, and addressing the demographics of all these is impractical and beyond the scope of this chapter. Nevertheless, both acute and chronic respiratory failure are major causes of morbidity and mortality. Data from intensive care units in the UK have demonstrated that 3%–4% of admissions are due to COPD, and 5.9% are due to pneumonia. When chronic ventilatory failure is considered, the UK prevalence of home mechanical ventilation (including tracheostomy ventilation) is 4.1 per 100 000 and, of the 2842 users in 2002, approximately one-third were ventilated for lung/airways disease, one-third for chest wall disease, including obesity, and one-third for neuromuscular disease. There are likely to be significant changes in these proportions over time. If current trends continue, 60% of adults in the UK will be obese by 2050. Studies have demonstrated that 31% of hospital patients with a BMI > 35 without lung or neuromuscular disease have daytime hypercapnoea, rising to a staggering 50% of those with a BMI > 50 .

Natural history, and complications of the disease

Respiratory failure has many causes. Therefore, the natural history, the complications, and the outcomes reflect the underlying disease and patient comorbidities.

Approach to diagnosing respiratory failure

Diagnosing oxygenation failure

As previously discussed, the diagnosis of oxygenation failure is strongly suggested by low oxygen saturations. Pulse oximeters are dependent on good pulsatile flow. Pitfalls include poor oximetry traces in states of poor peripheral perfusion or when nail varnish is present; such traces will lead to an inaccurate or inadequate signal for analysis. Different types of haemoglobin are not distinguished by pulse oximeters. In carbon monoxide poisoning (carboxyhaemoglobin), oxygen saturations will be falsely elevated, while, in methaemoglobinaemia, they may be erroneously low or high, depending on the level of methaemoglobin. Arterial blood gas analysis should

be performed in those with oxygen saturations of <93% on air. In addition, modern point-of-care gas analysers measure carboxy- and methaemoglobin directly. Many A & E departments or critical care units have point-of-care blood gas analysers. If the sample is being transported to a laboratory, it should be on ice, and any air bubbles should be expelled, to avoid spurious values. If arterial blood gas tests are performed while the patient is on oxygen, it is crucial that this fact be recorded in the notes and on the request form, so that a correct assessment of oxygenation can be made. Ideally, in patients on oxygen, the A–a gradient should be recorded, as this gives an indication of the extent of oxygenation failure.

Diagnosing ventilation failure

In patients with ventilatory failure, the key approach is to recognize those at risk and then perform blood gas analysis. While there are some symptoms and signs of ventilatory failure, these are often not present, and the patient may appear well with preserved oxygen saturations.

The following patient groups should be considered for blood gas analysis:

- those with severe obesity (BMI >40)
- those with kyphoscoliosis or other significant chest wall deformities
- those with moderate-to-severe COPD
- those with neuromuscular diseases, such as motor neuron disease; muscular dystrophies; or diaphragm palsy of any cause
- those with severe bronchiectasis or cystic fibrosis

Bicarbonate and PaCO₂ levels are not clinically significantly different, whether a venous, capillary (ear lobe), or arterial sample is taken, a fact that is frequently not appreciated.

Other diagnosis that should be considered

Patients with acute or acute-on-chronic respiratory failure are critically ill, and this syndrome should be considered in all critically ill patients. There are very few instances where it is not appropriate to obtain a blood gas in a critically ill patient, and this will establish a diagnosis of respiratory failure. Since the symptoms and signs of critical illness are non-specific, there are many instances where the patient may be thought on first inspection to be in respiratory failure. Thus, a patient with diabetic ketoacidosis may complain of dyspnoea and be extremely tachypnoeic (as a consequence of metabolic acidosis and increased work of breathing), and a similar presentation may be observed in severe sepsis. Potential pitfalls in the diagnosis of respiratory failure are due to misinterpretation of arterial blood gas samples. It is easy to establish if the patient is hypoxic or a large A–a gradient exists. If there is evidence of hypercapnia, one must remember to first look at the pH. Rarely, patients have a metabolic alkalosis (diuretics, nasogastric losses, or vomiting) which is partially corrected by alveolar hypoventilation (hypercapnia), but the primary abnormality will be an alkalosis.

'Gold-standard' diagnostic test

Arterial blood gas analysis remains the best method for diagnosing acute respiratory failure.

Acceptable diagnostic alternatives to the gold standard

Pulse oximetry may be used to detect hypoxaemia non-invasively. However, this method gives no information about ventilation (PaCO₂), and several factors can adversely affect readings, as previously discussed. Nevertheless, overnight oximetry is very helpful in the diagnosis of OSA. Transcutaneous CO₂ can also be measured, which is helpful during overnight studies in patients who hypoventilate. However, the readings should be anchored with a blood PaCO₂ level.

Other relevant investigations

Tests should be chosen in order to support or refute the clinical diagnosis. However, in general, these can be grouped into five main

categories: blood tests, imaging, lung function tests, cardiology tests, and sleep tests.

Blood tests

Blood tests relevant to respiratory failure include:

- a full blood count; for leucocytosis or neutropenia (infection), polycythaemia (chronic hypoxia), anaemia (cause of breathlessness)
- blood biochemistry; for electrolyte disturbance (which may precipitate arrhythmias or muscle weakness); amylase levels (pancreatitis); thyroid function (cardiac disease, muscle weakness); creatinine kinase (cardiac or muscle disease); and troponin (ischaemic heart disease, myocarditis)
- toxicology (overdose)

Imaging

Imaging relevant to respiratory failure includes:

- chest radiograph
- ultrasonography (to detect pleural effusions, pneumothorax, consolidation, lung water)
- CT scan (CT pulmonary angiogram, to exclude pulmonary emboli; high-resolution CT, to exclude fibrosis, bronchiectasis, or other structural abnormalities)

Lung function tests

Lung function tests relevant to respiratory failure include:

- spirometry, lung volumes (to determine obstructive and restrictive defects)
- gas diffusion
- tests of diaphragm function (sniff nasal inspiratory pressure, lying and sitting vital capacity); useful in neurological disease
- cardiopulmonary exercise tests (a powerful tool for determining the cause of breathlessness)

Cardiology tests

Cardiology tests relevant to respiratory failure include:

- ECG (ischaemia, arrhythmias)
- echocardiography (for estimates of left ventricular function, diastolic dysfunction, regional wall abnormality, valve function, pericardial disease, pulmonary hypertension, pulmonary emboli)

Sleep tests

Sleep tests relevant to respiratory failure include:

- simple oximetry (screening test for obstructive sleep apnea)
- limited channel sleep study (to differentiate obstructive and central apnoeas, paradoxical breathing)
- transcutaneous CO₂ measurement (helpful in determining nocturnal hypercapnoea in obesity hypoventilation)

Prognosis and how to estimate it

Respiratory failure is a syndrome with a wide aetiology and it is difficult to prognosticate. Clinical scoring systems exist for several of the clinical conditions, including pneumonia (e.g. CURB-65, or pneumonia severity index), which help identify those at high risk of death; however, for many conditions, such tools are not available. Once patients are admitted to a high-dependency or intensive care unit, a number of scoring systems such as the Acute Physiology and Chronic Health Evaluation (APACHE), the Simplified Acute Physiology Score (SAPS), and the Sequential Organ Failure Assessment (SOFA) help to define patient outcome. These scoring systems are similar in their predictive accuracy but describe outcome in groups of patients rather than individuals; therefore, prognosis is often determined by expert opinion.

For acute ventilatory failure, there is good evidence that increasing acidosis results in higher mortality and increased rates of endotracheal intubation and mechanical ventilation.

Treatment and its effectiveness

The differentiation of respiratory failure into oxygenation failure and ventilation failure is particularly important when considering

treatment. Simplistically, oxygenation failure requires oxygen, and ventilation failure requires ventilation. Conversely, giving oxygen to patients with ventilation failure may, on occasion, be dangerous.

Treatment of acute respiratory failure

Treatment of patients in acute respiratory failure requires a stepwise approach, addressing the key essentials first.

Resuscitation and Advanced Life Support

Resuscitation must be initiated as soon as respiratory failure is recognized and should follow the standard Airway, Breathing, Circulation (ABC) approach such that immediate threats to life such as airway compromise or tension pneumothorax are addressed first. The patient should be managed in an appropriate area with trained staff and monitoring (respiratory rate, continuous ECG, oximetry, arterial line (blood pressure, arterial blood gas analysis), and use of the Glasgow Coma Scale).

Maintaining oxygen saturations

Patients who are critically ill (peri-arrest, septic shock, multiple trauma) should have high-flow oxygen delivered via a non-rebreathing reservoir mask. However, after a blood gas has been taken and the patient is more stable, the target oxygen saturations for most people should be 94%–98%. There is increasing evidence that maintaining saturations above this level produces adverse outcomes in a variety of condition such as COPD, severe asthma, and cardiac arrest. In patients with known ventilatory failure (i.e. a raised PaCO₂ on this admission, or in the past), the target oxygen saturation range should be 88%–92%. For practical purposes, patients with moderate-to-severe COPD should be assumed to have ventilatory failure and given target saturations of 88%–92%, pending a blood gas result. Oxygen, if required at this stage, is best provided through a 24% or 28% Venturi mask, to achieve this range.

Physiotherapy

Sputum retention can lead to acute respiratory failure and may occur when there is an increased sputum load, tenacious sputum, and poor cough. This may be in the context of an acute respiratory infection, but also may occur in post-operative or trauma patients, particularly when pain prevents adequate coughing and sputum clearance. This is a frequent problem in patients who have been mechanically ventilated for a period of time and then extubated. Reintubation for respiratory failure secondary to sputum retention is common and again related to factors such as increased load and tenacity of sputum, poor cough, and physiological reserve. These individuals often require tracheostomy to liberate them from the ventilator and provide ongoing bronchopulmonary toilet.

Sputum retention is also important in those with chronic lung disease such as COPD, bronchiectasis, or cystic fibrosis, as well as those with neuromuscular disease, as the latter commonly have impaired cough reflexes. Physiotherapy, aided by mucolytics such as carbocysteine or dornase alfa, is often effective, but in patients in the high-dependency unit/intensive therapy unit setting, bronchial toilet via a nasopharyngeal airway, bronchoscopy, or even tracheostomy may be required.

Continuous positive airways pressure

Continuous positive airways pressure (CPAP) is an important intervention to improve oxygenation. CPAP is not a ventilatory mode per se, as it provides a constant pressure throughout the respiratory cycle; however, it improves oxygenation by increasing functional residual capacity, improving ventilation perfusion mismatch, and preventing upper airways obstruction.

Ventilatory support: Correcting a respiratory acidosis

Ventilatory support may either be provided non-invasively, via a mask applied to the nose, nose and mouth, or full face, or invasively, via a tracheostomy or endotracheal tube. In the acute setting, patients with a pH <7.25 are more likely to fail with non-invasive ventilation (NIV), and this should be attempted, if appropriate, in a high-dependency setting. Patients more profoundly

acidotic or with other organ instability may require immediate intubation.

The principles behind ventilation are simple. In a conscious patient given NIV, the patient initiates a breath and this triggers the machine to deliver a pressure, or volume, over a set period of time. This augmented breath is then terminated and the cycle repeats. In the UK and Europe, most ventilators are pressure driven. The inspiratory positive airway pressure (IPAP) is set and, at the end of the augmented breath, the machine usually returns not to the baseline, but a set expiratory positive airway pressure (EPAP), which functions like CPAP. It is the difference between the IPAP and EPAP, the pressure support, which determines ventilation and hence effective PCO₂ reduction. In practice, the keys to successful NIV are good communication with the patient, ensuring optimum mask fit, and adjusting the pressures to correct the ventilatory abnormality.

NIV is highly effective, reducing mortality by 50% when compared to standard medical treatment and reducing the need for invasive ventilation.

Treating the underlying pathology

Needless to say, the disease process which has led to the respiratory failure needs to be treated. In some cases, this may be an illness in which there will be complete resolution, such as a pneumonia treated with antibiotics. However, this may not always be possible, as in the case of progressive neuromuscular disease.

Treatment of chronic respiratory failure

Treatment of oxygenation failure

Two landmark studies from the 1980s demonstrated that giving oxygen to COPD patients who were hypoxaemic improved survival. Based on these studies, long-term oxygen therapy is recommended in the stable state if the PaO₂ <7.3 kPa, or less than 8 kPa in the presence of cor pulmonale, polycythaemia, or pulmonary hypertension. Oxygen is generally not recommended in those who continue to smoke.

Treatment of ventilation failure

Evidence for the benefit of long-term ventilation in neuromuscular and airways disease is evolving. Long-term ventilation provides definite survival and quality-of-life advantages in motor neuron disease patients developing ventilatory failure without predominant bulbar features, compared to controls. In addition, NIV is largely responsible for an increase in life expectancy of approximately 10 years in patients with Duchenne muscular dystrophy.

By contrast, it is surprising that only a single recent randomized trial has shown a survival benefit of long-term NIV in COPD patients with ventilatory failure. The likely explanation is that, historically, low ventilatory pressures have been used, and the current vogue is to try more aggressively to correct the abnormal physiology with a greater acceptance for using higher pressures.

Obesity is a growing indication for long-term ventilatory support. The umbrella term 'obesity-related respiratory failure' encompasses those with OSA, OSA and obesity hypoventilation syndrome (OHS), or lone OHS. Only a minority of OSA patients develop ventilatory failure and, even then, most can be managed with CPAP. OSA/OHS overlap or lone OHS requires NIV.

Lastly, severe bronchiectasis and cystic fibrosis can result in ventilatory failure. Usually, the disease is severe, and chronic sputum production may make tolerance more difficult. The evidence base, particularly in cystic fibrosis, is poor.

Invasive ventilation, and end-of-life care

Patients with respiratory failure may not respond to simple measures or NIV and it may be appropriate to escalate to invasive mechanical ventilation in critical care—this is discussed further in Chapter 149.

Escalation of treatment may not be in the patient's best interests or indeed desired by them. In chronic respiratory failure patients in whom the inevitable trajectory of illness is towards ventilator dependence, these issues are best discussed, well in advance of an acute deterioration, with the individuals concerned and their family.

End-of-life care in the context of more acute respiratory failure is discussed in Chapter 153.

136 Obstructive sleep apnoea

Sonya Craig and Sophie West

Definition of the disease

Obstructive sleep apnoea (OSA) is caused by the repetitive closure of the pharynx during sleep, leading to sleep fragmentation and, often, daytime somnolence. Traditionally, it is defined as either the number of apnoeas (complete cessation of breathing for longer than 10 seconds) or hyponoeas (reduction in air flow by >30% for more than 10 seconds with >3% oxygen dip) per hour in an overnight sleep study. However, it must be remembered that this definition is arbitrary, and OSA is better viewed as a spectrum with trivial snoring at one end and severe, almost continuous obstruction at the other. In addition to the sleep study findings, if the patient is sleepy during the day, as defined by the Epworth Sleepiness Scale, then this condition is termed 'obstructive sleep apnoea syndrome'. This distinction is important, as patients with this syndrome usually warrant treatment.

Aetiology of the disease

The majority of patients with OSA are overweight, and weight loss can certainly cure OSA. The evidence suggests that most OSA in adults is due to loading of the upper airway, with the loading being caused by obesity and fat deposits in the neck area. This external loading can be fended off during wakefulness but not during sleep, when the withdrawal of postural muscle tone allows the pharyngeal dilators to be overwhelmed, leading to excessive narrowing or collapse of the airway, with consequent apnoea and arousal.

Major risk factors

The major risk factors for developing OSA are:

- being a middle-aged male
- being overweight
- being a snorer
- having a collar size >17 inches
- having craniofacial abnormalities (e.g. retrognathia (may be genetic or acquired))

Less common/minor risk factors

The less common/minor risk factors for developing OSA are:

- having large tonsils
- hypothyroidism (leading to an increase in submucosal tissue)
- neuromuscular diseases with pharyngeal involvement (e.g. stroke, myotonic dystrophy, motor neurone disease)

Rare causes

Rare causes of OSA are:

- mucopolysaccharidoses
- acromegaly
- Marfan syndrome

Typical symptoms of the disease, and less common symptoms

The main symptom of OSA is excessive daytime somnolence, and this correlates broadly with the degree of sleep disruption. Initially, while occupied, there is little difficulty in concentrating and staying awake but, once activities become more boring, unwanted sleepiness intervenes. Driving, especially on motorways, is a particular problem, and accidents are more common in patients with OSA.

Common symptoms of OSA are:

- excessive sleepiness, as determined by the Epworth Sleepiness Score (>9 is abnormal; >15 is severely abnormal)
- loud snoring, witnessed apnoeas, and choking noises
- feeling unrefreshed on waking
- poor concentration
- mood swings, personality changes, or depression
- nocturia

Less common symptoms of OSA are:

- nocturnal sweating
- reduced libido
- oesophageal reflux

Demographics of the disease

OSA affects mainly men with upper body obesity, but the male preponderance is reduced once women have undergone menopause, as postmenopausal women have a threefold increased risk of developing OSA, compared to premenopausal women. The incidence of OSA is estimated to be 1%–2% of middle-aged men, but OSA may be much under-diagnosed, and its incidence has been estimated to be as much as 4% in some studies. Ethnicity also affects the risk of OSA; this is usually due to face shape and mandibular size, so non-obese Asians have a higher prevalence of OSA than Caucasians of similar weight. OSA prevalence generally increases with age, with a 2–3 times greater prevalence in those >65 compared to those aged 30–64.

Natural history, and complications of the disease

Most patients attending a sleep clinic have had symptoms of OSA for many years. It is usually some specific event that prompts initial consultation, such as falling asleep while driving or during a meeting. There will be a long history of gradually worsening snoring with apnoeas, possibly witnessed by the spouse. There is often weight gain over the previous few years, with a BMI >30 kg/m² and a collar size of 17 inches or more (see 'Approach to diagnosing the disease').

Complications from the syndrome are usually due to daytime somnolence and relate to sleep deprivation so that there is poor concentration, forgetfulness, depression, mood swings, and often marital and work problems related to these symptoms. There are also complications due to recurrent arousals and consequent blood pressure rises which can last into the waking hours, leading to hypertension which reduces with continuous positive airways pressure (CPAP) treatment. There may also be an increased incidence of atrial fibrillation and failure of cardioversion in OSA patients, possibly due to increased heart rate and sympathetic activation with OSA.

Approach to diagnosing the disease

In addition to finding apnoeic events on a sleep study, it is important to try to assess the degree of somnolence and how this is impacting on the patient's life. This can be done using the Epworth Sleepiness Score. However, this score should not necessarily be taken at face value: patients may under-report their level of sleepiness, due to concerns regarding driving, or over-report it to 'get something done'. It is also important to differentiate 'sleepiness' from 'tiredness', which has many other causes which are not necessarily related to sleep problems, as these terms are often interchanged by patients.

Examination findings are mostly non-contributory but the following may be helpful:

- neck circumference: collar size >17 inches
- oropharynx: large tonsils and boggy mucosa
- teeth: crowding suggests that the mandible is small
- nasal patency: snoring may be reduced, and CPAP therapy facilitated by improved patency
- respiratory function: signs of cor pulmonale, FEV₁/FVC ratio, oxygen saturation (SaO₂)
- blood pressure: may influence decision to treat with CPAP
- endocrine abnormalities (e.g. acromegaly, hypothyroidism)
- neuromuscular disorders (e.g. recent stroke; motor neuron disease)
- heart failure: can lead to Cheyne–Stokes breathing, or central apnoeas

Other diagnoses that should be considered

OSA should be relatively easy to diagnose in the presence of a patient who snores, has witnessed apnoeas, is sleepy, and has a compatible abnormal sleep study. However, the following alternative diagnoses should also be considered:

- depression: this is often missed and is a cause of daytime somnolence
- periodic leg movements during sleep: this can lead to multiple arousals and daytime somnolence; it is associated with restless legs syndrome during the day
- narcolepsy: excessive daytime somnolence, vivid dreams, and cataplexy should alert one to this diagnosis and lead to a referral to a specialist
- multisystem atrophy: this can present with ‘snoring’ which is actually due to laryngeal abductor weakness and laryngeal closure during sleep, with stridulous inspiratory obstruction; patients with multisystem atrophy can suddenly die from nocturnal respiratory arrest but can be successfully treated with standard CPAP therapy.
- previous head injury; a head injury can lead to hypothalamic damage and excessive sleepiness
- central sleep apnoea: there may be a few obstructed breaths at the end of the apnoea cycle secondary to the central apnoea
- overlap syndromes: OSA may coexist with COPD or obesity hypoventilation syndrome leading to ventilatory failure

‘Gold-standard’ diagnostic test

The supposed gold-standard test for OSA is polysomnography, which involves EEG monitoring and multiple ‘sleep’ channels. This test is not necessary for diagnosing OSA in most cases, but is still used in many sleep centres.

Acceptable diagnostic alternatives to the gold standard

A limited sleep study, with other channels such as snoring, body movement, heart rate, oronasal flow, and chest wall movements, is the usual routine investigation. Oximetry alone can be used, and is often adequate to make a diagnosis, especially in severe cases,

but does have limitations, namely poorly differentiating between Cheyne–Stokes/periodic breathing and OSA. Also, nocturnal hypoventilation in COPD can sometimes look similar to OSA on oximetry alone. Desaturation in COPD will be worse at night, because reduced activity in the intercostal muscles leads to significant desaturation on oximetry. There will be periods of desaturation (especially during REM), interpreted by the computer as ‘dips’. If there is a suggestion of an overlap, then limited sleep studies rather than simple oximetry may be needed.

The sleep study report will give information regarding overnight arterial SaO₂, the apnoea hypopnoea index (AHI; the number of such events per hour of sleep), the oxygen desaturation index (ODI; the number of >4% dips in SaO₂ per hour), body movements, pulse, and blood pressure. Generally, the higher the AHI or ODI, the more severe the OSA, but other factors such as daytime symptoms will determine whether treatment is necessary.

Other relevant investigations

Other relevant investigations include:

- blood gas estimation, if respiratory failure is suspected
- thyroid function
- routine haematology and biochemistry
- cholesterol, fasting triglycerides, and glucose, due to the high vascular risk in this population

Prognosis and how to estimate it

OSA patients, once treated, have a normal life expectancy. However, there is evidence from longitudinal studies that untreated OSA patients have reduced life expectancy, due to cardiovascular disease, although it is not clear whether this is an independent effect of OSA or due to obesity-related morbidity.

Treatment and its effectiveness

The most effective treatment for OSA is CPAP, in which pressurized air is blown from a pump, via a mask, into the pharynx to hold it open like a ‘pneumatic splint’. There are now numerous types of mask available and the comfort and acceptability of this treatment has increased greatly over recent years. Patients are usually offered a CPAP trial if they have evidence of significant OSA on a sleep study and have daytime symptoms. The patient’s health and general well-being is usually helped enormously with CPAP treatment. Patients often describe the abolition of sleepiness together with improvements in mood, concentration levels, and memory, once the effects of the sleep deprivation have been removed. The effects of treatment are mainly within the first few days or weeks, although there is a more gradual improvement in some patients over a few months.

137 Bronchiectasis

Andrew M. Jones and Rowland J. Bright-Thomas

Definition of the disease

Bronchiectasis may be defined clinically as the chronic daily production of copious mucopurulent sputum. Pathologically, the disease is characterized by inflamed, thick-walled, dilated bronchi.

Aetiology of the disease

Bronchiectasis has many potential underlying causes and associations with other diseases but, in individual cases, the underlying cause is often unknown.

Possible causes of bronchiectasis include the following:

- infection (e.g. following an episode of severe pneumonia, whooping cough, measles, tuberculosis, or opportunistic mycobacterial infection)
- allergic bronchopulmonary aspergillosis; this leads to a proximal bronchiectasis often with an upper lobe distribution; patients usually have a history of asthma, total serum IgE >1000; raised IgG or IgE to aspergillus; positive skin prick tests; peripheral eosinophilia; and pulmonary infiltrates
- immune deficiencies:
 - congenital (e.g. common variable immunodeficiency)
 - acquired (e.g. due to haematological malignancies, chemotherapy, HIV)
- ciliary disorders:
 - primary ciliary dyskinesia: features include autosomal recessive inheritance; childhood onset of symptoms; otitis media, often leading to hearing loss; sinusitis; middle lobe disease; subfertility; and dextrocardia (Kartagener's syndrome, which occurs in less than 50% of patients with primary ciliary dyskinesia)
 - Young's syndrome: azoospermia, sinusitis, and bronchiectasis
- cystic fibrosis: features include autosomal recessive inheritance, upper lobe distribution, steatorrhoea and malabsorption, male infertility, and *Staphylococcus aureus* and/or *Pseudomonas aeruginosa* as pathogens
- chronic asthma
- aspiration and inhalation injury (e.g. chronic gastric aspiration)
- bronchial obstruction (e.g. tumour or foreign body)
- structural large-airway defects:
 - oesophageal-bronchial fistula
 - Mounier-Kuhn syndrome (tracheobronchomegaly)
 - Williams-Campbell syndrome (cartilage deficiency)
 - tracheomalacia
 - connective tissue disorders (e.g. Marfan syndrome, Ehlers-Danlos syndrome)

Conditions associated with bronchiectasis include:

- inflammatory bowel disease (particularly ulcerative colitis)
- rheumatoid arthritis and other autoimmune arthropathies, including SLE, Sjögren's syndrome, and ankylosing spondylitis
- alpha-1-antitrypsin deficiency
- sickle cell disease
- sarcoidosis
- yellow nail syndrome (comprising bronchiectasis, yellow nails, lymphoedema, and pleural effusions)

Typical symptoms of the disease, and less common symptoms

The typical symptom is cough with sputum. Other common symptoms may include shortness of breath, chest pain, recurrent

haemoptysis, malaise, and fatigue. Patients often report a past history of frequent chest infections and may have coexistent symptoms of rhinosinusitis.

Demographics of bronchiectasis

The prevalence of bronchiectasis increases with age. The true prevalence of bronchiectasis remains unclear. It was previously considered to be a relatively rare condition but, with improved diagnostic techniques, it is now known to be much more common than previously thought.

Natural history, and complications of the disease

Bronchiectasis is a chronic condition. Systemic complications are common and include tiredness, malaise, and weight loss. Urinary incontinence is frequently encountered. A common respiratory complication is episodic small-volume haemoptysis. This can usually be managed conservatively with antibiotics and tranexamic acid. Massive haemoptysis is relatively rare, but may be life-threatening and can require urgent bronchial arterial angiography and embolization of the bleeding vessels. Other respiratory complications include pneumothorax and respiratory failure.

Approach to diagnosing the disease (including diagnostic pitfalls)

The diagnosis of bronchiectasis rests upon the clinical history and radiological imaging. Although examination findings may include lung crackles and/or wheeze, it should be noted that clinical signs are often absent. Nail clubbing is present in only a small minority of patients.

Clues to underlying causes for bronchiectasis include:

- a family history of bronchiectasis: consider inherited immune deficiencies, cystic fibrosis, and primary ciliary dyskinesia
- male infertility or subfertility: consider cystic fibrosis, Young's syndrome, and primary ciliary dyskinesia
- upper lobe distribution of disease: consider cystic fibrosis, post-tuberculous bronchiectasis, and allergic bronchopulmonary aspergillosis
- middle lobe distribution of disease: consider primary ciliary dyskinesia and *Mycobacterium avium intracellulare* infection
- malabsorption: consider cystic fibrosis and ulcerative colitis
- *Staphylococcus aureus* or *Pseudomonas aeruginosa* infection: consider cystic fibrosis
- chronic otitis media/hearing problems: consider primary ciliary dyskinesia
- dextrocardia: consider primary ciliary dyskinesia (Kartagener syndrome)
- musculoskeletal problems: consider rheumatoid arthritis, SLE, Sjögren's syndrome, ankylosing spondylitis, and Marfan syndrome

Other diagnoses that should be considered

Other common differential diagnoses include:

- COPD
- asthma
- pulmonary tuberculosis

- lung abscess
- lung cancer
- gastro-oesophageal reflux disease

For patients with obstructive airways disease, the presence of any of the following symptoms should raise the clinical suspicion that bronchiectasis may be the underlying disease:

- chronic purulent sputum production
- bacterial pathogens regularly cultured from sputum (especially if *Pseudomonas aeruginosa*)
- recurrent unexplained haemoptyses
- absence of smoking history
- young age at onset

'Gold-standard' diagnostic test

The gold-standard diagnostic test is a high-resolution CT (HRCT) scan of the chest. Criteria for a radiological diagnosis of bronchiectasis include bronchial dilation with an internal bronchial diameter greater than that of the adjacent artery, bronchi with mucus plugging, non-tapering bronchi, and bronchi visible within 1 cm of the non-mediastinal pleural surface.

Acceptable alternatives to the gold standard

Some patients may be diagnosed on the basis of the clinical history if the chest X-ray has typical features of the condition. However, it should be noted that the chest X-ray can appear normal, particularly in mild cases.

Other relevant investigations

Sputum should be sent for microbiological culture, including mycobacterial culture, to establish the infecting organism and guide choice of antibiotic therapy. Importantly, it should be noted that failure to culture a pathogen from a sputum sample neither excludes current infection nor contraindicates antibiotic therapy. For patients with symptoms of acute infection, antibiotic treatment should not be delayed; empirical antibiotic therapy can be commenced while awaiting the results of microbiological culture. Spirometry should be measured for all patients to establish if there is an obstructive pattern and the level of impairment. Oxygen saturations and/or arterial blood gas analysis should be recorded.

Tests for underlying causes should include:

- a full blood count
- immunoglobulin (IgG, IgA, and IgM) levels (note that IgG subclasses are often technically difficult to measure and so are not currently recommended)
- functional antibody levels to tetanus toxoid, pneumococcus, and *Haemophilus influenzae*
- total IgE level and specific IgE and IgG precipitins levels to aspergillus
- HIV test
- rheumatoid factor

Patients with abnormalities of immunoglobulin and/or functional antibody levels, or with a clinical suspicion of underlying immune abnormality, should be referred to an immunologist for more detailed immune-function testing.

Other investigations, as directed by clinical indication, include:

- bronchoscopy (not a standard investigation for bronchiectasis but should be considered for those patients with localized disease)
- cystic fibrosis; a sweat test and genotype screening can be performed; cases where clinical suspicion persists despite negative test results should be referred for an opinion to a specialist cystic fibrosis centre
- ciliary function testing; saccharin tests and nasal nitrogen oxide levels can be used as screening tests where available;

suspected cases should be referred to a specialist ciliary function testing centre

- alpha-1-antitrypsin level (if the patient has features of basal emphysema)

Prognosis and how to estimate it

The prognosis is generally good for the majority of patients, who will have an almost normal life expectancy despite significant morbidity. However, some patients do have progressive deterioration of their lung disease, with eventual risk of respiratory failure and death.

Treatment and its effectiveness

Treatment should be tailored to the individual patient. The aim of therapy should be to control symptoms and prevent complications and disease progression, while minimizing the treatment burden. Patient education should be an integral part of the treatment regimen.

The underlying cause or associated condition should be identified and treated as appropriate. Patients with cystic fibrosis should be under the care of a specialist cystic fibrosis centre. Patients with allergic bronchopulmonary aspergillosis can be treated using a combination of oral prednisolone and/or azole therapy.

Acute infective exacerbations should be treated with antibiotics, usually with at least 2 weeks duration of therapy. The choice of antibiotic should be guided, where possible, by the known pathogen harboured by the individual patient. If this information is not available, empirical antibiotic treatment should be started.

Chronic maintenance therapy involves a combination of regular toilet of the airways and drug therapy. Patients should be assessed by a physiotherapist experienced in the management of patients with chronic lung disease. In addition to physical therapy, pharmacological therapies such as hyperosmolar agents (e.g. nebulized hypertonic (7%) saline), mucolytics (e.g. N-acetylcysteine) and inhaled and nebulized bronchodilators can be used to enhance mucociliary clearance and help ease symptoms of breathlessness. The role of inhaled corticosteroids in bronchiectasis is unresolved, while use of daily, long-term oral corticosteroids should be avoided. Studies are emerging to support chronic maintenance antibiotic therapy using oral and/or inhaled antibiotics, particularly for patients who require frequent oral antibiotic courses or hospital admissions.

Other preventative measures to reduce the frequency and severity of exacerbations include smoking cessation, and influenza and pneumococcal vaccination. Regular cardiovascular exercise should be encouraged. Pulmonary rehabilitation is likely to be beneficial. Surgery is rarely indicated, and only in very localized disease which does not respond to medical management.

Supportive measures for those patients with more advanced disease may include supplemental oxygen and/or non-invasive mechanical ventilation. Lung transplantation is a viable option for some younger patients with end-stage lung disease.

138 Sarcoidosis and other granulomatous lung disease

Anjali Crawshaw

Definition of the disease

Sarcoidosis is a multisystem disorder characterized by the formation of non-caseating granulomas in many tissues. A granuloma is an organized aggregate of immune cells; it forms in response to an antigenic stimulus. It contains abnormal macrophages (epithelioid histiocytes, which fuse to form multinucleated giant cells), lymphocytes, neutrophils, eosinophils, fibroblasts, and collagen.

Aetiology of the disease

The aetiology of sarcoidosis is unknown, although it is widely believed that the disease occurs following a non-specific trigger in a genetically susceptible host. It is likely that both environmental and genetic factors contribute. The assumption that there is an important genetic component is based on the observations that (i) the prevalence and incidence of sarcoidosis differ between ethnic groups and (ii) the disease tends to cluster in families.

Typical symptoms of the disease, and less common symptoms

The clinical manifestations of sarcoidosis are heterogeneous and overlap with many other multisystem disorders. Pulmonary, cutaneous, and ocular manifestations are most common, but almost any tissue

can be affected; cardiac, neurological, gastrointestinal, and renal involvement are important (see Table 138.1).

Demographics of the disease

Sarcoidosis can present at any age, although there is a bimodal distribution, with the highest incidence at 20–39 years and a second peak (predominantly in women) at 65–69 years. There is geographic variation in the incidence of sarcoidosis. The highest incidence is observed in northern European countries (5–40 cases per 100 000 people).

Natural history, and complications of the disease

At presentation to secondary care with sarcoidosis, it is difficult to predict the clinical course and outcome. A third will resolve spontaneously or with minimal treatment, a third will develop relapsing remitting disease which may intermittently require treatment, and the remainder (up to 40%) may develop progressive pulmonary fibrosis, pulmonary hypertension, and respiratory failure. Cardiac involvement must be actively considered and excluded where relevant; sudden cardiac death and progressive right or left ventricular failure are significant contributors to the overall mortality rate of 1%–5%.

Patients presenting with the combination of erythema nodosum, bilateral hilar lymphadenopathy, and arthritis (Löfgren syndrome) have a good prognosis, with resolution of chest radiograph findings in 64% and clinical remission in 84% at 2 years. The remainder develop chronic sarcoidosis.

Overall, approximately two-thirds of patients with sarcoidosis have improved or have stable clinical features, spirometry, and radiographic changes at the 2-year follow-up. African-Caribbean patients have a worse prognosis than Caucasians presenting with disease of the same stage, as do those from families with lower annual income.

Approach to diagnosing the disease

The diagnosis of sarcoidosis is made on the basis of clinical and radiological findings of granulomatous disease in multiple organs with supporting histology. The findings on chest radiography have been

Table 138.1 Symptoms in sarcoidosis

System	Symptoms	Frequency
Pulmonary	Dyspnoea, non-productive cough, chest discomfort	90%, presenting complaint in 20%–50%
Ocular	Painful red eye, floaters, blurred vision, photophobia	25%–80% Anterior uveitis, posterior uveitis (65% and 30%, respectively, of those with ocular involvement)
Constitutional	Fever, lethargy, malaise	20%–50%
Lymphatic	Palpable, non-tender lymphadenopathy	35%
Cutaneous	Erythema nodosum Lupus pernio, hypo-/hyperpigmented areas, macules, papules, and plaques, occurring either in crops or isolation, usually less than 2 cm in diameter	10% 25%–35%
Renal	Hypercalciuria, hypercalcaemia, renal calculi	Hypercalciuria 40% Hypercalcaemia 11% Renal calculi 10%
Cardiac	Palpitations, syncope	5%–25%
Neurological	Cranial nerve palsies, headache, cognitive dysfunction weakness, seizures	10%–25%
Hepatic	Usually silent, cholestatic liver function tests	10%

Box 138.1 Chest X-ray findings and stage of sarcoidosis

- **stage 0:** normal chest radiograph
 - 5–10% of patients at presentation
- **stage I:** hilar or mediastinal nodal enlargement only
 - 45–65% of patients at presentation
 - 60% go onto complete resolution
- **stage II:** nodal enlargement and parenchymal disease
 - 25–30% of patients at presentation
- **stage III:** parenchymal disease only
 - 15% of patients at presentation
- **stage IV:** end-stage lung (pulmonary fibrosis)

Table 138.2 Granulomatous disorders

Infections	Non-infectious diseases
Mycobacteria (<i>Mycobacterium tuberculosis</i> , non-tuberculous mycobacteria)	Sarcoidosis
Fungi (<i>Histoplasma</i> , <i>Cryptococcus</i> , <i>Coccidioides</i> , <i>Pneumocystis</i> , <i>Aspergillus</i>)	Berylliosis
	Hypersensitivity pneumonitis
	Lymphoid interstitial pneumonia
	Vasculitis (Wegener's, Churg–Strauss)
	Aspiration pneumonia
	Rheumatoid
	Crohn's disease
	Chronic granulomatous disease

historically used to classify the stage of sarcoidosis (see Box 138.1). The increased availability of CT imaging has all but superseded the plain film and gives a better indication of disease-activity level, which can be used to guide treatment. CT is not always required for diagnosis, for example in typical Löfgren syndrome (acute sarcoidosis with erythema nodosum, bilateral hilar lymphadenopathy, migratory polyarthralgia and fever). However, it is important in excluding other causes of granulomatous adenitis. The CT imaging should preferably be reported by a radiologist with a special interest in interstitial lung disease.

In cases where there is no apparent pulmonary involvement, there have been reports that ¹⁸F-DG PET scanning may prove useful in identifying biopsy sites, although the sensitivity and specificity of this technique remains uncertain. Cardiac and neurological involvement may be better detected with ¹⁸F-DG PET, and MRI with gadolinium.

A biopsy should be obtained from the most accessible site (often the skin) and must demonstrate non-caseating granulomas without evidence of infective organisms or another focus for granuloma formation. In patients who present with Löfgren syndrome, a clinical diagnosis is usually sufficient and a biopsy may not be required. Transbronchial biopsy has a diagnostic yield of 40%–90%. The yield can be increased by performing endobronchial biopsy in conjunction with transbronchial biopsy, giving a rate closer to 90%. The yield can be increased yet further if endobronchial ultrasound is used.

Other diagnoses that should be considered

Lymphoma and TB are important differential diagnoses and should be actively excluded where there is clinical suspicion (dramatic weight loss, night sweats, significant adenopathy, TB exposure; see Table 138.2).

'Gold-standard' diagnostic test

Sarcoidosis is a diagnosis of exclusion. The histological confirmation of non-caseating granulomas and supportive imaging is considered the gold standard. The gold-standard diagnostic test for sarcoidosis is histological confirmation of non-caseating granulomas.

Acceptable diagnostic alternatives to the gold standard

Acceptable diagnostic alternatives to the gold-standard test for sarcoidosis are clinical history and radiological studies consistent with the diagnosis of sarcoidosis.

Other relevant investigations

Serum angiotensin-converting enzyme is an insensitive test (sensitivity, 57%; specificity, 90%; negative predictive value, 60%; positive predictive value, 90%) and is not useful as a diagnostic or therapeutic guide.

ECG, 24h ambulatory ECG and echocardiography should be performed at presentation to screen for cardiac involvement.

Examination of bronchoalveolar lavage fluid for lymphocytes (specifically the CD4/CD8 ratio) can be used as a complementary diagnostic test. If the fluid contains more than 15% lymphocytes, the sensitivity for diagnosing sarcoidosis approaches 90%; the specificity is low.

Prognosis and how to estimate it

The prognosis of pulmonary sarcoidosis can be estimated from the radiographic stage at presentation. In patients with Stage I (bilateral hilar lymphadenopathy only) or Stage II (hilar adenopathy and pulmonary infiltration) disease at presentation, 60%–80% have complete resolution of radiographic changes at 2 years, with a similar, slightly greater proportion showing clinical resolution. Stage III–IV at outset is associated with a poor prognosis; 38% showed radiographic resolution at 2 years.

Lupus pernio, or sarcoidosis in the mucosa of the upper respiratory tract, is associated with chronic fibrotic disease, and intrathoracic resolution is rare.

Ocular involvement is associated with two distinct clinical courses. Those with acute anterior uveitis appear to respond to steroid therapy and have low rates of relapse. In contrast, those with chronic uveitis with insidious onset respond less well to steroid therapy and may progress to glaucoma or cataract formation.

Pulmonary hypertension in sarcoidosis is associated with poor outcomes. Patients with sarcoidosis and high pulmonary artery pressures should undergo aggressive treatment including early referral for transplant.

Cardiac involvement carries a poor prognosis, with a 5-year survival rate of approximately 40%. The increased mortality is attributable to fatal arrhythmia and left ventricular dysfunction.

Treatment and its effectiveness

Oral and inhaled corticosteroids are widely used in the treatment of sarcoidosis, but their use has remained controversial since the 1960s. There is no consensus on when this therapy should be started, in whom, at what dose, and for how long. Indications for steroid therapy include severe pulmonary symptoms; radiographic evidence of active inflammatory disease; cardiac or neurological disease; hypercalcaemia; and sight-threatening ocular involvement.

A meta-analysis of 13 randomized controlled trials of variable quality is included in the Cochrane database. The analysis included 1066 participants on the equivalent of 4–40 mg of prednisolone. Radiographic improvement was reported at 3–24 months, but the authors highlight that this result should be interpreted with caution: differences in methodology and chest X-ray reporting in the different studies may have impacted the results seen. Despite a lack of evidence for steroid treatment, it is difficult to withhold when inflammatory processes seem to predominate or the patient is deteriorating. Patients with more severe disease are more likely to receive steroid treatment and are more likely to relapse.

Hydroxychloroquine is useful in the treatment of hypercalcaemia and skin lesions, but not in the treatment of pulmonary disease. There is some evidence to support the use of steroid-sparing agents such as azathioprine, methotrexate, and cyclophosphamide, but only limited evidence for newer therapies such as anti-tumour necrosis factor alpha.

139 Interstitial lung disease

Patrick Davey, Sherif Gonem, and David Sprigings

Definition

The interstitial lung diseases (ILDs), also known as the diffuse or diffuse parenchymal lung diseases, represent a broad group of pulmonary disorders which mainly affect the lung parenchyma as opposed to the airways. By convention, infectious and malignant conditions are excluded from this definition. Thus, ILDs comprise a group of conditions characterized by variable degrees of inflammation and fibrosis, centred on the lung interstitium and alveolar airspaces.

Aetiology

ILDs may be brought about by an extraordinary range of extrinsic and intrinsic insults. Extrinsic exposures include inorganic mineral dusts such as asbestos and silica; organic antigens; drugs and toxins; cigarette smoke; and radiation. ILD may also occur in association with a variety of systemic conditions, including connective tissue disorders, pulmonary vasculitis, sarcoidosis, and inflammatory bowel disease. Finally, a large group of ILDs have no identifiable underlying cause.

An etiological classification of ILDs is shown in Table 139.1.

Symptoms

The two main symptoms of ILD are:

Shortness of breath: This is typically exertional and progressive over a period of weeks or months. Less commonly, ILD may have an acute presentation (e.g. acute eosinophilic pneumonia, acute interstitial pneumonia, or lupus pneumonitis). Hypersensitivity pneumonitis may have a relapsing and remitting course due to variable exposure to the causative allergen.

Cough: This is usually dry and non-productive.

Demographics

The epidemiology of ILD varies according to the underlying condition. Among the idiopathic group, the incidence of idiopathic pulmonary fibrosis rises with increasing age, such that most patients present between the ages of 60 and 70, with men affected slightly more commonly than women. The other idiopathic ILDs, namely non-specific interstitial pneumonia (NSIP), acute interstitial pneumonia, and cryptogenic organizing pneumonia, generally have an earlier onset, with an average age of presentation between 50 and 55. The smoking-related ILDs present even earlier, typically between the ages of 20 and 40. Lymphangioleiomyomatosis is unique in that it is confined almost exclusively to premenopausal women.

Natural history, and complications

Among the idiopathic ILDs, idiopathic pulmonary fibrosis (IPF) has the worst prognosis, due to the inexorable nature of the disease. The median survival of this condition is approximately 3 years from diagnosis. The natural history of IPF is of a relentlessly progressive decline in pulmonary function, culminating in hypoxaemic respiratory failure and death. This may be interrupted at any stage by a distinct and catastrophic clinical entity known as 'acute exacerbation of idiopathic pulmonary fibrosis' (AEIPF). AEIPF is characterized by an accelerated decline over a period of weeks with worsening dyspnoea, hypoxaemia, and alveolar infiltrates on chest radiology, in the absence of infection or left ventricular failure. Treatment with pulsed corticosteroids is often attempted but mortality is high. Lung histology during AEIPF shows diffuse alveolar damage, a pattern similar to that seen with adult respiratory distress syndrome and acute interstitial

Table 139.1 The interstitial lung diseases

Aetiology	Examples
Idiopathic	Idiopathic pulmonary fibrosis Non-specific interstitial pneumonia Acute interstitial pneumonia Cryptogenic organizing pneumonia
Smoking	Respiratory bronchiolitis interstitial lung disease Desquamative interstitial pneumonia Langerhans cell histiocytosis
Inhaled mineral dusts	Asbestosis Silicosis Berylliosis Coal-worker's pneumoconiosis
Inhaled organic antigens	Hypersensitivity pneumonitis
Drugs, toxins, and physical insults	Methotrexate Busulfan Bleomycin Amiodarone Nitrofurantoin Paraquat Radiation pneumonitis
Systemic inflammatory diseases	Rheumatoid arthritis SLE Mixed connective tissue disease Systemic sclerosis Polymyositis Dermatomyositis Sjögren syndrome Ankylosing spondylitis Ulcerative colitis Crohn's disease
Pulmonary vasculitis	Granulomatosis with polyangiitis (Wegener's granulomatosis) [‡] Eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome) [‡] Microscopic polyangiitis Anti-glomerular basement membrane disease (Goodpasture's disease) [‡]
Miscellaneous	Sarcoidosis Eosinophilic pneumonia Lymphocytic interstitial pneumonia Obliterative bronchiolitis Lymphangioleiomyomatosis Pulmonary alveolar proteinosis Amyloidosis

[‡] Previous name in brackets.

pneumonia. Most other ILDs tend to follow a more benign course than IPF, with some patients remaining clinically stable for many years, and others displaying a slowly progressive decline.

Approach to diagnosis

Diagnostic efforts should be aimed at identifying the precise type of ILD, as this has important prognostic and therapeutic implications. Alternative diagnoses that may mimic ILD should be excluded.

History

The history should focus initially on the patient's symptoms and their time course. As previously described, slowly progressive exertional dyspnoea and dry cough are typical of ILD. Wheeze suggests an airway component to the disease and may occur with hypersensitivity pneumonitis or eosinophilic granulomatosis with polyangiitis (previously known as Churg–Strauss syndrome). Haemoptysis occurs with pulmonary vasculitis, due to associated alveolar haemorrhage. Systemic features such as fever and weight loss are particularly prominent in cryptogenic organizing pneumonia (COP) and hypersensitivity pneumonitis. Arthritis or arthralgia, skin rashes, dry eyes or mouth, and Raynaud's phenomenon are suggestive of associated connective tissue disease.

A meticulous drug history should be taken, including the use of over-the-counter drugs, alternative remedies, and illicit drugs. Recent exposures to drugs known to cause ILD should be elicited, even if these have now been stopped.

The smoking history is particularly important, since a number of ILDs occur mainly or exclusively in smokers, namely respiratory bronchiolitis interstitial lung disease, desquamative interstitial pneumonia, and Langerhans cell histiocytosis. IPF and NSIP occur more commonly in smokers but are reasonably prevalent in non-smokers, while pulmonary sarcoidosis and hypersensitivity pneumonitis are rare in smokers.

The occupational history should include all jobs that the patient has performed since leaving school, with details of the precise nature of the work carried out. Exposure to asbestos at any time in the past should be specifically sought, including secondary exposure; for instance, the wives of plumbers or shipyard workers may have been exposed through washing their husbands' work clothes. There are myriad organic antigens encountered in the workplace or through recreational activities that may cause hypersensitivity pneumonitis. While many of these exposures can be ruled out by a full occupational history, the following additional factors should be enquired about:

- exposure to birds or other animals
- swimming in an indoor pool or hot tub
- the presence of a humidifier or ventilator system at home or at work
- exposure to damp or mouldy environments
- gardening or DIY

Examination

General examination may reveal tachypnoea and cyanosis in advanced disease. Finger clubbing occurs most commonly in IPF and asbestosis. Evidence of an inflammatory arthritis is suggestive of connective tissue disease, and specific features of systemic sclerosis may be elicited, such as Raynaud's phenomenon, sclerodactyly, microstomia, telangiectasia, and calcinosis. Various skin rashes may be seen, including erythema nodosum (sarcoidosis), a purpuric or petechial rash (systemic vasculitis), or facial erythema in a 'butterfly' distribution (SLE). The hallmark of ILD on physical examination is the presence of fine inspiratory crackles on auscultation of the chest, although these are not present in all cases. Hypersensitivity pneumonitis may also cause characteristic inspiratory squeaks due to small airway inflammation (bronchiolitis).

Investigations

Blood tests

The following blood tests may be performed:

- antinuclear antibody, extractable nuclear antigens, and rheumatoid factor levels should be checked to screen for associated connective tissue disease
- antineutrophil cytoplasmic antibody (ANCA) may be positive in pulmonary vasculitis; in particular, cytoplasmic ANCA (cANCA) is associated with granulomatosis with polyangiitis (previously known as Wegener's granulomatosis), and perinuclear ANCA (pANCA) with eosinophilic granulomatosis with polyangiitis; however, a negative ANCA does not completely rule out vasculitis
- Serum angiotensin-converting enzyme is often raised in sarcoidosis; while it is not sensitive or specific enough to act as a definitive diagnostic test, it is a useful marker of disease activity once the diagnosis has been made

- avian and other precipitins should be checked as appropriate if hypersensitivity pneumonitis is suspected

Pulmonary function tests

ILD typically produces a restrictive pattern on spirometry, with a reduction in both forced vital capacity (FVC) and forced expiratory volume in 1 second (FEV₁), but with a normal or high FEV₁/FVC ratio. Measures of lung volume such as the residual volume and total lung capacity are low, whether measured by helium dilution or whole-body plethysmography. Carbon monoxide transfer factor (TLco) levels are also low, even after correcting for reduced lung volumes.

Chest radiograph

The plain chest radiograph (CXR) may reveal interstitial shadowing with a reticular, nodular or reticulonodular pattern. Single or multiple areas of consolidation are suggestive of pulmonary vasculitis with alveolar haemorrhage, COP, or eosinophilic pneumonia. Bilateral hilar lymphadenopathy occurs commonly with sarcoidosis. In a significant minority of cases, the CXR is normal in patients with ILD.

High-resolution CT

High-resolution CT (HRCT) is an important diagnostic modality in patients with ILD. The extent and distribution of fibrosis, honeycombing, nodular opacities, consolidation, ground-glass opacification, and cyst formation are used to produce a radiological differential diagnosis. It has been shown that, in the presence of typical HRCT appearances consisting of fibrosis and honeycombing with basal and subpleural predominance, and compatible history and examination findings, a diagnosis of IPF can be confidently made. In such cases, lung biopsy is not usually necessary as it is unlikely to alter the final diagnosis. However, many other cases are less clear-cut and thus histological examination of lung tissue is required to make the diagnosis. In particular, the distinction between atypical IPF and NSIP can be difficult to make radiologically.

Bronchoscopy

Bronchoalveolar lavage (BAL) generally has a minor role in the diagnosis of suspected ILD, although it may be helpful in selected cases. IPF is generally associated with BAL neutrophilia, while sarcoidosis and hypersensitivity pneumonitis cause BAL lymphocytosis. Eosinophilic pneumonia results in a high BAL eosinophil count.

Bronchoscopy is most helpful in patients with suspected sarcoidosis, since the disease process often has a bronchocentric distribution. Transbronchial biopsy may reveal characteristic non-caseating granulomas and, in some cases, visible endobronchial nodularity can be visualized and bronchial biopsies taken. Enlarged mediastinal lymph nodes may also be sampled either via blind transbronchial needle aspiration, or with the use of endobronchial ultrasound.

Surgical lung biopsy

Most ILDs cannot be sampled satisfactorily via the transbronchial route and thus surgical lung biopsy is frequently required. This is often performed using video-assisted thoracoscopic surgery. Multiple samples are taken from different segments of the lung, with the sampling sites chosen according to the areas of florid disease activity on HRCT.

Table 139.2 Conditions that may simulate interstitial lung disease

Category	Examples
Malignant	Lymphangitis carcinomatosa Bronchoalveolar cell carcinoma Pulmonary lymphoma
Infectious	Viral pneumonitis Bacterial pneumonia Fungal pneumonia Miliary tuberculosis <i>Pneumocystis jirovecii</i> pneumonia
Miscellaneous	Pulmonary oedema Acute respiratory distress syndrome Aspiration pneumonitis

Other diagnoses that should be considered

A number of conditions can simulate the clinical and radiographic features of ILD and therefore need to be considered in the differential diagnosis. These are listed in Table 139.2.

'Gold-standard' diagnostic test

Surgical lung biopsy is the single investigation with the greatest claim for being the gold-standard test for ILD diagnosis. However, the diagnosis of ILD is often challenging, since many patients present with radiological or histological features that are not completely typical of any one condition. Indeed, studies have shown only moderate inter-observer agreement between expert radiologists and between expert pathologists in cases of ILD. This means that neither a HRCT scan nor a surgical lung biopsy can be considered a true gold-standard diagnostic test.

It is now recognized that diagnostic accuracy is maximized by integrating clinical, radiological, and pathological information, and that this is best achieved through a multidisciplinary meeting (MDM). Thus, the gold standard for the diagnosis of ILD is currently considered to be an MDM consensus of expert clinicians, radiologists, and pathologists, with access to good quality clinical information, an HRCT scan, and a surgical lung biopsy, as well as the results of any of the previously mentioned ancillary tests which may be required.

Acceptable diagnostic alternatives to the gold standard

It is accepted that a surgical lung biopsy is not necessary if a HRCT scan shows the so-called usual interstitial pneumonia pattern, which consists of fibrosis and honeycombing with basal and subpleural predominance. In such cases, IPF can be confidently diagnosed on the basis of the clinical features and HRCT appearances alone. Furthermore, many patients will be too frail or elderly to undergo a surgical lung biopsy and, in other cases, this invasive procedure may be deemed unlikely to alter patient management and thus unnecessary. In such cases, a clinicoradiological diagnosis is an acceptable alternative to surgical lung biopsy.

Other relevant investigations

Other investigations should be focused on diagnosing or excluding the differential diagnoses of ILD (see Table 139.2), as well as assessing disease severity and prognosis. Such investigations include:

- bronchoscopy and washings; these may be indicated to exclude infectious or malignant conditions that can simulate ILD; washings should be sent for microscopy and culture, including staining for acid-fast bacilli and *Pneumocystis jiroveci*, as well as cytology
- HIV testing; this should be considered in high-risk groups, since a number of pulmonary complications of HIV can present as an ILD-like illness; these include *Pneumocystis jiroveci* pneumonia, miliary tuberculosis, cytomegalovirus pneumonitis, NSIP, lymphocytic interstitial pneumonia, and obliterative bronchiolitis
- echocardiography; this may show pulmonary hypertension and right ventricular failure in advanced ILD; referral to a tertiary pulmonary hypertension centre should be considered if patients exhibit pulmonary hypertension that is out of proportion to the severity of lung disease, and certainly in the case of pulmonary hypertension associated with a connective tissue disease such as systemic sclerosis

Prognosis and how to estimate it

The prognosis of the idiopathic ILDs varies according to the histological diagnosis. Patients with IPF have the worst prognosis, with a median survival of approximately 3 years from diagnosis. Prognosis is better in patients with NSIP, particularly those with the cellular rather than the fibrotic subtype. NSIP is characterized by more inflammation and less fibrosis than IPF, and is thus more responsive to corticosteroids and other immunosuppressive therapy. COP responds

extremely well to corticosteroids and treated cases have an excellent prognosis. Secondary ILDs have a varied prognosis according to whether the underlying cause can be identified and removed or treated. The best physiological parameter for predicting survival in patients with ILD is the percentage drop in FVC over a 6-month period, with a greater-than-10% drop indicating a poor prognosis.

Treatment and its effectiveness

General measures

The management of ILD may be divided into general supportive measures and specific treatments. General supportive measures include the appropriate provision of oxygen, pulmonary rehabilitation, and palliative care, including the use of opiates for distressing symptoms of shortness of breath.

Environmental exposures that may be contributing to the disease should be eliminated. Most notably, strenuous efforts must be made to achieve smoking cessation through a combination of specialist counselling and pharmacological therapy. In some conditions, namely respiratory bronchiolitis interstitial lung disease, desquamative interstitial pneumonia, and Langerhans cell histiocytosis, smoking cessation may alone result in resolution of the disease process. Drugs that may cause ILD, such as nitrofurantoin, should be withdrawn if possible. In proven hypersensitivity pneumonitis, patients should be strongly encouraged to cease any exposure to the causative antigen, although there is often strong resistance to giving up a much loved hobby or activity, such as keeping pigeons.

Corticosteroids and other immunosuppressants

The response of ILD to corticosteroids and other immunosuppressive treatment depends on whether the underlying pathology is mainly inflammatory or fibrotic. Inflammatory conditions such as COP respond extremely well to steroids, while fibrotic conditions such as IPF respond poorly. Table 139.3 shows examples of ILDs and their responsiveness to steroids.

When corticosteroids are used, they are usually started at moderate or high doses (e.g. prednisolone 30–40 mg daily) and, after an initial treatment period, slowly tapered down over a period of months. In some cases, relapse can occur after withdrawal of treatment, necessitating temporary reintroduction. High-dose steroids (more than 10 mg prednisolone per day) should be avoided in ILD associated with systemic sclerosis, due to the risk of scleroderma renal crisis. The addition of other immunosuppressive agents such as cyclophosphamide or azathioprine to corticosteroid therapy is essential in systemic vasculitis and is often required in connective tissue disease-related ILD.

Treatment of IPF

The treatment of IPF has previously been problematic due to the lack of effective disease-modifying therapies. IPF is predominantly a fibrotic condition and conventional anti-inflammatory treatments do not appear to affect its course. Thus, steroid monotherapy is not recommended in current guidelines.

Table 139.3 Steroid-responsiveness amongst the interstitial lung diseases

Good or moderate response to corticosteroids	Poor response to corticosteroids
Cryptogenic organizing pneumonia	Idiopathic pulmonary fibrosis
Cellular non-specific interstitial pneumonia	Fibrotic non-specific interstitial pneumonia
Hypersensitivity pneumonitis	Langerhans cell histiocytosis
Amiodarone-induced pneumonitis	Asbestosis
Methotrexate-induced pneumonitis	Coal worker's pneumoconiosis
Connective tissue disease-related interstitial lung disease	Lymphangioleiomyomatosis
Sarcoidosis	
Eosinophilic pneumonia	

A recent randomized controlled trial showed that the combination of acetylcysteine, azathioprine, and prednisolone actually increased mortality compared to placebo. However, there are now two new therapies available that appear to slow the progression of IPF, namely pirfenidone and nintedanib.

Lung transplantation is the only treatment that has been shown to improve survival in patients with IPF. Current British Thoracic Society guidelines suggest that patients should be referred for transplantation if the disease is severe (TLCO less than 40% predicted) or rapidly progressive (greater than 10% decline in FVC over 6 months). However, patients with significant comorbidities or of age greater than 65 are generally excluded. Similar referral criteria are used for other ILDs, such as fibrotic NSIP and sarcoidosis.

Treatment of acute ILD

The management of acute or rapidly progressive ILD is challenging due to a combination of diagnostic uncertainty and the urgency of initiating definitive treatment. Acute ILD may occur on a background of established ILD, the most common scenario, or de novo.

It is well recognized that IPF patients who were relatively stable previously may manifest a period of rapid decline over a number of weeks, associated with worsening pulmonary infiltrates and type 1 respiratory failure, the distinctive clinical entity AEIPF. The differential diagnosis in such cases includes infection, pulmonary oedema, and pulmonary embolism. Echocardiography and CT pulmonary angiography may be obtained to rule out left ventricular dysfunction and pulmonary embolism, respectively. Empirical antibiotics are often provided, although obtaining a specific microbiological diagnosis is difficult since most patients are too hypoxic to tolerate a bronchoscopy and lavage. Pulsed high-dose IV methylprednisolone may be attempted if infection is thought to be unlikely, although this is supported only by anecdotal evidence. A more pragmatic approach is to prescribe moderate doses of corticosteroids, for example, oral prednisolone 30 mg daily. The mortality of AEIPF is high, and invasive ventilation is almost always inappropriate. It is important to effectively communicate the prognosis to patients and their families, and to switch the focus of care to palliative when appropriate.

Genuine de novo presentations of acute ILD are uncommon. In many cases, a careful history and inspection of old chest radiographs reveals evidence of previously unrecognized chronic ILD. In patients

with apparent de novo ILD, a more aggressive approach to diagnosis and treatment is warranted. The ILDs most likely to present in this way are acute interstitial pneumonia, fulminant COP, drug-induced pneumonitis, acute eosinophilic pneumonia, and pulmonary vasculitis. Patients often require admission to the intensive care unit for invasive ventilation. It is vital that any possible drug precipitants are withdrawn unless they are absolutely necessary. Infection should be diagnosed or excluded using BAL, often in an intubated patient. Transbronchial biopsy or surgical lung biopsy should be considered if the results are likely to alter the management sufficiently to justify the risks. In most cases, once infection has been excluded, the mainstay of therapy in acute ILD is high-dose pulsed IV methylprednisolone. The addition of IV cyclophosphamide is occasionally required.

Treatment of rare ILDs

Two rare ILDs merit special mention since their treatments are unique. Pulmonary alveolar proteinosis is characterized by the progressive accumulation of lipoproteinaceous material within the alveolar spaces. It is treated with bronchoscopic whole-lung lavage under general anaesthetic, with both symptomatic and survival benefits. Both lungs are usually treated a few days apart.

Lymphangioleiomyomatosis occurs almost exclusively in women of child-bearing age and it has thus been hypothesized that oestrogen may play a role in the pathogenesis. Sirolimus has shown some promise as a treatment for this condition. Progressive disease may necessitate lung transplantation.

140 Pulmonary vasculitis

Rajini Sudhir

Definition of the disease

Pulmonary vasculitis comprises a heterogeneous group of disorders characterized by an inflammatory process damaging the vessel wall, leading to ischaemia and tissue necrosis. Granulomatosis with polyangiitis (Wegener's granulomatosis) Churg–Strauss syndrome (eosinophilic granulomatosis with polyangiitis, EGPA), and microscopic polyangiitis are primary, small-vessel, necrotizing vasculitides linked by an overlapping clinicopathological picture and are collectively referred to as ANCA-associated systemic vasculitis (AASV). The European Vasculitis Study Group has proposed a clinical staging system based on disease activity, to guide treatment (see Table 140.1).

Aetiology of the disease

The exact aetiology of pulmonary vasculitis is unclear, although the disease is associated with exposure to silica, quartz, occupational solvents, or livestock. Drugs such as propylthiouracil, carbimazole, allopurinol, and minocycline have been associated with AASV.

Specific disorders

Granulomatosis with polyangiitis

Definition

Granulomatosis with polyangiitis (abbreviated as GPA, and formerly known as Wegener's granulomatosis) is the most common pulmonary vasculitis. It classically involves the upper and lower respiratory tracts and the kidneys.

Aetiology

The aetiology of GPA is unclear, but the disease is characterized by the histopathological finding of small-vessel necrotizing vasculitis and granulomatous inflammation. Patients with type ZZ alpha-1 antitrypsin deficiency are at a 100-fold increased risk of GPA. *Staphylococcus aureus* nasal carriage is very common with GPA.

Typical symptoms, and less common symptoms

Upper respiratory symptoms

The upper respiratory features of GPA are ENT involvement in 70%–90% of patients, hearing loss in 15%–20%, and nasopharyngeal involvement in 60%, with the latter characterized by nasal crusting, pain, mucosal ulcers, and epistaxis. Septal perforation and saddle nose deformity occur in up to 25% of patients with GPA.

Lower respiratory symptoms

Lower respiratory symptoms of GPA include wheeze, dyspnoea, and stridor. Tracheal stenosis is associated with flattening of both limbs of the flow–volume loop. Subglottic stenosis invariably occurs with

nasopharyngeal disease. Lung parenchymal involvement presents as dyspnoea, cough, and haemoptysis with diffuse alveolar haemorrhage (DAH). The chest X-ray is abnormal in up to 70% of patients, showing nodules, cavitation, consolidation, infiltrates, or intra-thoracic lymphadenopathy.

Renal features

Renal features of GPA include glomerulonephritis with hypertension, acute renal failure with casts and proteinuria, and chronic renal impairment.

Optical features

Optical features of GPA include scleritis, episcleritis, and proptosis.

CNS-related features

CNS-related features of GPA include mononeuritis multiplex and cranial nerve palsy.

Demographics

The peak age of onset of GPA is 30–50 years. By the late 1990s, the incidence was around 10.3 per million. The disease is commoner in Northern Europe than elsewhere, with an increased incidence in winter months.

Natural history, and complications

The clinical spectrum of GPA ranges from an asymptomatic form to fulminant respiratory failure with DAH, the latter with a mortality of up to 50%. Subglottic stenosis can cause life-threatening airway compromise. Glomerulonephritis is the most worrying feature, and progressive renal failure can occur in the absence of any other features, needing aggressive immunosuppressive therapy. Even patients with limited GPA and no renal disease can have severe diffuse alveolar haemorrhage or neurological involvement. Consequently, the term 'limited GPA' is defined as necrotizing granulomatous inflammation with (a) no vasculitis component and (b) no disease manifestation that puts the affected organ at risk of irreversible damage. Complications occur in the form of relapse, infections, or drug toxicity and need close monitoring.

Approach to diagnosis

The approach to diagnosing GPA involves identification of the clinical features listed in 'Typical symptoms, and less common symptoms', and exclusion of the differentials listed in 'Other diagnoses that should be considered'.

Other diagnoses that should be considered

The differential diagnosis for granulomatous inflammation is mainly fungal or mycobacterial infection. Ophthalmological features may suggest sarcoidosis. Destructive nasopharyngeal disease should be

Table 140.1 The European Vasculitis Study Group clinical staging system

Class	Localized	Early systemic	Generalized systemic	Severe	Refractory
Constitutional	–	+	+	+	Any
Renal dysfunction	–	–	+	++	Any
Threatened vital organ function	–	–	–	++	+
Induction	Single agent CS, AZA, MTX	CYC/MTX + CS	CYC + CS	CYC + CS + PEX	Investigational drugs

Abbreviations: AZA, azathioprine; CS, corticosteroid; CYC, cyclophosphamide; MTX, methotrexate; PEX, plasma exchange.

Rasmussen N, Jayne DRW, Abraowicz D, et al. European therapeutic trials in ANCA-associated systemic vasculitis: disease scoring, consensus regimes and proposed clinical trials. European Community Study Group on Clinical Trials in Systemic Vasculitis ECSYSVASTRAL. Clin Exp Immunol. 1995;101(Suppl 1):29–34.

differentiated from cocaine-related disease or lymphoma. Relapsing polycondritis can cause saddle nose deformity or tracheobronchial involvement but ear involvement is the cardinal feature differentiating relapsing polycondritis from GPA. DAH could also be caused by Goodpasture's disease, rheumatoid vasculitis, or SLE.

'Gold-standard' diagnostic test

cANCA (PR3) positivity is a feature of 75%–90% of patients with GPA. The prevalence of this feature increases to 99% if immunofluorescence is used along with target-antigen-specific methods. This is often combined with biopsy of the affected area, showing necrotizing small-vessel vasculitis.

Acceptable diagnostic alternatives to the gold standard

There are no acceptable diagnostic alternatives to the gold standard for Wegener's granulomatosis. The criteria specified in 'Gold-standard' diagnostic test for granulomatosis with polyangiitis must be used for diagnosis.

Other relevant investigations

Chest X-ray abnormalities occur in around 70% of patients sometime during their disease activity. High-resolution CT thorax shows the extent of bronchial or peribronchial involvement. Flow-volume loops are either obstructive or restrictive, with flattening of limbs in tracheal stenosis. With DAH, there is an increase in the diffusing

Table 140.2 Non-Granulomatosis with polyangiitis (GPA) ANCA-associated systemic vasculitis

	Churg–Strauss syndrome (Eosinophilic granulomatosis with polyangiitis)	Microscopic polyangiitis
Definition	Allergic granulomatous angitis with asthma, small-vessel vasculitis, and hypereosinophilia	Necrotizing small-vessel vasculitis with predominant focal segmental glomerulonephritis
Aetiology	Unclear but similar to GPA	Unclear but similar to GPA
Symptoms	Asthma refractory to most treatments Allergic rhinitis and polyposis Peripheral neuropathy	DAH in 30% Pleurisy, effusion, and lung fibrosis (10%–12%) Focal glomerulonephritis; acute renal failure with casts and proteinuria in around 90% Headache, seizures (cerebral vasculitis) in 30% Abdominal pain, diarrhoea; bowel perforation in 30%–40%
Demographics	40–50 years peak Male = female Commoner in northern Spain	50–55 years peak incidence Male > female Commoner in middle-aged Caucasians
History and complications	First phase with rhinitis and asthma difficult to control, followed by eosinophilia (remitting and relapsing) and then vasculitis Renal involvement is uncommon Main mortality is due to cardiac disease and is a poor prognostic sign	Limited data but upper airway involvement is controversial Occasional acute interstitial pneumonitis or idiopathic pulmonary fibrosis Rapidly progressive glomerulonephritis from renal capillaritis has high mortality Relapses are common
Approach to diagnosis	Asthma with ANCA positivity and high eosinophil count	Renal failure with ANCA positivity
Differential diagnosis	GPA Microscopic polyangiitis Hypereosinophilic syndrome Chronic eosinophilic pneumonia	GPA Polyarteritis nodosa SLE Goodpasture's disease
'Gold-standard' test	Biopsy of peripheral nerve or lung shows eosinophilic exudates, fibrinoid necrosis, and epithelioid/giant cell granuloma	No unique histopathology on biopsy but presence of small-vessel pulmonary or renal capillaritis Pauci-immune glomerulonephritis (minimal or absent immune complex deposit), in contrast to polyarteritis nodosa or Goodpasture's disease
Acceptable alternatives to the gold-standard test; other investigations	PFT ANCA positivity Type of ANCA CXR/HRCT Blood	PFT ANCA positivity Type of ANCA CXR/HRCT Blood
PFT	Obstructive	Obstructive but restrictive with IPF Increased DLCO, with DAH
ANCA positivity	Up to 65%	Up to 90%
Type of ANCA	pANCA (MPO-ANCA)	pANCA (MPO-ANCA)
CXR/HRCT	Transient infiltrates Nodules unusual Ground glass opacities on HRCT	Infiltrates Ground glass opacities on HRCT
Blood	Peripheral eosinophilia	No eosinophilia
Prognosis	Remission in 90%, and relapses in 15%–25% Asthma is often refractory to treatment Mortality is high with cardiac involvement 60%–69% 5-year survival	90% improve, and 75% achieve complete remission; 30% relapse in 1–2 years Mortality high with rapidly progressive renal failure or DAH 45%–53% 5-year survival
Treatment	Glucocorticoids are the mainstay of treatment The role of cytotoxic agents is less well defined, but life-threatening disease is treated with glucocorticoids and cyclophosphamide Recent trials show promising maintenance of remission with IFN-alpha	Treatment similar to that for GPA Single studies are unavailable but mixed studies suggest response to glucocorticoids and cyclophosphamide in renal disease or DAH

Abbreviations: ANCA, antineutrophil cytoplasmic antibody; CXR, chest X-ray; DAH, diffuse alveolar haemorrhage; DLCO, diffusing capacity of the lung for carbon monoxide; GPA, granulomatosis with polyangiitis; HRCT, high-resolution CT; IFN-alpha, interferon alpha; IPF, idiopathic pulmonary fibrosis; MPO, myeloperoxidase; pANCA, perinuclear antineutrophil cytoplasmic antibody; PFT, pulmonary function testing; SLE, systemic lupus erythematosus.

capacity of the lung for carbon monoxide (DLCO). Bronchoscopy shows ulcerative tracheobronchitis, subglottic stenosis, or haemorrhagic fluid on bronchoalveolar lavage. Urine dipsticks for blood and protein, and microscopy for casts, are used to indicate renal disease. MRI brain is a sensitive modality for determining neurological involvement.

Prognosis, and how to estimate it

In GPA, there is 30%–93% remission with treatment, 1-year survival is at 80%–85%, and estimated 5-year survival is at 65%–78%. Clinical symptoms, and findings from chest X-ray, lung function, urine dipsticks, microscopy, and the cANCA test are all essential in estimating and monitoring disease activity, although the cANCA tests needs to be interpreted in conjunction with other indicators of disease activity. In addition, 40%–60% of patients will relapse on treatment.

Treatment, and its effectiveness

In the 1950s, glucocorticoid monotherapy was used in the treatment of GPA, since the 1-year mortality of the untreated disease was around 82%. However, an NIH cohort showed that, with steroids alone, there was no sustained improvement but instead progressive disease, leading to discontinuation of the monotherapy. Remission is induced with cyclophosphamide at 2 mg/kg day⁻¹, and prednisolone at 1 mg/kg day⁻¹, tapered over 6–12 months.

Significant toxicities from steroids include hypertension, diabetes, intercurrent infections, osteoporosis, psychosis, and Addison's disease. Cyclophosphamide toxicity includes myelosuppression (8%), cystitis (12%), infertility, and solid organ malignancies (5%). This can be reduced by intermittent administration of the drug, although relapse rates are higher on this regime.

Methotrexate (20–25 mg/week) is used with prednisolone for remission induction, and azathioprine (1 mg/kg day⁻¹) is useful in remission maintenance. Pneumocystis prophylaxis with co-trimoxazole is indicated in all patients on immunosuppressive therapy since this carries a mortality of around 35%. Co-trimoxazole at dose of 160/800 mg twice a day is useful in eliminating nasal carriage of *Staphylococcus aureus* and thereby reducing relapse of upper airway disease.

In fulminant disease (DAH; respiratory or renal failure), use pulsed methylprednisolone at 1 g/day for 3 days, with cyclophosphamide at 3–4 mg/day for 3 days and then reduced to 2 mg/day. If this doesn't work, use plasma exchange, with 60 mg/kg exchanged with 5% human albumin solution for 2 weeks.

Rituximab (RTX, a monoclonal antibody directed against the CD20 surface antigen of B lymphocytes) can be given if cyclophosphamide is contraindicated, e.g. because of high risk of infection, or to avoid its effect on fertility in a young patient. RTX is combined with glucocorticoid therapy. The licensed RTX dose is 375 mg/m² body surface area/week for 4 weeks; an alternative effective regimen is 1 g repeated after 2 weeks.

Sinus disease is treated with local irrigation, local corticosteroids, and antibiotics. Subglottic stenosis is often treated with tracheostomy or a combination of mechanical dilatation of trachea with intra-tracheal glucocorticoid injection.

In addition to GPA, there are two other types of ANCA-associated systemic vasculitis; their features are described in Table 140.2

Goodpasture's disease

Goodpasture's disease is a rare disorder with an incidence of 1–2/million. It is more common in young cigarette smokers who develop pulmonary haemorrhage; 25%–30% of cases have a viral prodrome. It is characterized by an insidious onset of dry cough, dyspnoea, haemoptysis, oligoanuria, uraemia, and respiratory failure.

It is diagnosed by renal biopsy showing crescentic glomerulonephritis with anti-glomerular basement membrane antibodies on immunofluorescence. The antibodies are directed to the alpha-3 chain of type IV collagen, which is present in the basement membrane. In addition, 32% of patients with Goodpasture's disease are ANCA positive. Treatment is by plasmapheresis, with concomitant use of glucocorticoids with cyclophosphamide, and smoking cessation is advised.

Patients who survive the first year with near-normal renal function do well but relapses occur with ANCA positivity.

Secondary pulmonary vasculitis

Secondary pulmonary vasculitis is usually associated with rheumatoid arthritis or SLE, and is often managed in conjunction with rheumatology. It is an immune-complex-mediated disease, and haemoptysis and pulmonary infiltrates with systemic upset are common clinical features. Alveolar haemorrhage with SLE has a mortality of over 50%. Survivors may progress to lung fibrosis. Synchronized plasmapheresis with pulsed methylprednisolone and IV cyclophosphamide therapy are useful in treatment.

Respiratory involvement in other vasculitides

Twenty-five per cent of patients with giant cell arteritis have pulmonary involvement. Large- and medium-vessel vasculitis with pulmonary hypertension is seen in up to 50% with Takayasu's disease, and 40% with Behçet's syndrome. Necrotizing sarcoid granuloma occurs with bilateral nodules and is treated with glucocorticoids.

141 Lung cancer (including management of an isolated lung lesion)

Raman Verma and Sarah Deacon

Definition of the disease

Lung cancer is the second most common type of cancer in the UK. It is a disease of uncontrolled cell growth in the lung tissue. It is termed 'primary' if it originates in the lungs, and 'secondary' if it manifests elsewhere in the body but then spreads to the lungs.

There are several types of primary lung cancer. The main types are small cell lung carcinoma (SCLC) and non-small cell lung carcinoma (NSCLC). This distinction is important, because the treatment varies.

SCLCs comprise 20% of lung cancers and are the most aggressive and rapidly growing. They are small cells that are mostly filled with the nucleus and contain dense neurosecretory granules, which give this tumour an endocrine/paraneoplastic syndrome association. They are strongly related to smoking, with only 1% of these tumours occurring in non-smokers. SCLCs metastasize rapidly to many sites within the body and are most often discovered after they have spread extensively.

There are three main types of NSCLC:

Squamous cell carcinoma (25%): Squamous cell carcinoma develops in the cells lining the airways. It usually starts near a central bronchus.

A hollow cavity and associated necrosis are commonly found at tumour center.

Adenocarcinoma (40%): Adenocarcinoma develops from cells producing mucus. It usually originates in peripheral lung tissue.

A subtype, bronchioloalveolar carcinoma, is more common in females who have never smoked. It occurs in less than 1 in 20 lung cancers.

Large cell carcinoma: In large cell carcinoma, large, rounded cells are seen under the microscope. This type tends to grow quite quickly.

Other types of lung cancers can arise; for example, bronchial carcinoids account for up to 5% of lung cancer. These are generally small when diagnosed and occur most commonly in people under 40 years of age. Unrelated to cigarette smoking, carcinoid tumours can metastasize and a small proportion of these tumours secrete hormone-like substances which may cause specific symptoms related to the hormone being produced. Carcinoids generally grow and spread more slowly than bronchogenic cancers, and many are detected early enough to be amenable to surgical resection.

Mesothelioma is a rare type of cancer that affects the pleura. It is associated with asbestos exposure. It is very different from lung cancer.

Aetiology of the disease

The most common cause of lung cancer is long-term exposure to tobacco smoke. The occurrence of lung cancer in non-smokers, who account for 10% of cases, is often attributed to a combination of genetic factors, radon gas, asbestos, and air pollution (including secondhand smoke).

Tobacco smoke contains carcinogens. The two primary carcinogenic chemicals are nitrosamines and polycyclic aromatic hydrocarbons. Additionally, nicotine appears to depress the immune response to malignant growth. About nine in ten cases are caused by smoking. Among male smokers, the lifetime risk of developing lung cancer is

17.2%; among female smokers, the risk is 11.6%. After about 15 years of smoking cessation, the risk of developing lung cancer is similar to that of a non-smoker. Those who are regularly exposed to passive smoke have a small increased risk.

A family history of lung cancer in a first-degree relative slightly increases the risk of lung cancer. However, most cases of lung cancer do not run in families.

People who have been in prolonged or close contact with asbestos have a higher risk of lung cancer, especially if they smoke. Asbestos and tobacco smoke act synergistically to increase the risk. Asbestos exposure also increases the risk of mesothelioma.

Radon gas is thought to increase risk in high concentrations. This colourless and odourless gas generated by the breakdown of radioactive radium, which in turn is the decay product of uranium, found in the Earth's crust. The decay products ionize genetic material, causing mutations that sometimes turn cancerous. This is more likely in certain parts of the UK where there is a lot of granite, for example in the West Country and the Peak District.

Typical symptoms of the disease, and less common symptoms

Symptoms that suggest lung cancer include:

- dyspnoea
- haemoptysis
- chronic coughing or change in regular coughing pattern
- wheezing
- chest pain (possible rib erosion)
- cachexia, fatigue, and loss of appetite
- hoarse voice (possible recurrent laryngeal nerve involvement)
- clubbing

If the cancer obstructs airflow, it can lead to secretion accumulation behind the blockage, predisposing the patient to pneumonia. A pleural effusion may accumulate which can cause worsening dyspnoea. Facial oedema may develop if a tumour compresses the superior vena cava. Apical lung cancers (Pancoast tumours) may invade the local part of the sympathetic nervous system, leading to Horner's syndrome as well as muscle weakness in the hands due to invasion of the brachial plexus.

Depending on the type of cancer, so-called paraneoplastic phenomena may initially attract attention to the disease (see Table 141.1).

Table 141.1 Paraneoplastic syndromes associated with cancer type

Cancer type	Paraneoplastic symptom
Squamous	Hypercalcaemia (due to parathyroid-like hormone production)
Adenocarcinoma	Hypertrophic pulmonary osteoarthropathy (joint stiffness, gynecomastia, clubbing) Trousseau syndrome of hypercoagulability
Small cell	Syndrome of inappropriate antidiuretic hormone Cushing's syndrome (ectopic adrenocorticotropic hormone)

Table 141.2 Complications of the metastatic spread of cancer

Site	Symptom
Brain	Confusion, fits, focal neurological deficit, cerebellar syndrome
Bone	Pain, hypercalcaemia, spinal cord compression
Liver	Pain, hepatomegaly, liver failure
Adrenal	Addison's disease

Demographics of the disease

Lung cancer is the most common cancer in the world, with 1.3 million new cases diagnosed every year. It is the UK's biggest cancer killer, claiming nearly 36 000 lives each year. It is responsible for 23% of all male cancer deaths, and 21% of all female cancer deaths. More than eight in ten lung cancer cases occur in people aged 60 and over. Within the UK, there is a clear north/south divide, with high lung cancer incidence rates in Scotland and northern England, and generally lower incidence in Wales, the Midlands, and southern England. Scottish men and women have amongst the highest rates in the world, reflecting the country's history of high smoking prevalence.

Natural history, and complications of the disease

In many patients, the cancer has already spread beyond the original site by the time they have symptoms and seek medical attention. Primary lung cancers mostly metastasize to the contralateral lung, adrenal glands, liver, brain, and bone. About 7%–10% of patients are asymptomatic at diagnosis, and cancers are often found incidentally on routine chest radiographs (CXR); 35% of cases present as an emergency. Complications can arise from locoregional or metastatic spread, paraneoplastic syndromes, or treatment regimes (see Tables 141.2 and 141.3).

Approach to diagnosing the disease

Gathering a history and physical examination will reveal the presence of symptoms or signs that are suspicious for lung cancer. Performing a CXR is the most common first diagnostic step. Thereafter, more sophisticated imaging techniques are used to determine the location and extent of the disease. Histological confirmation and staging is the gold standard to enable treatment planning. Further tests may be required to determine the functional and medical baseline of the patient prior to the initiation of treatment.

Other diagnoses that should be considered

The differential diagnoses for those who present with CXR abnormalities include lung cancer and non-malignant diseases. These include infectious causes such as tuberculosis or pneumonia, and inflammatory conditions such as sarcoidosis. These diseases can result in mediastinal lymphadenopathy or lung nodules and sometimes mimic lung cancers.

Table 141.3 Complications of lung cancer therapy

Therapy	Symptom
Chemotherapy	Febrile neutropenia or bleeding from bone marrow suppression
	Renal failure, ototoxicity, hyponatraemia, hypomagnesaemia from cisplatin nephrotoxicity
	Peripheral neuropathy from cisplatin, paclitaxel, and vinorelbine
Radiotherapy	Lung toxicity Bronchial stenosis
Surgery	Mortality: 6% pneumectomy 3% lobectomy 1% segmentectomy

'Gold-standard' diagnostic test

A number of diagnostic techniques are available for histology and staging:

- thoracentesis (aspiration of a pleural effusion)
- ultrasound-guided fine needle aspiration of enlarged cervical or supraclavicular lymph nodes
- bronchoscopy: examination of the airways may allow diagnostic sampling, including nodes, via transbronchial needle aspiration (TBNA), endobronchial ultrasound, washings, brushings, and direct biopsy
- CT/ultrasound-guided biopsy: 85%–90% sensitivity in lesions >2 cm
- mediastinoscopy: lymph node staging; confirming the presence and location of N2 disease (see Table 141.4) is important for treatment planning

Acceptable diagnostic alternatives to the gold standard

Acceptable diagnostic alternatives to the gold standard are as follows:

- medical thoracoscopy: to determine whether the parietal pleural contains malignant cells
- video-assisted thoracoscopic surgery (VATS): can be used to assess resectability and invasion into mediastinum, and to biopsy the tumour
- FDG-PET scan: while CT and MRI scans look at anatomical structures, PET scans measure metabolic activity and the function of tissues; they can determine whether a tumour tissue is actively growing and can aid in determining the type of cells within a particular tumour; FDG-PET also has a high sensitivity and specificity for metastases

Other relevant investigations

Other relevant investigations include:

- blood tests; these cannot diagnose lung cancer but may reveal the biochemical or metabolic abnormalities that accompany cancer
- spirometry, or pulmonary function tests; for baseline and pre-biopsy/surgery information
- sputum cytology (limited use); reserved for patients who cannot tolerate invasive tests
- MRI (not routinely performed); for assessment of brachial plexus, pericardial involvement, superior sulcus tumours
- bone scans (if metastatic bone disease suspected)

Prognosis and how to estimate it

The most important prognostic indicator is the extent, or stage, of disease. Clinical, laboratory, radiological, and pathological investigations combined aid staging. Severity can be determined using the TNM (for tumour, node, and metastases) staging system. Other major prognostic factors include performance status, serum lactate dehydrogenase, liver function tests, and serum sodium (see Table 141.4).

Staging

Staging (contrast-enhanced) CT scan of the lower neck, thorax and abdomen, including liver and adrenal glands remains the mainstay of radiological clinical staging, providing information about the nature and extent of spread of the tumour, thus guiding therapeutic options and prognosis.

FDG-PET (PET/CT) provides an accurate assessment of mediastinal lymph node involvement, aiding diagnostic sampling and assessment of indeterminate pulmonary nodules and distant metastases (high sensitivity and specificity); in addition, it aids radical radiotherapy planning. Any lymph node greater than 10 mm in diameter is deemed abnormal. If PET/CT of the mediastinum is negative (negative predictive value of 98.4%), biopsy is not required, but a positive study may require tissue sampling (especially N2/3 disease).

Concerning **surgical staging**, mediastinoscopy is recommended for PET-negative nodes measuring over 16 mm. VATS specifically

Table 141.4 International Association for the Study of Lung Cancer International Staging Committee TNM classification of lung cancer (seventh edition; includes non-small cell lung carcinoma, small cell lung carcinoma, and carcinoids)

Stage	Description
T1a	Tumour ≤ 2 cm
T1b	Tumour 2–3 cm
T2	Main bronchus > 2 cm from carina, invades visceral pleura, partial atelectasis
T2a	Tumour 3–5 cm
T2b	Tumour 5–7 cm
T3	Tumour > 7 cm or local invasion, total atelectasis, additional nodule(s) same lobe
T4	Invasion mediastinum, heart, vessels, carina, vertebrae, vocal nerve, oesophagus, or additional nodule(s) different ipsilateral lobe
N0	No lymph node metastasis
N1	Ipsilateral peribronchial, ipsilateral
N2	Ipsilateral mediastinal or subcarinal
N3	Contralateral mediastinal or hilar, scalene or supraclavicular
M1a	Intra-thoracic metastasis: additional nodule(s) contralateral lung; pleura nodules or malignant pleural or pericardial effusion
M1b	Extra-thoracic metastasis: distant metastases

This article was published in *Thorax Oncol*, Volume 2, Goldstraw et al., International Association for the Study of Lung Cancer International Staging Committee, Participating Institutions. The IASLC Lung Cancer Staging Project: proposals for the revision of the TNM stage groupings in the forthcoming (seventh) edition of the TNM Classification of malignant tumours, pp.706-714, Copyright Elsevier (2007).

assesses pleural and chest wall involvement and nodal stations not accessible by standard mediastinoscopy.

For **assessment of distant metastases** (50% NSCLC, 60%–80% SCLC), CT or MRI brain is used (cerebral metastases are common in SCLC/adenocarcinoma and are silent in only 2%–4% of NSCLC). Bone scintigraphy is used if there is bone pain or local tenderness (only 5% of cases are asymptomatic).

SCLC grows rapidly with early dissemination to regional lymph nodes and distant sites. Approximately two-thirds of patients have extensive metastatic disease at presentation, and only chemotherapy is suitable for these patients. SCLC has a worse prognosis and should be staged by a contrast-enhanced staging CT scan. It is staged as limited (LS; confined to a single hemithorax and regional lymph nodes), extensive (ES; metastatic lesions in the contralateral lung, lymph nodes and/or distant organs, or malignant pericardial/pleural effusion), or recurrent disease.

Performance status

Activity level, measured by a performance status (PS) scale, is an important prognostic factor which helps individualize treatment (see Table 141.5).

Treatment and its effectiveness

Treatment decisions depend on the histological cell type (NSCLC or SCLC); tumour stage; size and location (particularly in NSCLC);

Table 141.5 Performance status scale used in guidelines

WHO (Zubrod/ECOG) Scale	
0	Asymptomatic
1	Symptomatic, but ambulatory (able to carry out light work)
2	In bed $< 50\%$ of day (unable to work but able to live at home with some assistance)
3	In bed $> 50\%$ of day (unable to care for self)
4	Bedridden

Abbreviations: ECOG, Eastern Cooperative Oncology Group.

and the patients' general physical condition (performance status). Preoperative assessment of N2 or N3 disease (mediastinal staging) allows appropriate selection for radical treatment. Therapy options (e.g. surgery, chemotherapy, and radiation therapy) should be discussed in a specialist multidisciplinary meeting.

Surgery

Surgical resection is the preferred treatment for early stage (IA, IB, IIA, IIB) NSCLC in patients with adequate lung function ($FEV_1 > 1$ l) and considered in single zone, non-bulky, non-fixed N2 disease (IIIA). Nodal staging determines suitability for curative surgery and indicates a possible role for neoadjuvant or adjuvant chemotherapy and radiation therapy. Advanced or metastatic disease (Stage IIIB or IV, 60%–80% of all patients) is usually unresectable, the main exceptions being the presence of a solitary adrenal or brain metastasis. Surgery should be considered in early stage SCLC, but is an option in $< 5\%$.

Lobectomy is the standard surgical approach. Sleeve lobectomy offers an acceptable alternative for a central tumour, conserving lung function. Sublobar (segmental or wedge) resection is offered in patients with poorer pulmonary reserve. VATS procedures offer lower perioperative morbidity and mortality and less pain and hospitalization. Suitable patients with bronchioloalveolar carcinoma should be offered multiple wedge or anatomical lung resection.

Medical therapy

Chemotherapy and radiation may prolong life or lead to a cure in a small number of patients. SCLC patients should see an oncologist within 1 week of deciding to treat.

Radiation therapy

Radiation therapy is used as emergency treatment for spinal cord compression. **Continuous hyperfractionated accelerated radiotherapy** should be offered to patients with localized SCLC; NSCLC Stage I and II patients who are medically inoperable but suitable for radical radiotherapy (WHO PS 0–1); and Stage IIIA and IIIB NSCLC patients who cannot tolerate chemoradiotherapy. Baseline pulmonary function tests, including lung volumes and transfer factor, should be performed. **Post-operative radiotherapy** is controversial but should be considered in NSCLC, to reduce local recurrence if resection margins show residual microscopic disease.

Chemotherapy

NSCLC

Chemotherapy alone plays no curative role. Chemotherapy can be given as a neoadjuvant (pre-surgery) or as adjuvant (post-surgery) therapy. **Neoadjuvant chemotherapy** can downstage tumours prior to surgery; it can also be used to assess chemotherapy response and control micrometastatic disease. **Adjuvant platinum-based chemotherapy** has survival benefits in patients with good PS 0–1 and Stage II or IIIA NSCLC or if N2 nodes are positive at operation. It can be offered alone for palliative treatment (Stage IIIB or IV and WHO PS 0–1), improving disease control and quality of life.

Combined chemoradiation therapy

NSCLC

Cisplatin-based concurrent chemoradiotherapy improves survival (24.8% 3-year survival) and should be considered for inoperable Stage II and III NSCLC, especially in patients under 75 years of age, WHO PS 0–1, with reasonable lung function, and no major comorbidities. **Platinum-based sequential chemoradiotherapy** may be offered to patients with locally advanced NSCLC but who are not suitable for concurrent chemoradiotherapy.

SCLC

Cisplatin-etoposide concurrent chemoradiotherapy may be considered early in patients with LS-SCLC disease and who are WHO PS 0–1. **Platinum-based combination chemotherapy** should be considered in patients with ES-SCLC and good PS. **Thoracic radiotherapy** is unfit for concurrent chemoradiotherapy in patients with LS-SCLC disease but may be offered to patients with ES-SCLC after chemotherapy, depending on response. **Prophylactic**

cranial irradiation may be offered to patients with SCLC and who are WHO PS <2, following good response to initial chemotherapy.

Molecular-targeted therapies

NSCLC tumours should have specific mutation testing (e.g. for mutations in the epidermal growth factor receptor and anaplastic lymphoma kinase). Monoclonal antibodies and tyrosine kinase inhibitors, which, respectively, block receptors and inhibit the enzyme-mediated activation of cellular signalling pathways, thus preventing cell proliferation, can increase survival.

Palliative treatment

Appropriate skilled palliative care is an important treatment for patients with Stage IV NSCLC, especially non-drug interventions for breathlessness. Participation in clinical trials of radical treatment can be considered.

Other treatment modalities

Radiofrequency ablation may be considered for radical treatment and palliation in non-surgical candidates and for small tumours (≤ 3 cm). **Radical brachytherapy** (high-dose radiotherapy delivered via a catheter during bronchoscopy) is curative in early mucosal or submucosal disease (tumours ≤ 4 mm).

Management of solitary pulmonary nodules

British Thoracic Society guidelines outline algorithms for the investigation and management of solid and subsolid pulmonary nodules, including the use of malignancy prediction calculators. Solitary pulmonary nodules, defined as discrete, well-marginated, rounded opacities ≤ 3 cm in diameter, completely surrounded by lung parenchyma, not touching the hilum or mediastinum, and without associated atelectasis or pleural effusion, are often an incidental finding in asymptomatic patients (0.2% of CXRs, 1% of CTs). Most are benign

(infectious granulomas, 80%; hamatoma, 10%; inflammatory or vascular) but approximately 20%–30% are malignant; 47% of these are adenocarcinomas, 22% are squamous cell carcinomas, and 4% are SCLC or metastases.

Lesions with typical benign features (i.e. lack of change over 2 years, or with a benign pattern of calcification, especially in low-risk patients) require no further investigation. Lesions strongly suggestive of malignancy (>3 cm diameter) or with documented growth should be referred for surgical resection.

Lesions with intermediate probability (8–20 mm) pose a diagnostic challenge, and further imaging is appropriate. Around 95% of patients with a malignant nodule will have an abnormal PET. In selected cases, biopsies are undertaken via CT-guided transthoracic needle aspiration or bronchoscopically performed TBNA; alternatively, for peripheral lesions, a surgical diagnosis can be made thoracoscopically.

Surgical resection (via VATS or a thoracotomy) is indicated for indeterminate nodules with a high probability of malignancy, and especially for PET-positive and biopsy-positive nodules. If frozen sections show evidence of malignancy, lobectomy with mediastinal lymph node sampling or dissection is recommended because of their lower recurrence rates. Resection of nodules greater than 1 cm in diameter has a 5-year survival rate as high as 80%.

Survival

Overall (considering all types and stages of lung cancer), 5-year survival is 16%. Mean survival for extensive inoperable lung cancer is 9 months or less (see Figure 141.1).

SCLC survival

In LS-SCLC, with chemotherapy, the 2-year survival rate is 20%–30%, and the 5-yr survival rate is 10%–15%. In ES-SCLC, the 2-year survival rate is $<5\%$, and median survival time is 8–13 months. In recurrent SCLC, the mean survival time is 2–3 months.

Figure 141.1 One-year relative survival (%) by stage, for adults (age 15–99).

142 Occupational lung disease

Paul Cullinan and Joanna Szram

Definition of the disease

Some occupational lung diseases are defined by their clinical or pathological nature (e.g. occupational asthma or mesothelioma), while others are defined by their specific aetiology (e.g. silicosis, farmer's lung). Most fall into one of three categories:

- airways diseases, including occupational asthma (induced by a workplace agent), work-exacerbated asthma (pre-existing asthma provoked by one or more agents at work), and irritant-induced asthma (initiated by a single, toxic exposure to a respiratory irritant); COPD and obliterative bronchiolitis may arise from workplace exposures, and around 10% of lung cancers have an occupational aetiology
- parenchymal diseases, incorporating the many types of pneumoconiosis, differentiated by the dust that caused them, and extrinsic allergic alveolitis (EAA, or hypersensitivity pneumonitis (HP)) categorised by the occupations and exposures from which they arise
- pleural diseases with an occupational cause comprising pleural plaques, diffuse pleural thickening, and mesothelioma

Aetiology of the disease

Occupational lung diseases arise from the inhalation of toxic dusts, fumes, or gases at work:

- occupational asthma is caused by a specific respiratory hypersensitivity to an airborne allergen; around 300 workplace allergens have been reported but most cases occur in a handful of occupations (see Table 142.1); more comprehensive lists can be found online)
- a wide variety of irritant exposures at work can exacerbate pre-existing asthma; they include dusts or gases, cold or dry air, exertion, or simply an early shift pattern
- obliterative bronchiolitis has been reported in silo, textile, and food-processing workers
- the most common causes of pneumoconiosis are crystalline silica (masons, quarry workers), asbestos, and coal dust (underground mining); many cases are of long latency and reflect past exposures
- rarer causes of occupational lung disease include 'hard metal' (tool grinders) and beryllium (electronics manufacture)

- EAA follows inhalation of (usually) organic, often fungal antigens of small particle size in a very wide variety of occupations (farmers, bird breeders, mushroom pickers, brewers, etc.); in many cases of chronic EAA however, no cause can be identified
- occupational pleural disease is almost always the result of exposure to asbestos, particularly chrysotile ('blue asbestos') or amosite ('brown' asbestos)
- the most common occupational cause of lung cancer is asbestos exposure, which acts in synergy with smoking

Typical (and less common) symptoms of the disease

In most cases, occupational asthma has a short latency with symptoms appearing within 2 years (but rarely sooner than 6 months) of first exposure. Asthma symptoms are often accompanied by nasal and eye symptoms typical of those induced by an airborne, protein allergen such as grass pollen. Symptoms tend to improve away from work, especially during holidays. Less commonly, differences in day-to-day exposures within a job or isolated 'late phase' reactions (felt **after** rather than **at** work) can make a work relationship less clear. Patients with established disease may have persistent bronchial hyper-reactivity with symptoms provoked by exposure to a variety of non-specific respiratory irritants, both at and away from work.

In contrast, patients who have developed irritant-induced asthma generally do so within 48 hours of a clearly identifiable irritant exposure in the workplace.

Simple pneumoconiosis is often asymptomatic, but more advanced 'complicated' disease (progressive massive fibrosis), is characterized by the gradual onset of cough and increasing breathlessness. Some forms of pneumoconiosis (e.g. stannosis) produce only radiographic changes. Chronic beryllium disease is clinically and radiographically indistinguishable from pulmonary sarcoidosis.

EAA has both acute and chronic forms. Acute attacks are characterized by cough, breathlessness, and flu-like symptoms within 12 hours of high antigen exposure and, provided there is no further exposure, resolution within a day or two. Weight loss is common and characteristic. Chronic EAA may be asymptomatic but more usually causes breathlessness of gradual onset after years of exposure.

Table 142.1 Common, high-risk occupations (and relevant exposures) for occupational asthma

Protein allergens		Chemical allergens	
Occupation(s)	Agent(s)	Occupation	Agent
Baking, milling, pastry, and pizza making	Flour(s), alpha-amylase, other enzymes, egg white	Spray painters, French polishers	Diisocyanates
Laboratory animal researchers and technicians; veterinary workers	Mouse, rat, and other animal proteins; egg proteins (embryological research)	Plastics and foam manufacturers and assemblers, chemical processors	Diisocyanates, acid anhydrides, epoxy resins, complex platinum salts, chrome, cyanoacrylates
Seafood processors	Prawn, crab, other fish proteins	Electronic solderers	Colophony fume
Tea packers, coffee processors	Herbal teas, green coffee bean	Healthcare workers	Glutaraldehyde, methyl-/butyl methacrylate
Other food processors	Egg, enzymes, flours, legumes, spices	Pharmaceutical manufacturers, healthcare workers	Penicillins, morphine, cimetidine, other drugs
Healthcare workers	Latex	Woodworkers	Red cedar, iroko, other tropical sawdusts
Detergent enzyme manufacturers	Detergent protease, amylase, lipase, cellulase	Textile workers	Reactive dyes
Flower and vegetable farmers	Pollens	Hairdressers, manufacturers of circuit boards	Persulphates

Pleural plaques do not give rise to either symptoms or lung function abnormalities. In contrast, diffuse pleural thickening may be sufficiently restrictive to cause breathlessness. Patients with mesothelioma generally present with chest pain and/or symptoms of a (large) pleural effusion.

Demographics of the disease

The age, sex, and geographic distributions of occupational lung diseases reflect those of current and/or past industrial activities. Overall, there is little doubt the diseases are under-recognized. Population-based surveys suggest that 10% of all new or recurrent asthma in working-age adults is attributable to occupational exposures. Rates of true occupational asthma are high in some groups such as bakers, vehicle spray painters, and those who work with animals.

In most developed economies, new cases of pneumoconiosis are rare and, given the long latency of much disease, may first be recognized in those who have retired, reflecting historic exposures; some types of 'accelerated' silicosis are an exception. EAA that is readily attributable to occupational exposures is uncommon in most settings.

In (post-)industrial communities, pleural plaques are identifiable on CT chest scan in 25% of men aged 50 years or more. Similarly, rates of mesothelioma closely reflect exposures to asbestos 30–40 years previously and are not expected to decline until 2015–2020.

Natural history, and complications of the disease

With continuing allergen exposure, the symptoms of occupational asthma persist, usually deteriorate, are increasingly difficult to treat pharmacologically, and may become irreversible; the natural history of EAA is probably similar.

The fibrosis induced by asbestos or silica tends to progress even after exposure has ceased. Abrupt clinical deterioration is usually a reflection of secondary pulmonary hypertension. Patients with asbestosis, especially those who smoke, have an increased risk of lung cancer.

Pleural plaques frequently calcify but are not premalignant. Given equivalent exposures to asbestos, patients with pleural plaques have the same risk of subsequent mesothelioma as those without.

Approach to diagnosing the disease

All patients of working age with respiratory disease should be asked about their occupation(s), since therein may lie an etiological explanation and the potential for cure or prevention of progression. For diseases of long latency such as pneumoconiosis, a comprehensive and detailed lifetime occupational history is required in order to identify the cause of the disease. Patients with non-occupational respiratory diseases often have difficulties with finding and maintaining productive employment.

Other diagnoses that should be considered

Many occupational lung diseases—especially the pneumoconioses and pleural diseases—are clinically and/or radiologically specific. In the context of an appropriate history of exposure, alternative diagnoses do not need to be considered.

Others are non-specific and have important non-occupational etiologies. Occupational asthma can be demonstrated at an individual level but it is rarely possible to make a firm occupational attribution for a patient with COPD or lung cancer, as most of these patients have a history of heavy smoking.

The distinction between occupational asthma and pre-existing (or coincidental) asthma which is simply exacerbated by one or more exposures at work can be difficult. Injury and repair due to a single, heavy ('toxic') occupational exposure to a respiratory irritant can result in a non-immunologically mediated irritant-induced asthma; fortunately, most 'inhalation incidents' cause temporary symptoms only.

Box 142.1 Criteria for a diagnosis of irritant-induced asthma ('reactive airways dysfunction syndrome')

- onset after a single exposure at very high concentration to a gas, smoke, fume, or vapour with irritant qualities
- onset within 24 hours of the exposure and persistence for at least 3 weeks
- symptoms consistent with asthma (cough, wheezing, dyspnoea)
- evidence of subsequent airflow obstruction
- evidence of subsequent non-specific bronchial hyper-reactivity (methacholine or histamine challenge test)
- absence of prior respiratory symptoms
- other pulmonary disease excluded

'Gold-standard' diagnostic approach

Occupational asthma should be suspected in any working adult with new, recurrent, or difficult asthma. The gold-standard diagnostic test is specific inhalation challenge as an inpatient, a procedure offered at very few hospitals. For occupational asthma arising from protein allergens, evidence of specific IgE sensitization has a very high sensitivity, and a negative result effectively rules out the diagnosis. Immunological testing is generally less helpful with chemical agents and expert advice should be sought.

Criteria for the diagnosis of irritant-induced asthma ('reactive airways dysfunction syndrome') are outlined in Box 142.1.

Acute EAA induces an inflammatory blood picture with peripheral and bronchoalveolar lymphocytosis, pulmonary infiltration on chest X-ray, a reversible fall in gas transfer, and a specific IgG response.

A full occupational history should be taken from all patients with pulmonary fibrosis. Pulmonary function testing reveals a loss of lung volumes, restrictive spirometry, and a reduction in gas transfer. The radiographic changes of many types of pneumoconiosis are characteristic but those of asbestosis are often indistinguishable from idiopathic pulmonary fibrosis. While the co-presence of pleural plaques is confirmatory of asbestos exposure they may develop from far lower levels than the prolonged, heavy exposures required to induce asbestosis.

Mesothelioma is diagnosed using immunohistological techniques from lung tissue obtained at open or video-assisted biopsy.

In chronic beryllium disease, there is a positive response to a specific lymphocyte proliferation test using fresh blood; this assay is performed in very few laboratories.

In cases of suspected pneumoconiosis, a full semi-quantitative occupational history is required; high-resolution CT of the chest is far more sensitive than simple radiology for the detection of fibrosis and pleural disease.

Acceptable diagnostic alternatives to the gold standard

For occupational asthma, the most widely available and best-validated investigative tool is serial measurement of peak flow, which in expert hands has a sensitivity and specificity of approximately 80%. Measurements need to be made both at home and at work, at least four times a day over a period of several weeks; interpretation requires experienced personnel. Cross-shift monitoring of FEV₁ and bronchial reactivity is sometimes used in place of specific inhalation challenge but is logistically complex.

Other relevant investigations

Spirometry in the clinical setting is an insensitive indicator of both occupational asthma and work-exacerbated asthma.

Prognosis and how to estimate it

Once occupational asthma has developed, further exposure to the causative workplace allergen leads, in most cases, to persistent disease which is increasingly difficult to manage, and the risk of irreversible disease is increased by prolonged exposure after onset.

Conversely, avoidance of further exposure is often curative. The prognosis of acute EAA is similar.

The prognosis of the fibrosing pneumoconioses (asbestosis, silicosis) is directly related to the extent of disease but is usually better than that for idiopathic pulmonary fibrosis. The development of secondary pulmonary hypertension carries a very poor prognosis.

Mesothelioma is currently universally fatal, with a median life expectancy of about 12 months.

Treatment and its effectiveness

There are no specific treatments for the occupational lung diseases. In occupational asthma, avoidance of exposure is the most successful intervention and is frequently curative. It may, however, lead to employment difficulties, and successful management requires appropriate support, including, where it is available, occupational health input. Likewise, the cornerstone of treatment

for EAA is the avoidance of further exposure; in this disease, respiratory protection may be sufficient. Conventional pharmacological treatment of asthma and rhinitis is rarely effective in occupational asthma when there is continuing allergen exposure but it is often successful in the management of work-exacerbated asthma.

143 Pleural infection and malignancy

Seamus Grundy

Pleural infection

Definition of pleural infection

Pleural infection transitions from simple parapneumonic effusion, to complex parapneumonic effusion, to empyema. Primary empyema occurs without an underlying pneumonic process.

Aetiology of pleural infection

Forty per cent of pleural infections are culture negative. When culture positive, the bacteriology of empyema differs between community-acquired and hospital-acquired empyema (see Table 143.1).

Anaerobes commonly co-infect the pleural space and are not always cultured in the laboratory.

Typical symptoms of pleural infection

Pleural infection commonly presents identically to pneumonia with dyspnoea, purulent sputum, and fevers. It may be associated with pleuritic chest pain. Empyema can cause systemic sepsis leading to cardiovascular instability and multi-organ failure.

Demographics of pleural infection

Often patients will have no known risk factor. However, there is increased risk in the presence of alcohol abuse, immunosuppression, diabetes, and chronic aspiration.

Natural history, and complications of pleural infection

A parapneumonic effusion, if left untreated, will progress through three stages:

Stage 1: Simple parapneumonic effusion

- clear fluid, exudate, sterile, pH >7.20
- normally responds to antibiotics

Stage 2: Complicated parapneumonic effusion

- cloudy fluid, exudate, pH <7.20, culture sometimes positive, septae form
- requires drainage and antibiotics

Stage 3: Empyema

- purulent fluid, pH <7.20, culture sometimes positive, if left untreated pleural thickening develops
- requires drainage and antibiotics and may require surgical intervention

This disease progression emphasizes the importance of early appropriate management of patients with parapneumonic effusions.

Rarely, empyema can drain spontaneously through the chest wall (empyema necessitatis) or can lead to a bronchopleural fistula.

Approach to the diagnosis of pleural infection

All patients with a suspected pleural infection should have a diagnostic pleural aspiration. This should be done under ultrasound guidance,

which will also allow for evaluation of the presence of septae, which would suggest a complicated parapneumonic effusion which will require drainage.

The following tests should be carried out on the pleural fluid:

- biochemistry: pH (measured accurately with a blood gas analyser), protein, and lactate dehydrogenase
- microbiology: Gram stain and culture; acid/alcohol fast bacilli should be stained for, although pleural fluid culture alone is only positive in 25% of tuberculous effusions; pleural fluid should be sent in blood culture bottles as this increases the pick-up rate for anaerobes

Other diagnoses that should be considered aside from pleural infection

The differential diagnosis of pleural infection includes other causes of exudative effusion, such as malignancy and autoimmune diseases.

'Gold-standard' diagnostic test for pleural infection

The gold-standard diagnostic test for pleural infection is microbiological culture of the pleural fluid. However, this is only positive in 60% of cases and, as such, clinical judgement is always required.

Other relevant investigations for pleural infection

Thoracic ultrasound should be used both to guide any diagnostic aspiration and also to assess for the presence of septae/locules. Contrast-enhanced CT of the thorax may be useful in empyema in order to assess the distribution of the disease and evaluate for the presence of an underlying pulmonary abscess or obstructing bronchial lesion.

If a tuberculous effusion is suspected, pleural biopsy should be undertaken. Tuberculous effusions lead to diffuse infiltration of the pleura with granulomas and, as such, this is the one indication for a blind pleural biopsy. When combined with pleural fluid staining/culture, it has a sensitivity of 90%.

Prognosis of pleural infection, and how to estimate it

The 1-year mortality rate for patients who require intercostal drainage for pleural infection is approximately 20%. Approximately 15% will require surgical intervention within 3 months of the initial drain. Risk factors for a poor outcome include old age, hospital-acquired infection, and markers of associated systemic sepsis, such as hypotension, renal dysfunction, and hypoalbuminaemia.

Treatment of pleural infection, and its effectiveness

Pleural infection should be treated with antibiotics according to local guidelines. Given that the organisms which give rise to hospital-acquired infections are different from those which give rise to community-acquired infections, it is important to differentiate between these two sources of infection when making empirical prescribing decisions. Antibiotics should be rationalized according to microbiology results. It is important to remember, however, that anaerobes commonly co-infect with other bacteria and may not always be identified in the culture. As with pneumonia, early administration of the first dose of antibiotics is essential.

Malignant pleural effusion and mesothelioma

Definition of malignant pleural effusion and mesothelioma

A malignant pleural effusion arises when malignant cells infiltrate the pleura, resulting in increased production and decreased lymphatic

Table 143.1 Microbiology of pleural infection

Community acquired	Hospital acquired
<i>Streptococcus milleri</i> (28%)	MRSA (27%)
Anaerobes (19%)	Staphylococci (22%)
<i>Streptococcus pneumoniae</i> (14%)	Enterobacteria (20%)
Staphylococci (12%)	Enterococci (12%)

Table 143.2 Primary site of malignant pleural effusion

Primary site	Frequency (%)
Lung	37
Breast	16
Lymphoma	11
Mesothelioma	10
Gastrointestinal	9
Genito-urinary	7
Unknown	10

drainage of pleural fluid (see Table 143.2). Malignant pleural effusions are either metastatic or primary mesothelioma.

Aetiology of malignant pleural effusion and mesothelioma

Malignancy is the commonest cause of an exudative effusion in patients over the age of 60. Mesothelioma is almost always associated with previous asbestos exposure. There is no dose–response relationship between asbestos exposure and the risk of developing mesothelioma. A single exposure may be etiological.

Typical symptoms of malignant pleural effusion and mesothelioma

Malignant pleural effusions may be detected incidentally when a chest X-ray is performed for other reasons. The commonest associated symptoms are breathlessness, chest pain, weight loss, and cough.

Demographics of malignant pleural effusion and mesothelioma

As with malignancy in general, malignant pleural effusion is more common with advancing age and in smokers. The average lag time between asbestos exposure and developing mesothelioma is approximately 35 years. It is rare for mesothelioma to occur within 15 years of asbestos exposure.

Natural history, and complications, of malignant pleural effusion and mesothelioma

When any malignancy presents with a pleural effusion, it is suggestive of advanced disease and a poor prognosis. The major complication associated with malignant pleural effusion is ‘trapped lung’. The encasement of the lung by the visceral pleura means that, despite complete drainage of all pleural fluid, the lung will not re-expand and the effusion rapidly recurs.

Approach to diagnosing malignant pleural effusion and mesothelioma

The diagnostic algorithm for determining the cause of any pleural effusion should be systematic and logical (see Chapter 19). Pleural fluid aspiration is the mainstay of diagnosis. If the initial pleural aspirate is non-diagnostic, a second aspiration increases the diagnostic sensitivity, but further samples are unlikely to be beneficial.

Pleural fluid cytology will reveal the diagnosis in approximately 60% of malignant pleural effusions. In cytology-negative cases, a biopsy of the pleura is the next step. This can be performed either with a cutting needle under radiological guidance or with thoracoscopy. The benefit of carrying out thoracoscopy is that the procedure can be both diagnostic, with a sensitivity of >90%, and therapeutic, as talc poudrage can be carried out at the same time.

There is a risk of introducing seeding metastases after therapeutic/diagnostic pleural intervention of mesothelioma. The usefulness of prophylactic radiotherapy to the intervention site is a debated issue, with different studies obtaining conflicting results.

Other diagnoses that should be considered aside from malignant pleural effusion and mesothelioma

The major differential of an exudative effusion is infection. Rarer causes include pulmonary embolism, autoimmune disease, pancreatitis, and drugs. The histological diagnosis of malignant mesothelioma can be challenging, as its appearance can be very similar to that of adenocarcinoma. If the histology is inconclusive, a multidisciplinary team must review the case and come to a consensus diagnosis.

‘Gold-standard’ diagnostic test for malignant pleural effusion and mesothelioma

There is no single ‘gold-standard’ test for the diagnosis of a malignant effusion. The gold standard is to make a diagnosis in a timely fashion and in a way that is as minimally invasive as possible. The first test in that algorithm is always a diagnostic pleural aspiration.

Prognosis of malignant pleural effusion and mesothelioma, and how to estimate it

The median survival after diagnosis of a malignant effusion is between 3 and 12 months. This varies according to the primary site of malignancy, with lung cancer having the worst prognosis. As well as tumour staging, pleural fluid pH can be used as a tool for estimating prognosis, with a low pH being associated with a worse outcome.

The prognosis of mesothelioma is poor, with a median survival of less than 1 year. Worse prognosis is associated with the sarcomatoid subtype compared with the epithelioid subtype.

Treatment of malignant pleural effusion and mesothelioma, and its effectiveness

The management of patients with malignant pleural effusion involves symptom control, with drainage of pleural fluid and prevention of its recurrence with pleurodesis, alongside treatment of the underlying condition.

A pleural effusion should not be completely drained until a diagnosis has been obtained, as it may mean that thoracoscopy or radiologically guided biopsy is not possible until the fluid reaccumulates.

Pleurodesis aims to seal the pleural space by causing a fibrous reaction between the parietal and visceral pleura. The most effective sclerosing agent is talc. There have been previous reports of acute respiratory distress syndrome being caused by talc, but a recent study showed that graded talc is safe to use for pleurodesis. Although less effective, other options include bleomycin, tetracycline, or autologous blood. Pleurodesis can be achieved either with talc slurry via an intercostal drain or with talc poudrage at thoracoscopy. Talc poudrage has a better long-term success rate but is more invasive.

If the effusion is recurrent despite attempts at pleurodesis or if trapped lung is present, a long-term indwelling pleural catheter can be sited which allows the patient to drain the pleural fluid intermittently.

The treatment of mesothelioma is palliative in all cases. Radiotherapy can be used to control chest wall pain or painful nodules. Palliative chemotherapy has been shown to improve survival by 2–3 months, but is associated with significant side effects.

144 Drug-induced lung disease

Salman Siddiqui and Dhananjay Desai

Background

Pulmonary drug toxicity is being increasingly recognized as a cause of various forms of lung disease. The spectrum of disease can range from transient, minor reactions to rapidly progressive disease with fatal consequences. A large number of drugs are linked to pulmonary disease; however, causality is often difficult to establish, because the length of the latency period between exposure and the onset of disease can vary and because there can be discordance between symptom development and the appearance of radiological changes, which may not be present at all (e.g. angiotensin-converting enzyme (ACE) inhibitors can cause cough-related airways disease in the absence of radiological change).

Pathophysiology and patterns of involvement

Although the lung is often undervalued as a metabolic organ (compared to the kidneys and the liver), it plays an important role in drug metabolism. The total alveolar area available for gas transfer is in the region of 70 m². This allows inhaled agents to be deposited over a very large area and, consequently, they may induce diffuse and heterogeneous damage. Drugs administered systemically can undergo both Phase I and Phase II metabolism in the lungs, albeit to a very minor degree compared to the extent of drug metabolism in the liver. Nonetheless, there is scope for local toxicity due to this metabolism; in addition, drugs metabolized elsewhere in the body may exert their effects by being deposited in the lungs. Overall, however, most drug-induced lung disease (DILD) is idiosyncratic.

A diverse range of structural sites may be involved in DILD. Involvement of bronchial epithelium and pneumocytes may cause central airways disease, such as cough-related syndromes and bronchospasm, as well as peripheral airways disease related to airway narrowing, such as obliterative bronchiolitis, which causes airflow limitation and pulmonary fibrosis. Involvement of the pulmonary vasculature may induce vasculitis or pulmonary hypertension. The pleura and thoracic lymph nodes can also be involved, leading to pleural effusion and lymphadenopathy, respectively. Neuromuscular involvement may lead to ventilatory failure. Allergic drug reactions may involve any of these pulmonary components.

Risk factors for developing DILD

Dose-related drug toxicity is linked with amiodarone and bleomycin (as well as radiation). However, DILD may occur at unpredictably low doses and, therefore, cumulative accrued dose may not be clinically important in some cases (e.g. those due to NSAIDs or eosinophilic pneumonia). In other cases, a combination of several pneumotoxins may result in lung injury, suggesting that multiple hits are necessary for the induction of lung disease. The website <http://www.pneumotox.com> lists all drugs implicated in lung injury and provides an estimate of the frequency of toxicity. Oral and parenteral routes seem to be associated with the highest incidence of DILD.

Risk factors for developing DILD include low hepatic enzyme activity (e.g. isoniazid acetylation), which can be due to a genetic mutation. Drugs such as gefitinib and erlotinib, which inhibit the EGF receptor, also inhibit other tyrosine kinases and are causally linked to pulmonary toxicity. Overall, patients with a history of previous chemotherapy, those with rheumatoid disease, or those with existing underlying fibrosis appear to be at a higher risk of DILD.

Diagnosis of DILD

Diagnosing DILD can be challenging, as previously discussed; the mechanisms of drug toxicity are often unclear and there may be a variable latency period between exposure and disease. Similarly, laboratory studies are often unhelpful and radiographic or even histopathological findings may be non-specific. A detailed history outlining prescription drugs, over-the-counter remedies, herbal remedies, and illicit drugs is necessary to try and identify potential causative agents. Involvement of a dedicated pharmacist with access to primary-care repeat prescription records may be useful.

Physical examination is necessary in order to rule out other diseases that may manifest with interstitial lung disease (ILD). Finger clubbing is not seen in DILD but crackles may be present if the process involves fibrosis. Wheeze may indicate a bronchospastic disorder (e.g. aspirin-induced asthma), and the presence of a pleural effusion is often associated with drug exposure, which is often overlooked.

Pulmonary function tests, on the other hand, are a useful guide to diagnosis. For example, early pulmonary vascular disease may be indicated by a reduced gas transfer coefficient before the onset of established radiological changes of pulmonary hypertension. Furthermore, serial monitoring of static lung volumes and gas transfer may allow determination of disease progression (currently defined by guidelines as a >10% fall in forced vital capacity, and a 15% fall in DLCO (the diffusing capacity of the lung for carbon monoxide) between serial tests). This is especially useful where the causative drug may have been stopped, so the disease process would be expected to improve or remain static.

Radiology involves a high-resolution CT chest scan (HRCT), which may offer some guide to distinguishing disease and response to therapy. For example, the presence of honeycombing and traction bronchiectasis indicates a fibrotic process, whereas the presence of ground-glass opacity (GGO) changes is indicative of active alveolar inflammation that may be steroid responsive. In addition, the HRCT may help to identify the pattern of ILD, for example, hypersensitivity pneumonitis may present with upper lobe predominant centrilobular nodules and GGO change, whereas eosinophilic pneumonia has a characteristic appearance that is the radiographic negative of pulmonary oedema.

Bronchoalveolar lavage, when used in conjunction with HRCT imaging, may be diagnostic. For example, the presence of haemosiderin-laden macrophages in the setting of diffuse pulmonary infiltrates and a fall in haemoglobin would favour diffuse alveolar haemorrhage. Other examples where the lavage may be diagnostic are listed in Table 144.1. Invasive measures such as surgical lung biopsy have low

Table 144.1 Scenarios in which bronchoalveolar lavage may be diagnostic of drug-induced lung disease

Drug-induced lung disease	Typical bronchoalveolar lavage findings
Eosinophilic pneumonia	Eosinophils >25% (preferably >40%)
Amiodarone lung	Foamy macrophages; there may be an increase in neutrophils, lymphocytes, or both; alternatively, neutrophil and lymphocyte counts may be normal (20%)
Lipoid pneumonia	Alveolar macrophages with empty vacuoles; positive result from Oil Red O stain
Hypersensitivity pneumonitis	Bronchoalveolar lavage lymphocytosis
Diffuse alveolar haemorrhage	Progressively bloody lavage return; haemosiderin-laden macrophages

diagnostic yield. Up to 20% of patients who had diffuse infiltrates and who underwent surgical lung biopsy have pathologic findings that can be attributed to a drug reaction.

DILD should remain a diagnosis of exclusion. Rechallenge with the causative agent may be the only way of proving causality but, if these reactions are severe, the consequences may be fatal.

Drugs implicated in DILD

Medications most commonly responsible for lung toxicity include methotrexate, amiodarone, NSAIDs, nitrofurantoin, and ACE inhibitors. These appear in Figure 144.1, with their patterns of involvement.

Amiodarone

With this commonly used antiarrhythmic drug, there appears to be a dose-related toxicity, with a far higher incidence of lung disease in those taking >500 mg per day, and length of treatment is also proportional to the risk of developing DILD. Due to its high lipophilicity and tissue storage, patients taking amiodarone may present with DILD after cessation of therapy (usually within 3 months). The disease spectrum is most commonly in the form of an acute presentation, with cough, fever, and infiltrates on X-ray, with pathological changes that are in keeping with acute interstitial pneumonitis. A more insidious onset with dyspnoea and chronic cough, crackles, and pleural effusions may be seen. An increase in serum lactate dehydrogenase may be seen. HRCT is usually helpful in diagnosis, showing migrating opacities and infiltrates, as well as nodules which may mimic tumours. Some cases may have fibrosis and interlobular septal thickening. Corticosteroid treatment is indicated if no improvement is seen in imaging or lung function after stopping the drug for 1–2 months; the treatment needs to be given over typically 6 months and gradually tapered, as there is a risk of relapse if it is withdrawn too early. The vast majority of cases will improve with this therapy but amiodarone pneumonitis may progress to acute respiratory distress syndrome (ARDS), with poor outcomes. Therefore, a pragmatic step may be to perform pulmonary function tests at the baseline before offering amiodarone therapy to those with no history of underlying lung disease.

Methotrexate

This is the most commonly prescribed disease-modifying anti-rheumatic drug and is estimated to cause DILD in 1% of treated patients. The incidence of rheumatoid ILD is estimated to be 10%–50%, with a higher incidence seen with increasing severity of rheumatoid disease. Therefore, the causality may be very difficult to attribute to drugs unless the temporal association is narrow, and clear evidence of reversibility is demonstrated on withdrawal of the drug. Unlike amiodarone, toxicity is not dose dependent, but the maximal incidence is seen within 1 year of commencing therapy. Clinical symptoms are fever, progressive breathlessness, and cough. HRCT may show reticulation, nodules, or GGO. There may be an accelerated

phase, with worsening dyspnoea and hypoxaemia; at such times, a careful exclusion of atypical lung infection may become necessary. High-dose corticosteroid therapy and ventilatory support if appropriate is the only other management apart from withdrawing the drug. Mortality at these times is estimated in the region of 10%.

Nitrofurantoin

Use of the drug nitrofurantoin for the treatment of chronic urinary tract infection carries the risk of pneumotoxicity leading to 'nitrofurantoin lung'. The acute form may occur within a few days of starting therapy and may cause an ARDS type of picture. The chronic form may cause interstitial pneumonitis or fibrosis. Steroid therapy may be useful.

ACE inhibitors

These drugs are used extensively and well tolerated in a large majority of patients, and the adverse effects are largely manifest as dry cough or airways disease. The potential mechanism of this adverse effect is known but cannot explain why some patient subsets are more prone than others. ACE inhibition causes an accumulation of airway 'irritant' molecules like bradykinin and leukotrienes, resulting mainly in cough (particularly in females) and, to a lesser extent, bronchospasm. Therefore, caution is advised when prescribing these drugs in airways disease patients who have bronchial hyper-reactivity. Up to 20% of patients using an ACE inhibitor may develop a dry cough; however, in only a minority will this be so severe as to cause discontinuation of the drug. In patients that had a 'chronic' cough before commencing therapy, an ACE inhibitor may be proven to be the exacerbating cause, but this may only come to light after discontinuing the drugs for 4–6 weeks. Current national guidelines advocate stopping ACE inhibitors in all patients with chronic cough. Angiotensin II receptor blockers are the logical choice for patients that are intolerant of ACE inhibitors.

NSAIDs

NSAIDs are well tolerated but are associated with a wide variety of airways disease manifestations as a result of their pulmonary adverse effects. Increased levels of leukotrienes from selective cyclooxygenase-1 enzyme inhibition results in cough, bronchospasm, and exacerbations of underlying airways disease and there is a subset of patients that clearly are prone to these effects but why specifically is still unclear. Hypersensitivity pneumonitis-like reactions are also described with fever, cough, eosinophilia, and pulmonary infiltrates. Corticosteroids cause rapid resolution of these effects.

Biological agents

Over the past decade, both the production and the use of biological agents have increased significantly. Pulmonary toxicity has been notably reported with tumour necrosis factor alpha (TNF α) blockers, interferons (IFNs), and anti-CD20 antibodies (rituximab).

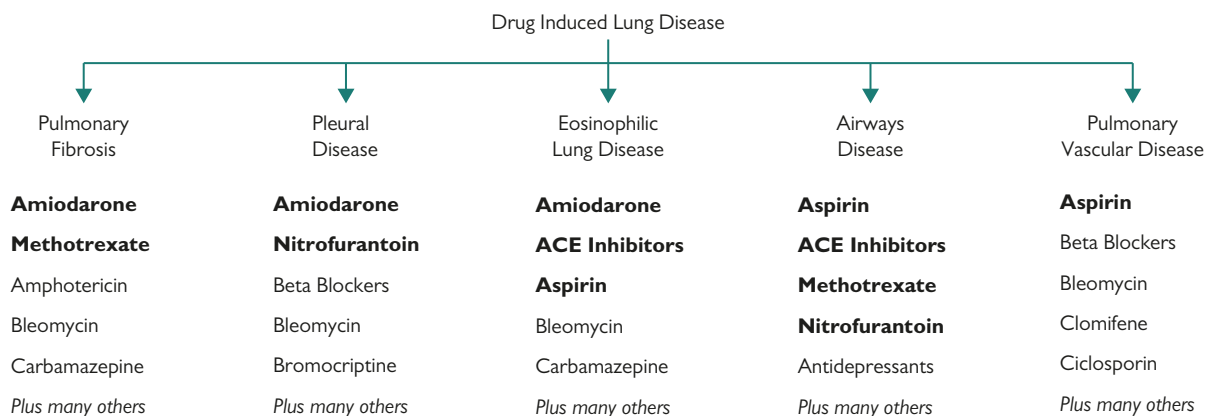

Figure 144.1 Drugs implicated in lung disease, classified by the nature of the lung injury; the drugs most commonly implicated in each disease are indicated in bold; ACE, angiotensin-converting enzyme.

Anti-TNF α agents are usually administered to patients with rheumatoid arthritis, who concurrently use or had used methotrexate; hence these drugs have the potential to potentiate lung adverse effects, but cases have also been seen in patients that were never exposed to methotrexate. Agents such as infliximab and etanercept most commonly cause interstitial fibrosis or pulmonary sarcoid-like reactions (estimated incidence 0.5%). Whether these are class effects is unclear, as some case reports suggest an alternative anti-TNF α agent may be safe, but others have reported relapse with this strategy.

Rituximab is an anti-CD20 B-cell antibody widely used in non-Hodgkin's lymphoma and in rheumatoid arthritis. The most common lung toxicity presents typically with an insidious onset. HRCT may reveal GGO in addition to focal alveolar infiltrates. More severe reactions with pulmonary haemorrhage causing acute respiratory failure, and others with pneumonitis, have also been reported. Treatment with corticosteroids and stopping the drug appears to be of benefit.

The interferons interferon alfa-2a and interferon alfa-2b are used for the treatment of hepatitis C viral infection. Pulmonary toxicity from these has been implicated in airways disease exacerbations (asthma), interstitial pneumonitis, OP, and pleural effusions. As earlier, prompt withdrawal is of most benefit but corticosteroids may be administered concomitantly if continuing IFN therapy is indicated, as they may have a protective effect.

Statins

The widespread use of statins, compounded by the fact that the association between statins and DILD has only recently been

recognized, means there are relatively few case reports; therefore, there may be a large number of patients who are using statins and who are consequently at risk of DILD. The mechanism of injury with statins is unknown, and the time to the onset of symptoms, which are non-specific, can vary from months to years after initiation of statin therapy. HRCT findings may include reticular opacities or GGOs. The use of steroids together with the discontinuation of statins results in resolution. At this point, it is still contentious if statins do cause ILD, and the only way to improve our understanding is to increase awareness of this association and 'yellow-card' report any suspected cases.

Recommendations and practical management of DILD

DILD remains largely under-recognized and under-reported. Risk factors include cumulative dose for some drugs and concomitant administration of pneumotoxic drugs. Basic investigations are lung function tests and HRCT. Withdrawal of the offending agent, in combination with supportive management, is the only treatment. The only way of definitely establishing causality is to rechallenge with the drug, but this method cannot be recommended.

145 Psychology in respiratory disease, including dysfunctional breathing

Andrew Jeffrey

Introduction

The real burden to any sufferer of respiratory disease is shown in the human suffering of the individual. It is increasingly understood that there is a link between the psychological aspects of respiratory disease and morbidity and that patients' attitudes to illness can affect their ways of coping and, indeed, impact upon their compliance with treatment. Breathlessness is a symptom of many psychological states, both positive and negative; indeed, it is embedded within the English language—'It took my breath away! I was breathless with anticipation!' An understanding of the links between psychological factors and physical symptoms and behaviours is essential to achieve the best possible outcomes for many patients.

Dysfunctional breathing

Dysfunctional breathing is an umbrella term that refers to the disordered breathing that results from psychological distress. It can occur in the absence of physical lung or cardiovascular disease (usually referred to as hyperventilation), although it is commonly found in association with a physical cause of breathlessness such as asthma, COPD, or heart failure.

Hyperventilation in the absence of physical cardiopulmonary disease can occur at any age after infancy but the onset is usually between the ages of 15 and 55 years, with a female preponderance of around 7:1. Acute hyperventilation comes on suddenly during panic attacks, causing dizziness, breathlessness, and pins-and-needles in the fingers. Chronic hyperventilation is more difficult to diagnose because the body compensates for the chemical changes, so symptoms are less clear. Common complaints are light-headedness, breathlessness, difficulty in taking a deep breath, and even chest pain. These usually occur at rest or when talking rather than during exercise, which is the opposite of significant lung or heart conditions.

Hyperventilation, particularly in its chronic form, can be very debilitating and life-limiting. It is important to acknowledge with the patient that, although not dangerous, it is nonetheless a serious condition that requires appropriate treatment and can be greatly improved by appropriate interventions. This chronic form of dysfunctional breathing is particularly common in association with asthma and COPD (see 'Asthma' and 'COPD').

Precipitation of specific symptoms through voluntary hyperventilation can be a very effective technique for confirming a diagnosis of hyperventilation. This can have the extra beneficial effect of demonstrating to the patient that the symptom and the excess breathing are linked.

Combinations of breath-control training and interventions to target underlying psychological problems are the most effective treatments.

Anxiety and depression

It has been well documented that there is a substantial similarity in symptoms of anxiety and those of respiratory diseases. Individuals often confuse symptoms of anxiety (breathlessness, chest pain, depersonalization, hyperventilation, fainting, etc.) with a worsening of their physical condition. When symptoms seem confusing, patients catastrophize their body sensations; this can lead to inappropriate treatment for respiratory disease. Indeed, the side effects of drugs used to control physical symptoms of respiratory disease, such as

salbutamol, can increase anxiety. Symptoms of anxiety can affect the production of cytokines, leading to inflammation of the airways and potentially exacerbating any physical inflammatory-based airways disease.

Indeed, patients with COPD or other lung conditions may also suffer neuropsychological functioning problems due to chronic hypoxemia, which results in memory difficulties, attention deficits, and difficulty with verbal tasks and motor processing.

Psychological factors have a large role to play in the perception of breathlessness. In terms of self-management, it has been shown that anxiety, depression, and alcohol abuse strongly influence how a person self-manages their illness. Self-management plans that better equip and educate patients to make their own decisions improve confidence as well as knowledge. This confidence is believed to be an important element in the improved self-management observed in patients with such plans.

Dyspnoea

Dyspnoea, or breathlessness, is often a strong feature of respiratory disease. It causes a reduction in the quality of life by imposing limitations on functionality and is frequently experienced as life-threatening and terrifying. Emotional perception of breathlessness can contribute to poor outcome. Asthma patients with high negative emotionality were found to be more likely to show breathlessness symptoms than patients who showed low negative emotionality. Generally, these patients also demonstrated a higher degree of asthma-related complaints, a finding which may indicate that this group of patients is less accurate in their perception of breathlessness than groups of patients are.

Asthma

Coexistence of asthma and panic disorder is believed to produce greater morbidity than either alone, as the two disorders essentially overlap, with similar symptoms of breathlessness, chest pain, and tightness, thus leading to symptom confusion. It is accepted that beta-sympathetic agonists used in the treatment of asthma can trigger feelings of panic, as patients catastrophize the bodily sensations produced by this close analogue of adrenaline.

Such has been the confusion for some patients regarding their symptomology that this has resulted in inappropriate treatment and near-deaths, and has even been shown to be implicated in deaths from asthma. Patients who panic may overreact to their asthma symptomology and consequently overuse medication, which can increase anxiety. Evidence that panic disorder and asthma can coexist and lead to misperceptions of symptoms has led to a combined treatment approach using cognitive behaviour therapy (CBT) and education, and improvements were reported in a group of patients using this approach. Patients taught how to differentiate between asthma and panic symptoms reported a significant decrease of more than 50% in panic symptoms alongside a decrease in asthma symptoms, improvement in quality of life, and clinical stability.

Current patient education does not always fulfil the needs of good asthma management, as it frequently does not address the ability to cope. Poor coping skills can interfere with disease management.

Psychological help needs to be culturally appropriate and community based; particularly, it needs to take into account empowerment in minority communities. Social norms help shape attitudes and

behaviour. An empowering approach based on active learning rather than didactic teaching in the management of respiratory disease is therefore most likely to be effective. This has significant implications for the manner in which patient education should be undertaken to be effective.

A recent study attempted to determine if a self-management programme could improve psychological outcome by using problem-solving approaches, social support, behaviour modification, and discussion, as determined by measuring peak flow, medication adherence, and other lifestyle behaviours. Improvements in outcome of quality of life, depression, and self-efficacy were demonstrated.

A Cochrane review (Gibson et al., 2002) indicated that teaching adult asthma sufferers self-management skills does have a positive impact on outcome. However, learner-centred self-management programmes that use a facilitator approach rather than a didactic teaching approach may have a better long-term outcome. This is arguably because sufferers manage their physical, emotional, and cognitive aspects of their disease to enhance their quality of life.

COPD

The emotional consequence of disease is often seen in a high prevalence of depression. Depression is frequently unrecognized in COPD patients and may manifest in decreased libido, decreased energy, social withdrawal, and general feelings of hopelessness, with anxiety and panic attacks also being common in this group. COPD sufferers also suffer a decrease in their recreational abilities, domestic management, activities of daily living, and possible reduction in employment opportunities. The impact this has on relationships are problems with social isolation, sexual dysfunction, and general levels of loneliness.

One large-scale study has indicated that, in COPD patients, the prevalence of depression was approximately 42%, and that of anxiety was around 50%; thus, patients with COPD are 2–3 times more likely to be suffering from anxiety and depression, compared to members of the general population. Depression worsens the outcome and mortality of many physical conditions. Routine screening of COPD patients for anxiety and depression has shown that undetected and untreated depression in COPD patients was a common occurrence and associated with increased disability, increased healthcare usage, and impaired quality of life.

Treatment of patients with COPD has increasingly become focused upon quality of life, assessing the patient's subjective experience of the disease and general satisfaction with their life. The construct of quality of life is, however, very difficult to measure, and what gives this quality differs between individuals and societies. A suggested definition of quality of life is the gap between what is desired and what is achievable in life. A comprehensive measure of quality of life will assess subjective experience of the illness in three dimensions: emotional functioning, physical functioning, and social functioning. Psychological health is clearly a key element in all three domains.

Role of clinical psychology

Much of the evidence for psychological interventions comes from studies of COPD patients, although there is no reason to assume that it does not apply to patients with other chronic respiratory diseases. There are five potential areas of psychological intervention:

- understanding basic personality traits and characteristics
- neuropsychological consequences of the disease, such as memory difficulties and concentration problems
- quality-of-life improvement, facilitating self-efficacy, medical adherence, and the ability to cope
- rehabilitation for patients, encompassing psychological, social, and/or behavioural issues
- CBT interventions to help to modify negative cognitive and behavioural responses

It has been found that clinical psychologists have a great deal to contribute to the management of respiratory disease, with respect to facilitating quality of life, expectations, adjustment difficulties, neuropsychological problems, and so on. At the same time, they have much to offer in terms of the development of rehabilitation

programmes, effective smoking cessation and prevention programmes, and improving the quality of care for patients with respiratory disease. Psychological and behavioural interventions need to be embedded within rehabilitation programmes, delivering education, discussion, and relaxation, with a target of improving the patient's quality of life with respect to anxiety, depression, breathlessness, self-efficacy, and motivation.

While education in physical self-management can be useful, some argue that patients need to know less about the pathophysiology of the disease and more about how to integrate and modify their behaviour to accommodate their disease. This is an area in which the skills and knowledge of the clinical psychologist can be useful.

Significantly, CBT group treatments for both anxiety and depression have been shown to improve mental well-being, quality of life, and education. Antidepressants have often been the treatment of choice for depressed patients and do significantly help in terms of improving mood and symptom management. However, they do not reliably affect self-management skills in chronically ill patients, while this can be achieved with CBT. The effects of relaxation and guided imagery with COPD patients are being explored but further studies are needed to identify the efficacy of these approaches as coping strategies for breathlessness.

Many of these approaches can, with suitable training and support, be integrated into the work of other health professionals.

A holistic approach to care

Holistic approaches take account of the complex mind–body experience, interpreting physical symptoms and taking account of the psychological distress caused to sufferers of respiratory disease. A holistic approach to healthcare can be defined as the appreciation that the impact of physical disease processes extend beyond the usual appreciation of physical health. This includes the emotional challenge that long-term chronic sickness imposes, includes the patient's ways of coping, as well as considering social support that can impact upon a patient's progress.

The management of respiratory disease, like any chronic illness, relies heavily on the patient's perception of their illness. They often have to adapt to their physical limitations, cope with dietary and lifestyle changes, and learn how to deal with difficult life-changing circumstances while taking on the responsibility for monitoring their condition and administering their medication. This may encompass the need to become more dependent on family, carers, and the medical profession. Indeed, this can be in itself very stressful, along with the additional issue of dealing with societal expectations that can lead to anxiety and distortions in their perceptions of their sensations.

In summary, respiratory disease is common across the UK; the direct costs to the NHS include medication, presentations at emergency admissions, treatment, inpatient stays, and outpatient appointments, as well as staffing costs. However, the less obvious costs are to the economy in working days lost, travel, and equipment and also have financial and social implications for the individual. The cost to the individual is, however, far greater as they grieve for their lost healthy self and strive to make the necessary adjustments to chronic respiratory disease and the impact such disease has upon them, their partners, family, and social network.

146 Terminal care in respiratory illness

Alys Scadding

Introduction

The terminal phase is the period of time between living with a reasonable quality of life, and the process of dying. While lung cancer and pulmonary fibrosis have the potential to deteriorate rapidly, the majority of lung diseases worsen over years. Every exacerbation of the condition leads to a decline in both lung function and performance status, and often the pre-exacerbation level of functioning is never regained. There is not a defining point to indicate whether a patient is entering the terminal stages of their illness but practice shows that the following signs are suggestive:

- increasing breathlessness and thus becoming increasingly housebound
- increasing oxygen requirements
- declining pulmonary function test results
- increasingly frequent exacerbations requiring hospital admission and/or non-invasive ventilation
- developing cor pulmonale
- weight loss and difficulty maintaining weight
- anxiety and depression
- if the death of the patient within the next year would not be a surprise

Symptom control

The symptoms suffered by patients with terminal respiratory disease are often indistinguishable from those experienced by patients with terminal cancer. Recently, the focus has moved towards advance care planning and symptom control. Most commonly, a patient with lung cancer will be cared for by a multidisciplinary team often consisting of respiratory doctors, oncologists, a specialist lung cancer nurse, and palliative care teams, whereas it is the 'Hospital at Home' teams who mainly support patients with chronic respiratory conditions in the community. For the final phases of life, many hospitals have adopted a protocol such as the Liverpool Care Pathway in order to standardize the care received by the dying patient, with a primary aim of reducing any unnecessary interventions, such as routine observations or blood tests, and focusing on improving patient comfort at a time when death is inevitable. Good symptom control benefits both the patient and their loved ones and the management of the most common symptoms is as follows:

Anxiety and dyspnoea: Cochrane reviews have suggested a three-step approach. Non-pharmacokinetic therapies such as relaxation techniques, diaphragmatic breathing, and the use of handheld fans are the first-line treatments. Second-line therapies involve the use of small doses of opiates, such as 1–10 mg morphine sulfate solution, as required. Third-line agents include the use of short-acting benzodiazepines, such as 0.5–1 mg sublingual or oral lorazepam, 5 mg diazepam, or 1–3 mg subcutaneous midazolam, as required. The risk of opiate- or benzodiazepine-related respiratory depression in breathless or hypoxic patients is a concern for many doctors, yet the situation rarely occurs in practice, provided small doses of the medication are used.

Respiratory tract secretions: Subcutaneous hyoscine hydrobromide 400–600 µg every 4–8 hours can help settle this distressing symptom. A dry mouth is a potential side effect; if this occurs, glycopyrronium 200 µg subcutaneously every 4 hours is a good alternative.

Pain: Aim to work up the WHO pain ladder. Once opiates are required, morphine sulfate solution and then subcutaneous morphine or diamorphine are the first-line analgesics. The medication can be given via a syringe driver if multiple doses are required. Pain

from bony metastases can be treated with localized radiotherapy and bisphosphonates.

Agitation: Haloperidol 1–3 mg or lorazepam 0.5–1 mg, subcutaneous or oral, can be given as needed.

Nausea: Increasing doses of opiates, particularly in an opiate-naive patient, can cause nausea and vomiting. Good anti-emetics include cyclizine 50 mg three times daily, metoclopramide 10 mg three times daily, and haloperidol starting at 1.5 mg twice daily. If first-line therapies fail, levomepromazine via a syringe driver at a dose of 5–25 mg per 24 hours can be tried.

Loss of appetite: This is very common and can lead to respiratory muscle weakness and exacerbate preexisting breathlessness. This may be due to the cachexia–anorexia syndrome or it could be due to related problems such as oral candidiasis, nausea, or depression. The underlying cause should be treated. Nutritional supplements should be considered in addition to usual meals. In the short term, 20 mg prednisolone for several weeks can help improve the appetite.

Common symptoms in respiratory disease

Haemoptysis

Haemoptysis is a very distressing symptom, particularly when profuse. The usual approach of intubation and bronchoscopy in massive haemoptysis is unlikely to be appropriate in a patient who, for example, has end-stage lung cancer with a tumour adjacent to a large vessel. In this instance, haemoptysis should be anticipated and treated palliatively with anxiolytics and opiates. Less severe haemoptysis can be controlled using tranexamic acid 500 mg orally three times a day.

Pleural effusion

The main causes of pleural effusion are primary lung cancer and pleural metastases. Drainage of the effusion is a palliative measure and should only be performed if the patient is breathless, able to tolerate a chest drain, and likely to survive for sufficient time to feel any benefit. Talc pleurodesis is recommended if the effusion is likely to recur; however, the pleural inflammatory reaction can result in flu-like symptoms, chest pain, and, uncommonly, pulmonary infiltrates.

Fluid retention

Fluid retention forms part of the cor pulmonale syndrome as a result of renal hypoxia, and patients frequently find the leg oedema distressing. Oxygen and diuretics comprise the mainstay of treatment but a balance between mobility, trips to the bathroom, renal function, and control of the oedema needs to be struck.

Intractable cough

For intractable cough, nebulized 0.9% saline and simple cough linctus can be tried. An opiate, such as codeine 30 mg four times daily or morphine sulfate solution 5–10 mg when required, is the preferred choice.

Hypercalcaemia

Hypercalcaemia is often secondary to squamous cell cancers and bone metastases and causes dehydration, confusion, and abdominal pain. Treatment involves IV rehydration with around 4 l of saline over 24 hours, with the concurrent administration of a bisphosphonate. Good choices are disodium pamidronate 30–90 mg IV, zoledronic acid 4 mg IV, or sodium clodronate 300 mg IV daily for 7–10 days or 1.5 g as a single dose.

Advance care planning

Involving the patient and their loved ones in the decision-making regarding future treatment and care in terminal respiratory illness can help alleviate distressing symptoms such as anxiety and fear. Ideally, this is best done when the patient is in a stable condition, in quiet room, and when there is plenty of time to address any concerns. The acute management of poorly inpatients prompts a similar discussion, although, ideally, these topics should be covered early in the admission rather than at the moment when the patient's condition deteriorates. The most important areas to cover are:

- whether the patient wishes to be admitted to hospital if their health deteriorates for any reason
- whether the patient would agree to try non-invasive ventilation should it be required
- whether intensive care treatment, ventilation, and resuscitation would be appropriate based on spirometry results, baseline level of function, quality of life, and underlying diagnosis
- whether the patient has a desired place of care for the end of their life

Discussing the practical issues surrounding dying can help patients regain a sense of control over their future, and approaching the following areas can be helpful:

Making a will and planning a funeral: This enables a nominated executor to follow the patient's wishes regarding the division of their estate, and their desired funeral.

Lasting power of attorney: The nomination of one of the next of kin to hold the lasting power of attorney allows that person to make decisions regarding the patient's welfare and finances in the patient's best interests. The process requires a solicitor and the patient to demonstrate capacity.

Advance directive (living will): This document allows a patient to express their wishes regarding future treatment within specific situations. It can include information about cardiorespiratory resuscitation and assisted ventilation. It is wise to involve a solicitor in this process.

Specific respiratory situations

Chronic respiratory failure

The main causes of chronic respiratory failure are COPD, bronchiectasis, pulmonary fibrosis, and neuromuscular disease. The management of these conditions in the terminal phases are outlined in 'Symptom control'; however, patients with neuromuscular disease managed on nasal intermittent positive pressure ventilation (NIPPV) may experience an increasing reliance on ventilatory support requiring nocturnal then daytime NIPPV. Handheld mouthpieces can allow the patient to 'sip' the NIPPV whenever they wish and can alleviate

breathless. Advance care planning is important, and this group of patients in particular are often known to the palliative care services. Hospice admissions are common as their condition deteriorates. During the patient's final hours or days, the decision to switch off the NIPPV machine is often made and the end-of-life medications are given as required.

Acute respiratory failure

All pulmonary conditions can cause acute respiratory failure. In these situations, the ceiling of treatment depends upon the underlying diagnosis and the premorbid function of the patient. If the patient is extremely unwell and previously had a good quality of life, consideration should be given to invasive ventilation. However, if ward care is felt to be more appropriate, the patient can be trialled on non-invasive ventilation such as continuous positive airway pressure or NIPPV. In all these scenarios, the deterioration of the patient's condition should prompt a discussion with the relatives regarding removing the ventilatory support. Once the decision for palliative treatment is made, the end-of-life medications are administered.

Lung cancer

The prognosis and progression to the terminal phase is largely dependent upon the staging of the cancer. Best supportive care and symptom control measures in lung cancer can involve interventions such as stenting in superior vena cava obstruction, low dose radiotherapy in chest wall pain and low grade haemoptysis from invasive tumours. However, these interventions would not be appropriate for a person entering the final phase of life and the symptom control measures discussed previously would be more appropriate.

PART 5

Intensive care medicine

147 Critical illness

Matt Wise and Paul Frost

Defining critical illness

Critical illness can be considered to be any disease process which causes physiological instability that leads to disability or death within minutes or hours. Fortunately, physiological instability associated with critical illness is easily detected by perturbations of simple clinical observations such as blood pressure, heart rate, respiratory rate, oxygen saturations, level of consciousness, and urine output. Individual abnormalities in these observations are sensitive for the presence of critical illness but non-specific. Unfortunately, poor specificity may contribute to their importance in an individual patient being overlooked. Specificity for critical illness improves as the number of abnormal clinical observations increases. Indeed, the risk of death at 30 days for ward patients can be calculated by the number of these observations that are abnormal, being 0.7% for none, 4.4% for one, 9.2% for two, and 21.3% for three or more.

Over recent years, a greater appreciation of the importance of deviations in simple clinical observations as a method of detecting critical illness has led to the development of a number of 'early warning' or 'track and trigger' systems. These systems attribute a score according to the magnitude and number of abnormal observations that are present, and a high score prompts immediate medical review. Although intuitively sensible, the evidence that these systems are effective in ameliorating or preventing critical illness is currently lacking.

Many routine observations that track physiological instability, particularly respiratory rate, are not reliably recorded either by omission or inter-observer error. Moreover, in the UK there has been no standardized rapid response system with hospitals deploying different early warning scores. In an attempt to address these shortcomings, the Royal College of Physicians has produced the National Early Warning Score (NEWS), which provides for a graded response strategy to acute illness (see Table 147.1 and go to <http://www.rcplondon.ac.uk/national-early-warning-score> for the full details of NEWS, as well as a detailed observational chart).

Approach to diagnosing critical illness

It remains a common problem that healthcare professionals fail to recognize when a patient is critically ill, and this leads to excess morbidity and mortality. As with any illness, it is impossible to make a diagnosis unless it is specifically considered. One can think of two

groups of patients with critical illness: in the first, the aetiology of their critical illness is already known (e.g. a pneumonia); in the second, it remains to be established. The approach to diagnosing critical illness differs from the routine clerking and management of patients in whom critical illness is not present, as it involves a focused examination combined with treatment.

The referral route of potentially critically ill patients may be diverse and include another doctor, a nurse, a physiotherapist, a dietician, or even a visitor. The referral needs to be taken seriously and not dismissed because of the role of the referrer. Outcomes in the critically ill are time dependent, and lengthy interrogation of the referrer is inappropriate. However, it is important to ascertain the patient's name, age, location, diagnosis (if known), and resuscitation status. Assessment of the patient begins with an introduction to the patient by the examiner. This immediately provides information about the patient's level of consciousness. Lengthy history taking is inappropriate, but the patient should be briefly questioned about any key symptoms, such as pain or breathlessness. In many cases, the patient will be too ill to provide any direct information and this will be obtained later from other sources, such as notes, charts, other healthcare workers, or visitors.

A brief structured examination should be performed which follows the Airway, Breathing, Circulation, Disability (conscious state), and Exposure (ABCDE) approach. Critically ill patients have little physiological reserve and tolerate prolonged examination and changes in body position poorly. This structure of examining for critical illness is fundamentally different to the standard approach to examination because it focuses on key clinical observations which are abnormal in critical illness, but it also combines treatment with examination. Thus, if a patient has an obstructed airway, further examination is futile unless airway patency is restored, as this is a prerequisite for survival. The ABCDE approach is more than a simple mnemonic but represents a hierarchy to patient survival. For example, a reduced level of consciousness (D) may be the consequence of hypotension (C) caused by haemorrhage; similarly, hypotension (C) may be the result of hypoxia (B) caused by airway obstruction (A). As soon as critical illness is recognized, help should be sought; in some cases, this might require a medical emergency or cardiac arrest team.

Airway

The airway must be patent and this can be assumed if the patient can speak to the individual performing the examination. Partial

Table 147.1 Clinical response to National Early Warning Score (NEWS) triggers

NEWS score	Frequency of monitoring	Clinical response
0	Minimum 12 hourly	Continue routine NEWS monitoring with every set of observations
Total: 1–4	Minimum 4–6 hourly	Inform registered nurse who must assess the patient; Registered nurse to decide if increased frequency of monitoring and/or escalation of clinical care is required;
Total: 5 or more or 3 in one parameter	Increased frequency to a minimum of 1 hourly	Registered nurse to urgently inform the medical team caring for the patient; Urgent assessment by a clinician with core competencies to assess acutely ill patients; Clinical care in an environment with monitoring facilities;
Total: 7 or more	Continuous monitoring of vital signs	Registered nurse to immediately inform the medical team caring for the patient—this should be at least at Specialist Registrar level; Emergency assessment by a clinical team with critical care competencies, which also includes a practitioner/s with advanced airway skills; Consider transfer of Clinical care to a level 2 or 3 care facility, i.e. higher dependency or ITU;

Reproduced with permission from National Early Warning Score (NEWS): Standardising the assessment of acute-illness severity in the NHS, Working party report, July 2012, Royal College of Physicians (www.rcplondon.ac.uk/national-early-warning-score).

airway obstruction leads to noisy breathing and is common if consciousness is impaired. Partial obstruction may occur at several levels within the airway and lead to characteristic sounds, such as snoring (tongue obstructing the oropharynx), stridor (obstruction at larynx by oedema, a foreign body, or a tumour), and wheeze (bronchospasm of small airways). Obstruction of the oropharynx by the tongue in an unconscious patient can be relieved by simple airway manoeuvres, such as a chin lift or jaw thrust. The oropharynx should be inspected and any foreign body such as dentures, food, vomit, or blood removed. If airway patency cannot be restored by these simple measures, then experienced help should be sought. The inappropriate insertion of airway adjuncts or suction catheters into semi-conscious patients can precipitate laryngospasm and complete airway obstruction. Endotracheal intubation or surgical airway placement should only be performed by appropriately trained staff.

Complete airway obstruction is uncommon; there is no movement of air at the mouth, and paradoxical movement of the chest and abdomen. It requires immediate intervention by an individual trained in airway management, as cardiac arrest and death will occur within minutes.

High-flow oxygen should be applied to all patients to avoid hypoxia.

Breathing

Observation is the most rewarding aspect of examining the breathing system. The respiratory rate should be recorded. Tachypnoea (>20 breaths/min) is the most frequent physiological abnormality amongst patients admitted to the ICU. Patient may also have a reduced respiratory rate (<8 breaths/min) as a consequence of drugs or CNS infection or trauma. The respiratory pattern should be noted and brief auscultation performed. Reduced chest expansion always occurs on the side of disease (pneumonia, pneumothorax, haemothorax, collapse). A pulse oximeter must be applied and the oxygen saturations recorded.

Hypoxaemia can precipitate cardiac arrest, and oxygen must be applied with the aim of maintaining saturations >90%. Oxygen is administered by using a mask with a reservoir bag and a non-rebreathing valve and at high flow (15 l/min), as this will achieve an inspired oxygen of >80%. An arterial blood gas should be performed on oxygen to assess the adequacy of oxygenation (as determined by the oxygen saturation (SaO₂), the partial pressure of oxygen (PaO₂), and the alveolar–arterial oxygen gradient) and ventilation (as determined by the partial pressure of carbon dioxide (PaCO₂) and by pH). It may also provide information about the acid–base balance and the circulation (via the base deficit, pH, and lactate level). Lactate is frequently raised in critical illness often long before other indices, usually reflecting an inadequate circulation and a switch to anaerobic metabolism. Removal of oxygen to perform an arterial blood gas is dangerous, as it may precipitate cardiorespiratory arrest, and is therefore avoided. In patients with COPD and type II respiratory failure, a small proportion of individuals retain carbon dioxide on oxygen. In these patients, it is acceptable to initiate a fixed-performance oxygen mask delivering inspired oxygen of 40%. The amount of oxygen delivered can be titrated upwards if oxygen saturations fall to <90%, and downwards if SaO₂ is >93% or consciousness decreases. Oxygen saturations <90%, a rising PaCO₂, and a falling Glasgow Coma Scale (GCS) score indicate ventilatory support is needed.

Diagnosis of a tension pneumothorax requires immediate intercostal tube drainage before proceeding to examination of the circulation system.

Circulation

Circulatory dysfunction is characterized by hypotension (systolic blood pressure <90 mm Hg or showing a drop of 30 mm Hg), tachycardia, bradycardia, prolonged capillary refill, low urine output (<0.5 ml/kg hour⁻¹), a falling GCS, raised arterial lactate, and acidosis. It is useful to know the patient's usual blood pressure, as an apparently normal value may represent hypotension in an individual who is normally hypertensive. Circulatory shock can exist in the absence of hypotension, especially in young individuals who have a large physiological reserve. IV access should be set up, and continuous ECG and blood-pressure monitoring established. Invasive blood-pressure monitoring has an advantage in that it is continuous and that

it allows arterial samples to be drawn easily for blood gas analysis. A rapid infusion of fluid is a prerequisite when circulatory failure exists (fluid challenge). The fluid should be given as a bolus of 250–500 ml over a period of 10–15 min. Response to treatment is judged against improvements in blood pressure, pulse, capillary refill, urine output, GCS score, lactate levels, and cardiac output, if this is being measured. Further aliquots may be given if there is a response to therapy. Even in cardiogenic shock, fluid may result in improved tissue perfusion; however, it should be avoided if there is evidence of pulmonary oedema.

Disability

The patient's conscious state should be assessed by recording a response to verbal or painful stimuli. Either a GCS score or the simpler AVPU (alert, voice, pain, unresponsive) score may be used. The response of pupils to light should also be recorded, and a blood sugar taken. Hypoglycaemia must be corrected immediately and the patient's conscious state reassessed. If the GCS score is <8, the patient is unlikely to protect their airway and may aspirate. Endotracheal intubation is indicated under these circumstances, and not only protects the airway but may also facilitate further investigations (such as CT) or treatment (such as surgery).

Exposure

The patient should be fully exposed. Pay particular attention to details such as drains, wounds, deformities, bruising or haematomas, and rashes.

Response to treatment

At each stage of the ABCDE approach, response to any treatment should be assessed. Following resuscitation, outcome depends on establishing the cause of critical illness and having a definitive management plan. A thorough review of notes, charts, investigations, and a corroborative history is appropriate at this stage. Extensive needless history and examination may precipitate further decline. Emphasis should be placed on key findings that will define the management plan, such as a history of abdominal pain, and signs of peritonitis. Definitive treatment and investigation, such as echocardiography for acute mitral regurgitation, CT for suspected subdural haematoma, removal of an infected central line in sepsis, surgical drainage of abscesses, coronary reperfusion in myocardial infarction, and repair of a ruptured abdominal aortic aneurysm, should not be delayed, as this increases mortality.

It is always important to consider in critically ill patients, if treatment is futile and the patient is already destined to die, whether any advanced directives or resuscitation orders are in place. These decisions should ideally be made with the involvement of the consultant in charge.

Pitfalls in diagnosing critical illness

Failure of critically ill patients to improve with the plan of treatment should always prompt one to consider if the diagnosis is correct or whether a new complication has arisen.

Young, previously fit individuals have a large physiological reserve and often initially tolerate a catastrophic insult with little physiological instability prior to cardiac arrest. For example, following a road traffic accident, a young patient with impact to the chest but without any fractures may have little complaints other than pain. The only abnormal findings might be tachycardia, hypertension, and a raised lactate. This should prompt investigations for causes of shock, such as a ruptured spleen or acute aortic valve rupture.

148 Role of the intensive care unit

Matt Wise and Paul Frost

Organization

The intensive care unit (ICU) can be defined as an area reserved for patients with potential or established organ failure and has the facilities for the diagnosis, prevention, and treatment of multi-organ failure. Usually, the ICU is located in close proximity to the emergency department, the radiology department, and the operating theatres, as it is between these areas that patient flows are greatest.

In large urban hospitals, there may be more than one ICU, some of which serve specific patient populations, such as paediatrics, neurosurgery, cardiothoracic surgery, liver failure, and burns. Many hospitals also have high-dependency units (HDUs) that offer higher nurse-to-patient ratios and more advanced monitoring than a general ward does, as well as limited organ support.

In the UK, the distinction between ICU, HDU, and general ward has been abandoned in favour of a classification based on the patient's needs rather than their location (Table 148.1).

One advantage of this classification is that it increases capacity when compared to the same number of fixed HDU and ICU beds, because there can be flexing between Level 2 and Level 3 beds, depending on patient demand. Despite a recent large investment in critical care services and an expansion in the number of Level 2 and Level 3 beds, the UK still has less capacity than many other European countries.

The ICU may function as either a 'closed' unit or an 'open' unit. This nomenclature refers to how care is undertaken by medical staff. In a closed unit, trained resident intensivists direct all patient care, while, in an open unit, the intensivist is consulted at the discretion of the admitting physician. The closed model of care is associated with a reduction in both morbidity and mortality.

In the UK, many ICUs have developed outreach services with the aim of improving the care of general ward patients at risk or recovering from critical illness. The three main aims of outreach are (1) to identify which ward patients are at risk of critical illness and either avert or facilitate admission, as appropriate, (2) to ensure safe discharge, and (3) to improve critical care skills outside the ICU.

Case mix

Admissions to the critical care unit may be either elective following complex planned surgery or as an emergency in a patient who has become critically ill. The latter tends to form the majority of cases in the ICU, although there are exceptions, such as cardiothoracic ICUs where patients are admitted following elective surgery. It has been recognized for several years that many patients who are admitted to ICU, as emergencies or who sustain a cardiorespiratory arrest on a ward, have a prolonged physiological deterioration that has often gone unrecognized. This has led to greater emphasis on training healthcare workers to recognize critical illness, and a number of specialist postgraduate courses on this topic are available (e.g. Acute Life-threatening Events Recognition and Treatment

(ALERT), Ill Medical Patients' Acute Care and Treatment (IMPACT), Care of the Critically Ill Surgical Patient (CCrISP)).

It does not follow that all critically ill patients require admission to ICU, as many patients will be dying from irreversible end-stage disease. These decisions, and the recognition that further treatment may be futile, are complex. It is for these reasons that potential admissions to critical care should be discussed between the consultant from the referring team, and the consultant intensivist. Generally, patients deemed suitable for ICU admission should have one or more organ failures but a reasonable prospect of recovery to a level of function that is acceptable to the patient. Clearly, there is great variability amongst patients as to what represents a reasonable level of function, and this should be discussed directly with patients or relatives when the opportunity arises.

Management

Referring physicians may have patients admitted infrequently to ICU and therefore have limited contact with this service. Consequently, physicians without previous exposure to ICU may be unfamiliar with what happens to patients in this area and what might be expected when visiting ICU. However, in practice, intensive care medicine should be considered as an extension of general medicine, albeit with more sophisticated monitoring and organ support. The cornerstone of managing any patient in ICU is to establish the correct diagnosis so that an appropriate management plan can be embarked upon. For example, two identical patients may be admitted with respiratory failure: in one, caused by acute asthma; in the other, due to community-acquired pneumonia. Although both patients may require similar support (i.e. endotracheal intubation, mechanical ventilation, sedation, fluid therapy, and enteral feeding), the treatment and expected course of recovery between the two are very different. It is, therefore, insufficient to monitor and 'correct' physiological abnormalities without a diagnosis or plan of treatment.

History and examination

As is the case for patients without critical illness, a detailed history is essential in making a diagnosis. However, little of this may be available from the patient and instead must be obtained from notes, charts, other healthcare workers, or relatives. Examination of the patient remains an important facet of diagnosis but is generally more difficult than in patients who are not critically ill. In particular, sedation, analgesia, and ambient noise may confound aspects of the clinical examination, for example, limiting neurological examination and making auscultation impossible. Moreover, critically ill patients have limited physiological reserves and tolerate changes in body position for clinical examination poorly. Great care must be taken to avoid the accidental removal of medical devices such as the endotracheal tube, IV lines, and monitoring leads. The bedside nurse can be of

Table 148.1 Needs-based classification of high-dependency areas in hospital

Level	Description
0	Patients whose needs are met by normal ward care in acute hospitals
1	Patients at risk of deterioration, or recently moved from higher levels of care and whose needs can be met on a ward with additional support from intensive care
2	Patients requiring single-organ support or post-operative care, or stepping down from Level 3
3	Patients requiring advanced respiratory support (intubation) alone, or the support of two other organ systems

great help in assisting with these issues so that the examination can be performed safely. Many important aspects of the clinical examination can be accomplished by careful inspection alone of, for example, line sites and wounds for evidence of infection.

Investigation

The majority of hospital investigations are available to the critically ill patient and, given the difficulties of clinical examination, imaging is particularly important. However, transfer of a physiologically unstable patient, for example, for CT, requires careful consideration of the risks and benefits of the investigation being undertaken.

Treatment

Most patients in the ICU will be suffering from one or more organ failures. Although no therapies can reverse this process, most organ failures can be monitored and supported while the underlying disease is treated, as follows:

- respiratory organ failure:
 - monitoring: pulse oximetry, arterial blood gases, capnography, flow-volume loops, respiratory mechanics, chest radiograph, pleural ultrasound, CT chest, bronchoalveolar lavage
 - support: invasive or non-invasive ventilation, continuous positive airway pressure, inhaled nitric oxide or prostacyclin
- cardiovascular organ failure:
 - monitoring: ECG, arterial pressure, central venous pressure, echocardiography, cardiac output measurement, lactate, central mixed venous oxygen saturations
 - support: vasopressors, cardiac pacing, antiarrhythmic drugs, intra-aortic balloon pump, ventricular assist device
- renal organ failure:
 - monitoring: urine analysis, urine output, ultrasound
 - support: intermittent or continuous renal replacement therapy
- gastrointestinal organ failure:
 - monitoring: abdominal radiographs, ultrasound, CT, gastric aspirate volumes, gastric tonometry, intra-abdominal pressure
 - support: enteral or parenteral nutrition, laparostomy, prokinetic drugs
- liver failure:
 - monitoring: liver function tests, ultrasound, indocyanine green dye clearance
 - support: molecular absorbents recirculation system
- neurological organ failure:
 - monitoring: CT, MRI, PET, CT angiography, intracranial pressure monitoring, jugulovenous bulb oximetry, CSF sampling, EEG, microdialysis
 - support: sedation, osmotherapy, cooling, barbiturate coma, CSF drainage

Visiting

Good communication is essential when attending the ICU, and visiting physicians should introduce themselves and their reason for seeing the patient. Any opinions regarding the patient should be discussed with the intensivist and clearly documented in the notes. Critically ill patients are particularly susceptible to nosocomial infection, which is an important attributor to morbidity and mortality. Care must be given to preventing horizontal cross infection, which can be greatly reduced by the use of alcoholic hand gel prior to patient contact. White coats may also be a vector for infection and should be left outside.

Discharges

Discharge from the ICU at night is associated with higher mortality and should be avoided if possible, particularly as many hospitals have reduced medical cover during this period compared to daytime levels. There should be handover of the patient to the receiving physician, outlining the diagnosis, treatment, and any outstanding issues such as pending investigations. A plan should also be in place as to what will happen if the patient subsequently deteriorates, as readmission to ICU may not be appropriate. Ideally, this handover should be performed at the bedside rather than over the telephone, so that both parties have a visual record of the patient. This information should also be clearly documented in the notes.

Outcomes

Mortality varies depending on the case mix of patients; however, a figure of 20%–30% in a general ICU would not be unrepresentative. A number of scoring systems such as the Acute Physiology, Age, Chronic Health Evaluation (APACHE) system or the Simplified Acute Physiology Score (SAPS) have been developed to predict patient outcome. However, these scoring systems describe outcome in groups of patients, not in individuals, and expert opinion is important in estimating outcome. Unfortunately, many patients do not survive ICU. Following death, the referring physician and general practitioner should be informed and hospital records should be amended so that any outstanding appointments can be cancelled. Many ICU now offer a bereavement follow-up service for relatives.

149 ICU treatment of respiratory failure

Matt Wise and Paul Frost

Definition of the disease

Respiratory failure is a syndrome characterized by defective gas exchange due to inadequate function of the respiratory system. There is a failure to oxygenate blood (hypoxaemia) and/or eliminate carbon dioxide (hypercapnoea). Generally, hypoxaemia is defined as a value for the partial pressure of oxygen in arterial blood (PaO_2) of <8 kPa, and hypercapnoea as a value for the partial pressure of carbon dioxide in arterial blood (PaCO_2) of >6 kPa. Type I respiratory failure describes hypoxaemic respiratory failure with a low or normal PaCO_2 , while type II respiratory failure is characterized by an elevated PaCO_2 . Type II failure frequently follows type I as the 'respiratory pump' fatigues.

Respiratory failure can develop over years when it is due to conditions such as kyphoscoliosis or motor neuron disease, or minutes in the case of an acute asthma attack or pneumothorax. In this context, respiratory failure is often called acute (e.g. asthma), chronic (e.g. kyphoscoliosis), or acute on chronic (kyphoscoliosis complicated by pneumonia). Chronic respiratory failure is characterized by compensatory mechanisms which aim to adjust the pH of the blood back to the normal physiological range and involve the retention of bicarbonate by the kidney.

Aetiology of respiratory failure

Hypoxia may be caused by:

- low inspired oxygen (altitude)
- a right-to-left shunt
- diffusion limitation
- alveolar hypoventilation
- ventilation-perfusion mismatch

Ventilation-perfusion mismatch is by far the commonest cause of hypoxic respiratory failure.

Hypercapnoea results from alveolar hypoventilation and may be caused by:

- abnormalities of the chest wall
- depressed respiratory drive
- neuromuscular disease
- increased dead space ventilation

Conditions causing respiratory failure in intensive care include:

- pneumonia (community-acquired pneumonia, healthcare-associated pneumonia, hospital-acquired pneumonia, or ventilator-associated pneumonia (VAP))
- COPD
- asthma
- pulmonary oedema (cardiogenic pulmonary oedema, drug-induced pulmonary oedema, or negative pressure pulmonary oedema)
- pleural disease (pneumothorax, pleural effusions, haemothorax, empyema, chylothorax)
- pulmonary embolus
- adult respiratory distress syndrome (ARDS)
- sputum retention
- drug overdose (opiates, barbiturates, benzodiazepines, gamma-hydroxybutyric acid (GHB))
- central nervous system disease (subarachnoid haemorrhage, traumatic brain injury, stroke, tumour, meningitis, encephalitis)
- aspiration pneumonia
- chest wall deformity (flail chest/rib fractures, kyphoscoliosis, obesity)
- neuromuscular diseases (Guillain-Barré syndrome, spinal injury, myasthenia gravis, motor neuron disease, muscular dystrophy, poliomyelitis)

- hypothyroidism
- tetanus
- obesity hypoventilation syndrome
- pulmonary hypertension
- interstitial lung disease

This list is large but not exhaustive: although some conditions are rare, all (with the exception of polio) have been encountered by the authors in UK intensive care patients. Respiratory failure is often multifactorial in critically ill patients, for example, in an obese, narcotized patient with sputum retention following a laparotomy.

Typical and less common symptoms and signs of respiratory failure

The patient symptoms vary depending on the disease that is leading to respiratory failure; however, dyspnoea, chest pain, cough, snoring, haemoptysis, or headaches may be present. The signs of acute respiratory failure are non-specific and include:

- abnormal respiratory rate (>20 (? >30) or <8 breaths/min)
- tachycardia initially, proceeding to bradycardia and cardiac arrest
- hypotension
- vasoconstriction (hypoxia) or vasodilation (hypercapnoea)
- central cyanosis
- confusion, agitation, drowsiness, seizures, coma

Significant respiratory failure may be present with few symptoms or signs. Therefore, following assessment of the patient, if there is a suspicion that the patient is in respiratory failure, an arterial blood gas should be rapidly obtained.

Demographics of the disease

Respiratory failure is one of the commonest causes of admission to ICU.

Natural history and complications of the disease

Respiratory failure has many causes. Therefore, the natural history of the disease, as well as its complications, and outcome, reflects the underlying disease and patient comorbidities.

Approach to diagnosing respiratory failure

The cornerstone of managing patients with respiratory failure is to establish that they are, in fact, in respiratory failure and then define the underlying aetiology. The diagnosis may be suspected if the patient is known to have a disease (e.g. motor neuron disease or asthma) which may progress or be complicated by respiratory failure. Individuals in whom the onset is acute or acute on chronic are critically ill and may rapidly progress to coma and death. Hypoxaemia and hypercapnoea define respiratory failure but the symptoms and signs attributable to these abnormalities are non-specific and largely cause perturbations of the respiratory, cardiovascular, and neurological systems. An approach to the diagnosis and management of these patients requires a brief history and a clinical examination focused on simple, physiological variables along the lines of the Airway, Breathing, Circulation, Disability, and Environment (ABCDE) approach. It is essential to remember that 'ABCDE' is more than a simple mnemonic but represents a hierarchy of abnormalities which determine patient survival. If the airway is obstructed, attempts to correct hypoxia and the subsequent

hypotension and bradycardia will prove unsuccessful unless airway patency is restored. This approach involves both examination and treatment of the patient.

An arterial blood gas sample should be obtained to confirm the diagnosis of respiratory failure. Many emergency departments and critical care units have point-of-care blood gas analysers. If the sample is being transported to a laboratory, it should be on ice, with any air bubbles expelled to avoid spurious values. Respiratory failure is present when the PaO_2 is <8 kPa and/or the PaCO_2 is >6 kPa. However, in acutely ill patients, oxygen should not be removed to perform an arterial blood gas, as this may precipitate cardiorespiratory arrest due to hypoxia. Adequate oxygenation should be maintained by delivering sufficient inspired oxygen to maintain oxygen saturations $>90\%$ on pulse oximetry. The extent to which oxygenation is impaired may instead be established by using the alveolar gas equation to calculate the alveolar-to-arterial (A–a) gradient. The normal range of the A–a gradient is 2–4 kPa (but increases with age and at inspired oxygen concentrations above 28%) and is a reflection of imperfect ventilation–perfusion matching in normal lungs. The A–a gradient will be normal in hypoxia due to pure hypoventilation and no intrinsic lung disease, and elevated in respiratory failure due to lung pathology:

$$\text{A–a gradient} = \text{PAO}_2 - \text{PaO}_2,$$

where PAO_2 is the partial pressure of alveolar oxygen, which can be determined from the alveolar gas equation

$$\text{PAO}_2 = \text{FIO}_2 (\text{atmospheric pressure} - \text{water vapour pressure}) - 1.25(\text{PaCO}_2),$$

where FIO_2 is the percentage inspired oxygen. Thus, the A–a gradient can be calculated as

$$\text{A–a gradient} = [\text{FIO}_2 (\text{atmospheric pressure} - \text{water vapour pressure}) - 1.25(\text{PaCO}_2)] - \text{PaO}_2$$

This equation can be used to evaluate the A–a gradient under various circumstances, as in the following two scenarios (both at sea level, where the atmospheric pressure is 101 kPa, and the water vapour pressure is 6.3 kPa):

1. Morphine overdose (pure hypoventilation), with the patient on air (which is 21% oxygen); $\text{PaO}_2 = 7$ kPa, and $\text{PaCO}_2 = 8.8$ kPa:

$$\begin{aligned} \text{A–a gradient} &= [0.21(101 \text{ kPa} - 6.3 \text{ kPa}) - 1.25(\text{PaCO}_2)] - \text{PaO}_2 \\ &= (19.9 \text{ kPa} - 11 \text{ kPa}) - 7 \text{ kPa} \\ &= 1.9 \text{ kPa} \text{ (normal A–a gradient)} \end{aligned}$$

2. Acute pulmonary oedema, with the patient on an inspired oxygen concentration of 40%; $\text{PaO}_2 = 15$ kPa, and $\text{PaCO}_2 = 5.6$ kPa:

$$\begin{aligned} \text{A–a gradient} &= [0.40(101 \text{ kPa} - 6.3 \text{ kPa}) - 1.25(\text{PaCO}_2)] - \text{PaO}_2 \\ &= (37.9 \text{ kPa} - 7 \text{ kPa}) - 15 \text{ kPa} \\ &= 15.9 \text{ kPa} \text{ (elevated A–a gradient)} \end{aligned}$$

A rough guide to estimating what the PAO_2 should be for a patient on oxygen if there is no lung pathology is to subtract 10 from FIO_2 . In the second scenario, where the inspired oxygen concentration is 40%, this would give a PAO_2 of $40 - 10 = 30$ kPa for normal lungs; as the measured PaO_2 was 15 kPa, the 'guesstimated' A–a gradient would be 15 kPa (i.e. $30 \text{ kPa} - 15 \text{ kPa}$).

The arterial blood gas should be scrutinized to see if hypercapnoea is acute or chronic. Hypoventilation that occurs over a long period of time, such as in some neuromuscular disease, is accompanied by the retention of plasma bicarbonate and a shift of arterial pH back to the normal range. Acute rises in the PaCO_2 result in a respiratory acidosis and only small changes in plasma bicarbonate. A change in the PaCO_2 of 1 kPa causes a change of 0.06 pH units in the opposite direction.

Other diagnosis that should be considered

Patients with acute or acute on chronic respiratory failure are critically ill, and this syndrome should be considered in all critically ill patients. There are very few instances where it is not appropriate to obtain a blood gas in a critically ill patient, and this will establish a diagnosis of respiratory failure. Since the symptoms and signs of critical illness are non-specific, there are many instances where the patient may be thought on first inspection to be in respiratory failure. Thus, a patient with diabetic ketoacidosis may complain of dyspnoea and be extremely tachypnoeic (as a consequence of metabolic acidosis and increased work of breathing), and a similar presentation may be observed in severe sepsis. Potential pitfalls in the diagnosis of respiratory failure are due to misinterpretation of arterial blood gas samples. It is easy to establish if the patient is hypoxic or if a large A–a gradient exists. If there is evidence of hypercapnoea, one must remember to first look at the pH. Rarely, patients have a metabolic alkalosis (due to diuretics, nasogastric losses, or vomiting), which is partially corrected by alveolar hypoventilation (hypercapnoea), but the primary abnormality will be an alkalosis.

'Gold-standard' diagnostic test

Arterial blood gas analysis remains the best method for diagnosing acute respiratory failure.

Acceptable diagnostic alternatives to the gold standard

Pulse oximetry may be used to detect hypoxaemia non-invasively. However, this method gives no information about ventilation (PaCO_2); furthermore, several factors can adversely affect readings. These include poor peripheral perfusion; motion artefact; fluorescent lights; nail polish (causes falsely low or undetectable readings); carboxyhaemoglobin; and methaemoglobin (causes high readings).

Other relevant investigations

Investigations largely centre on establishing the disease that is causing respiratory failure and this will be determined by the history and examination. A focused clinical approach, rather than merely performing a panel of tests, is essential. However, the following investigations are commonly used and may be useful:

- full blood count (to determine leucocytosis or neutropenia (infection), polycythaemia (chronic hypoxia))
- blood biochemistry:
 - electrolytes (electrolyte disturbances may precipitate arrhythmias and muscle weakness)
 - amylase (to exclude pancreatitis)
 - thyroid function (thyroid disease can contribute to cardiac disease, muscle weakness)
 - creatinine kinase (to exclude cardiac or muscle disease)
 - troponin (to exclude ischaemic heart disease, myocarditis)
 - toxicology (to exclude overdose)
- samples for infectious causes (bacteria, viruses, mycobacteria):
 - blood cultures
 - sputum
 - bronchoalveolar lavage
 - nasopharyngeal swabs (influenza)
 - pleural fluid
 - CSF
- pleural fluid analysis:
 - protein
 - pH
 - lactate dehydrogenase
 - cytology
 - TB
 - amylase
- peak flow rate
- lung biopsy

- imaging:
 - chest radiography
 - ultrasound (to detect pleural disease)
 - CT chest (high resolution and/or volume, angiography); CT head (to exclude subarachnoid haemorrhage, which can lead to neurogenic pulmonary oedema); CT abdomen (to exclude peritonitis, pancreatitis)
 - ECG (to exclude ischaemia, arrhythmias)
 - echocardiography (for left ventricular function, diastolic dysfunction, regional wall abnormality, valve function, pericardial disease, pulmonary hypertension, pulmonary emboli)

Prognosis and how to estimate it

Respiratory failure is a syndrome with a wide aetiology and it is difficult to prognosticate. Even when looking at respiratory failure from a single cause such as pneumonia or ARDS, there is a wide variation in survival rates or hospital discharge between studies. Outcome is dependent on many variables, which include the age of the patient, comorbidities, and the degree of physiological deterioration before diagnosis and commencement of appropriate treatment. A number of scoring systems are used in intensive care, such as the Acute Physiology and Chronic Health Evaluation (APACHE), the Simplified Acute Physiology Score (SAPS), and the Sequential Organ Failure Assessment (SOFA), to define patient outcome. These scoring systems are similar in their predictive accuracy but describe outcome in groups of patients rather than in individuals, and therefore prognosis is often determined by expert opinion.

Treatment and its effectiveness

The cornerstone of managing respiratory failure is to provide organ support, establish the diagnosis, and treat the underlying disease. Resuscitation must be initiated as soon as respiratory failure is recognized and should follow the standard Airway, Breathing, Circulation (ABC) approach, so that immediate threats to life, such as airway compromise or tension pneumothorax, are addressed first. The patient should be managed in an appropriate area with trained staff and monitoring (e.g. respiratory rate, continuous ECG, oximetry, arterial line (blood pressure, arterial blood gas analysis), and Glasgow Coma Scale scoring).

Acute hypoxia is poorly tolerated and, if left untreated, may precipitate cardiorespiratory arrest. Oxygen should be administered. This may be by a fixed device (e.g. a Venturi mask) or via a variable-performance device (e.g. nasal prongs, Hudson mask, or non-rebreathing mask and reservoir bag). In most patients with respiratory failure, a non-rebreathing mask and reservoir bag should be used with high-flow oxygen (15 l/min) and will deliver inspired oxygen in excess of 60% (often approaching 100%). Oxygen saturations >90% represent adequate oxygenation, as most oxygen is carried bound to haemoglobin. Caution should be exercised in COPD patients who are hypercapnic, as approximately 5% of such patients retain more carbon dioxide when the hypoxic respiratory drive is removed. This can be managed with controlled oxygen therapy and repeat blood gas analysis.

Oxygen therapy alone is insufficient in many patients who require ventilatory support to improve oxygenation and eliminate carbon dioxide. This support may be administered as non-invasive positive pressure ventilation or as invasive ventilation via an endotracheal tube.

Non-invasive ventilation (NIV) is suitable for a proportion of critical care patients with respiratory failure. Although both volume- and pressure-cycled ventilators exist, the commonest modes of delivering non-invasive support are pressure-support ventilation, bi-level positive airway pressure (BIPAP) ventilation, and continuous positive airway pressure (CPAP). NIV is delivered to the airway via an interface, which may be a face mask, a nasal mask, a full-face mask, or a helmet. The advantages of NIV over invasive mechanical ventilation are that less sedation is needed, the patient retains the ability to talk, eat, and drink, and airway trauma and VAP are avoided.

CPAP is not a ventilatory mode per se, as it provides a constant pressure throughout the respiratory cycle; however, it improves oxygenation by increasing functional residual capacity and reduces the work of breathing and left ventricular afterload. It is commonly used in type I respiratory failure due to pulmonary oedema and pneumonia. In the pressure-support mode of CPAP, patients initiate, terminate, and control the size of breaths, while the ventilator delivers to a preset inspiratory

pressure. The BIPAP mode alternates between two levels of CPAP, with the switch between levels providing inspiratory drive. Both modes eliminate CO₂ as well as improve oxygenation. NIV is suitable for cooperative patients who have a rapidly reversible cause of respiratory failure and are haemodynamically stable, without severe acidosis. Excessive pulmonary secretions are a relative contraindication. Most frequently used in exacerbations of COPD, NIV has also been used in the treatment of pneumonia, ARDS, asthma, and pulmonary oedema.

Invasive mechanical ventilation is indicated in patients with a Glasgow Coma Scale score <8, apnoea, increasing acidosis, refractory hypoxia, an inability to clear secretions, or who are tiring and have a dyskinetic respiratory pattern and tachycardia. Following endotracheal intubation, the cuff pressure should be maintained <25 mm Hg to avoid tracheal necrosis. Patients in whom long-term ventilation (>7 days) is required may have the endotracheal tube replaced with a tracheostomy. The majority of tracheostomies are performed at the bedside using a percutaneous dilatational technique.

The terminology concerning modes of ventilation is often confusing, and explaining it is outside the scope of this text. Modern ventilators are complex devices allowing a change from mandatory to partial support modes that minimize sedation requirements and allow patients to be conscious but comfortable. Positive end-expiratory pressure (PEEP) is applied to all modes of invasive mechanical ventilation. The principles of ventilation in respiratory failure are:

- treat the underlying cause of respiratory failure
- avoid excessive fluid (which is associated with worse outcome in ARDS)
- set optimal PEEP and minimize FIO₂
- limit plateau pressures to <30 cm H₂O and avoid tidal volumes >6 ml/kg ideal body weight; both of these measures are associated with a reduction in ventilator-induced lung injury (e.g. barotrauma, atelectrauma, volutrauma, biotrauma) in ARDS but will often result in patients having a respiratory acidosis known as permissive hypercapnoea, in which the arterial pH will frequently be 7.2 or lower
- interrupt sedation at least daily (this reduces length of stay on ventilation, and VAP incidence)
- elevate the head of the bed to 30° (this reduces VAP incidence)
- perform microbiological surveillance for VAP
- maintain bronchopulmonary toilet (secretion clearance)
- provide stress ulcer prophylaxis (H₂ blocker or proton-pump inhibitor) and thromboprophylaxis
- provide enteral nutrition at an early stage
- ensure that blood glucose levels are controlled in the range 3.8–8.3 mmol/l
- extubate the patient and discontinue ventilation when the cause of respiratory failure has resolved

Note that some of these elements (i.e. sedation break, bed elevation, and DVT and stress ulcer prophylaxis) are grouped together and referred to as 'ventilator care bundles' because, when they are instituted together, there is a reduction in VAP.

150 ICU treatment of cardiovascular failure

Matt Wise and Paul Frost

Definition of the cardiovascular failure

Cardiovascular failure or shock is best defined as inadequate delivery or utilization of oxygen for cellular metabolic needs. The majority of shock states are characterized by limitations in perfusion rather than extraction of oxygen by tissues. It is important to recognize that ineffectual tissue perfusion may occur in the absence of hypotension and, therefore, a normal blood pressure does not exclude shock.

Aetiology of shock

Shock can be classified as cardiogenic, obstructive, hypovolaemic, or distributive according to the predominant underlying mechanism.

Cardiogenic shock

In cardiogenic shock, there is inadequate forward flow of blood from the heart. This most frequently occurs following acute myocardial infarction (MI) and complicates between 3% and 10% of infarcts. The incidence of cardiogenic shock following MI increases with failure to establish coronary reperfusion. Less frequent causes of cardiogenic shock include:

- acute valve dysfunction or rupture, most often due to infective endocarditis
- acute ventricular septal rupture complicating acute MI
- myocarditis
- myocardial contusion
- myocardial depression during septic shock (relatively common because of the high prevalence of septic shock)

Obstructive shock

Obstructive shock is defined by pathologies which restrict the outflow of blood from the heart:

- pulmonary embolus
- cardiac tamponade
- tension pneumothorax
- severe asthma

Hypovolaemic shock

Hypovolaemic shock is defined by a pathological reduction in circulating blood volume and is caused by:

- blood loss
- plasma loss

Distributive shock

Distributive shock is characterized by loss of peripheral vascular tone and maldistribution of blood flow:

- septic shock (cardiac output may be increased or decreased)
- spinal shock (disruption of the spinal cord above the sympathetic outflow T1–L2 leads to reduced sympathetic activity resulting in vasodilatation, hypotension, and bradycardia)
- Addisonian crisis
- fulminant hepatic failure
- anaphylactic shock (release of vasoactive histamine and prostaglandins; also accompanied by hypovolaemia due to increased vascular permeability)

It is important to remember that there may be considerable overlap between shock states. Distributive shock, which characterizes sepsis, is compounded by relative hypovolaemia and myocardial

depression. Moreover, sepsis with positive blood cultures may occur in up to a fifth of patients with cardiogenic shock. Cardiogenic shock is the common final pathway to death in most severe shock states, particularly when there is severe acidosis.

Typical symptoms of the disease, and less common symptoms

The majority of symptoms associated with shock are attributable to the underlying cause. Diagnoses may be suggested by characteristic pain (MI, pulmonary embolus, or pancreatitis); breathlessness and purulent sputum (pneumonia); and haematemesis and melaena (gastrointestinal haemorrhage). Symptoms attributable to the shock state per se include breathlessness, syncope, and a feeling of impending death.

The presentation of shock is greatly influenced by age, comorbidities, and the time of presentation. At one extreme, an individual may be obtunded while, in another case, they may be sitting up talking with a normal blood pressure and few symptoms. The latter is particularly true in young, previously healthy individuals, who have a large physiological reserve and can compensate during the early stages of shock.

Natural history, and complications of the disease

Untreated shock progresses to multi-organ failure and death. Mortality rises as the number of failing organ systems increases and typically exceeds 50% when four or more organs have failed, whatever the underlying aetiology.

In individuals who survive, the sequelae depend on the underlying cause. Patients with cardiogenic shock due to MI may be left severely limited due to the development of heart failure, while there may be no long-term consequences if cardiogenic shock was the consequence of an overdose of beta blockers. Individuals with shock due to anaphylaxis or pancreatitis may make a full recovery but have recurrent episodes. Survivors of septic shock have a 50% reduction in survival over the following 5 years.

Approach to diagnosing the disease

The diagnosis of shock may be self-evident when there is a corroborating history and clinical findings. There would be little doubt that a patient with known portal hypertension and oesophageal varices who presents with massive haematemesis, hypotension, tachycardia, and oliguria has hypovolaemic shock. However, in clinical practice, the situation is often less clear, as there may be limited history at the time of presentation, and confounding comorbidities, such as hypertension, which may obscure the diagnosis. It is important to appreciate that patients with shock are critically ill; therefore, although the clinical history is crucial in reaching a diagnosis, it is important not to needlessly exhaust the patient with questions that can be answered from other sources, such as staff, and relatives, and medical notes. Following a brief targeted history, clinical examination should focus on the cardiorespiratory and neurological systems. Observations consistent with a diagnosis of shock would be hypotension (systolic blood pressure <90 mm Hg), tachycardia (pulse >100 bpm), tachypnoea (respiratory rate >20 breaths/min), cold peripheries, cyanosis, prolonged capillary refill, oliguria (<0.5 ml/kg hour⁻¹) or anuria, and altered mental

status. These observations are non-specific but nevertheless sensitive for shock states and are more useful diagnostically when they are considered together, particularly in the context of any history (e.g. haematemesis or ischaemic chest pain) or investigations (e.g. low haemoglobin levels, raised lactate levels, ST elevation on ECG).

The aetiology of the shock state may be suggested by specific features of the history and examination:

- a history of bee sting or ingestion of nuts: anaphylaxis
- chest trauma: tension pneumothorax, myocardial contusion, aortic arch dissection, or traumatic aortic valve rupture
- bronchial breath sounds: pneumonia
- Beck's triad of hypotension, muffled heart sounds, and raised jugular venous pressure: cardiac tamponade
- subcutaneous emphysema: tension pneumothorax
- new murmur: mitral valve rupture, ventricular septal defect, or infective endocarditis
- splinter haemorrhages: infective endocarditis
- purpuric rash: meningococcaemia
- Grey Turner's or Cullen's sign: pancreatitis

The underlying aetiology may not be immediately obvious; however, the classification of shock into cardiogenic, obstructive, hypovolaemic, and distributive is a useful clinical sieve which can be used to plan further investigations which may elucidate the cause. The following investigations may be diagnostic:

- full blood count: to detect low haemoglobin (haemorrhage), raised white-cell count (sepsis), low platelets (haemorrhage)
- amylase: to exclude pancreatitis
- urea and electrolytes: to detect raised urea (Addison's disease, gastrointestinal haemorrhage, vomiting, diarrhoea, polyuria, pericarditis/tamponade) and/or abnormal electrolytes (fluid losses, Addison's disease)
- mast cell tryptase: to exclude anaphylaxis
- blood cultures: to exclude septic shock
- arterial blood gas analysis: lactate levels are frequently abnormal before hypotension, oliguria, and altered mental status are present and is elevated as a consequence of inadequate oxygen delivery and a switch to anaerobic metabolism
- ECG: to exclude MI (indicated by ST elevation), cardiac tamponade (indicated by concave ST elevation and low voltage or electrical alternans), pulmonary embolism (indicated by an S1Q3T3 pattern, right bundle branch block, right-axis deviation), arrhythmias (e.g. ventricular tachycardia)
- chest radiograph: to detect pulmonary oedema (suggests MI), enlarged cardiac silhouette (suggests pulmonary embolism, cardiac tamponade), pneumothorax, consolidation (suggests sepsis)
- echocardiogram: this is an extremely useful investigation because it can be performed at the bedside and can quickly confirm and exclude some major causes of shock; it can be used to detect impaired contractility (suggests MI, contusion, myocarditis), valve lesions (via colour-flow Doppler), hypovolaemia (suggested by small left ventricle chamber size), pulmonary embolism (e.g. clot in transit; pulmonary hypertension; right ventricular dysfunction), pericardial tamponade (indicated by right ventricular collapse in systole, or a large effusion)

In addition, other specialized investigations may be required, such as CT pulmonary angiography (in pulmonary embolism), ultrasonography (in abdominal trauma), CT (in trauma), and angiography (in trauma, gastrointestinal haemorrhage).

Other diagnosis that should be considered

Most often, shock is associated with a single diagnosis, such as MI. Occasionally, other shock-associated diseases may complicate the primary diagnosis. Examples of this include MI precipitating diabetic ketoacidosis, sepsis precipitating an Addisonian crisis, or acute valvular regurgitation complicating endocarditis. Thus, the possibility of dual or even multiple pathologies must always be considered in the shocked patient. Whatever the initial pathology, cardiogenic shock is generally a feature of most advanced shock states as multi-organ failure, severe acidosis, and metabolic mayhem develop.

'Gold-standard' diagnostic test

There is no gold-standard diagnostic test for the presence of shock. Shock is invariably accompanied by abnormalities in cardiac output and blood pressure, and measuring these parameters is important in management; however, there is no number which is diagnostic. Although most shock states have a low cardiac index ($<2.2 \text{ l/min m}^{-2}$), this index is elevated in some patients with septic shock. Furthermore, critically ill patients are catabolic, with higher metabolic demands, and so what might be considered an acceptable cardiac output in a healthy individual might be insufficient to meet metabolic demands. Hypotension (systolic blood pressure $<90 \text{ mm Hg}$, or a drop in systolic pressure $>30 \text{ mm Hg}$ from normal) is usually present; however, systolic blood pressure may be preserved or even elevated during the early stages of shock, due to compensatory vasoconstriction. This is particularly true of young, otherwise fit, individuals (e.g. with traumatic blood loss) who maintain blood pressure despite a low cardiac output and poor tissue perfusion up to the point of cardiac arrest. Arterial increments of lactate often precede changes in other parameters such as cardiac output, blood pressure, or urine output, while this may be abnormal in other conditions, so a raised lactate level should raise the possibility the patient is shocked.

Prognosis and how to estimate it

A number of scoring systems, such as the Acute Physiology and Chronic Health Evaluation (APACHE), the Simplified Acute Physiology Score (SAPS), and the Sequential Organ Failure Assessment (SOFA), are used in intensive care to define patient outcome. These scoring systems are similar in their predictive accuracy and are best at describing outcome in groups of patients rather than in individuals.

Treatment and its effectiveness

The treatment of septic shock is discussed in detail in Chapter 152 and therefore will not be considered further here.

General measures

Patients diagnosed with shock are critically ill, and the first stage in the management of these individuals is the recognition of this fact. Resuscitation should follow the standard Airway, Breathing, Circulation (ABC) approach. Treatment within the ICU consists largely of preventing or supporting organ failures, while the underlying condition that precipitated the shock state is treated definitively.

It should be ensured that the airway is patent, high-flow oxygen is applied, and adequate venous access is secured. Intubation and mechanical ventilation protects the airway when consciousness is reduced but also optimizes oxygen delivery and reduces oxygen demand. Even in circumstances where the airway is patent, the patient may require intubation and mechanical ventilation because, in shock states, a high proportion of cardiac output may be consumed by the work of breathing. Moreover, once the patient is intubated, it can be easier and safer to facilitate further investigations (e.g. CT, angiography) or treatments (e.g. surgery, cardiac catheterization).

Monitoring

The patient should be managed in an area with appropriate nursing and medical staff, and monitoring. According to circumstances, this may be the A & E resuscitation room, the CT scanner room, the angiography suite, the surgical theatre, or the ICU. The minimal requirements for monitoring are continuous ECG; blood pressure; pulse oximetry; respiratory rate; hourly urine output; Glasgow Coma Scale score; and blood glucose. If shock does not rapidly resolve with simple measures, additional haemodynamic monitoring, such as arterial line monitoring, central venous access monitoring, or continuous cardiac output monitoring, is required.

Arterial line monitoring

Arterial line monitoring allows continuous display of arterial pressure, and serial measurement of arterial blood gas samples. The latter

provides information on oxygenation (e.g. the partial pressure of arterial oxygen; arterial oxygen saturation), ventilation (e.g. the partial pressure of arterial carbon dioxide) and acid–base balance (e.g. pH, base deficit, and lactate levels). Failure of the acid–base balance to improve should lead the physician to reconsider whether the diagnosis and treatment are correct.

Central venous access monitoring

Central venous access monitoring allows continuous measurement of central venous pressure (CVP) and central venous oxygen saturation (ScvO₂). Although the CVP is considered a measure of cardiac preload, a specific value does not predict preload responsiveness. Thus, a CVP of 12 mm Hg may represent hypovolaemia, normovolaemia, or hypervolaemia in three different patients. The CVP may be used to guide fluid therapy, with a rise of 2–3 mm Hg following a rapid bolus of fluid representing an adequate change in preload. Ideally, the response to a fluid bolus should be measured against a change in cardiac output; however, when this is unavailable, improvement in heart rate, blood pressure, urine output, or lactate levels may be used instead. ScvO₂, which is a measure of the balance between oxygen delivery and extraction by the tissues, can be measured continuously or intermittently and can be a useful guide to the effectiveness of therapy such as fluids and inotropes. In broad terms, the aim is to restore ScvO₂ to a value of >70%.

Cardiac output monitoring

There are a number of monitors available which measure cardiac output; generally, familiarity with a device is more important than a specific choice of monitor.

Although the use of pulmonary artery catheters has diminished in Europe, they are capable of measuring cardiac output continuously using a thermodilution technique. They can also measure right atrial, pulmonary artery, and pulmonary wedge (left atrial) pressures. Newer devices such as PiCCO or LiDCO use an injectate dilution step for calibration (cold saline and lithium, respectively) and analysis of the arterial waveform (pulse contour analysis) for continuous cardiac output measurements. Oesophageal Doppler uses a probe which detects blood flow in the descending aorta and calculates cardiac output continuously.

Fluid therapy

Fluid therapy is mandatory in all shock states, with the exception of cardiogenic shock, for restoring tissue perfusion. There is no evidence to support the use of colloid over crystalloid. Fluid should be administered as a rapid bolus; if cardiac output or stroke volume increases by >10%, further fluid is indicated. If no cardiac output monitor is in situ, fluid responsiveness may be titrated against other parameters such as blood pressure, heart rate, urine output, and lactate levels. Additional fluid therapy should be avoided if there is no increase in cardiac output, as this will result in deleterious effects such as oedema, coagulopathy, and hypoxia.

Aside from specific treatment measures, outcomes from shock are equally dependent on the provision of good general intensive care, as outlined in Chapter 152.

Specific measures

Cardiogenic shock

When cardiogenic shock is due to MI, definitive treatment is aimed at the restoration of coronary perfusion, ideally with percutaneous coronary intervention or surgery when available. Early revascularization reduces mortality at 6 months. An intra-aortic balloon pump may be used as a bridge to definitive treatment or recovery of hibernating myocardium by improving coronary perfusion and reducing afterload and myocardial oxygen demand. Inotropic support with vasoactive drugs such as dobutamine, dopamine, adrenaline, milrinone, or levosimendan may be required to achieve adequate perfusion. As is the case with cardiac output monitors, familiarity of use is more important than the specific choice of drug. Patients in the recovery phase (inotropes discontinued) should be treated with normal medical therapy, including angiotensin-converting enzyme inhibitors.

Surgery is also required for acute valve leaks or ventricular septal defect complicating MI; delayed surgery merely hastens the onset of multi-organ failure and death.

Obstructive shock

Specific measures for obstructive shock are as follows:

- for tension pneumothorax: intercostal tube drainage
- for cardiac tamponade: pericardial drain, pericardial window
- for pulmonary embolus: thrombolysis in massive pulmonary embolism is followed by anticoagulation

Hypovolaemic shock

Hypovolaemic shock requires fluid therapy given in rapid boluses, according to improvements in haemodynamic variables. In the case of haemorrhage, fluid is usually given as blood and fresh frozen plasma. In haemorrhage due to trauma fluid, therapy is given sparingly until a definitive surgical approach to bleeding is undertaken. This so-called permissive hypotension involves resuscitation until a radial pulse is palpable. In a trauma setting, aggressive fluid therapy to conventional endpoints leads to clot instability, increased blood loss, and higher mortality.

Distributive shock

Specific measures for distributive shock are as follows:

- for Addisonian crisis: steroids, fluid, treatment of underlying infection
- for anaphylaxis: steroids, adrenaline, antihistamines, fluid
- for septic shock: see Chapter 152

151 ICU treatment of acute kidney injury

Matt Wise and Paul Frost

Definition of acute kidney injury

The Kidney Disease: Improving Global Outcomes (KDIGO) clinical practice guideline for acute kidney injury (AKI) defines AKI as any of the following:

- increase in serum creatinine ≥ 0.3 mg/dl (≥ 26.5 $\mu\text{mol/l}$) within 48 hours
- increase in serum creatinine to ≥ 1.5 times baseline within the previous 7 days
- urine volume < 0.5 ml/kg hour⁻¹ for 6 hours

Etiology of AKI

Traditionally, the etiology of AKI is considered in terms of prerenal, renal, and obstructive causes. However, this categorization is less useful in the ICU, where the etiology of AKI is usually multifactorial and often occurs in the context of multi-organ failure (MOF). Hypotension, nephrotoxic drugs, and sepsis or septic shock are the most important identifiable factors. Less frequently encountered causes include pancreatitis, abdominal compartment syndrome, and rhabdomyolysis. Primary intrinsic renal disease such as glomerulonephritis is extremely uncommon.

A previous history of cirrhosis, cardiac failure, or haematological malignancy, and age > 65 years, are important risk factors.

Typical symptoms of AKI

The patient may complain of dyspnoea as a consequence of metabolic acidosis or fluid overload. A reduction in urine output may have been noticed or lower abdominal pain may be a complaint if bladder outflow obstruction is present. Occasionally, cardiac arrest (hyperkalaemia, hypoxia due to pulmonary oedema, metabolic acidosis) may be the first manifestation of AKI.

Demographics of AKI

AKI occurs in up to two-thirds of ICU patients; its incidence is increasing, reflecting an ageing population with multiple comorbidities (cardiac failure, cirrhosis, diabetes, malignancy) and a rising prevalence of sepsis.

Natural history of AKI, and its complications

Patients with any form of AKI have increased mortality, as compared to non-AKI patients. Approximately 4%–5% of critically ill patients with AKI require renal replacement therapy. Sequelae of AKI include hyperkalaemia, acidosis, fluid overload, electrolyte disequilibrium, accumulation of waste products of metabolism, and sepsis. Profoundly uraemic patients can become encephalopathic and develop pericarditis and impaired platelet function. Non-resolution of AKI results in chronic renal failure.

Approach to diagnosing AKI

The diagnosis of AKI has been greatly simplified by the development of the KDIGO criteria, which only require a baseline comparison of serum creatinine and hourly urine output measurements. It is important to remember that, occasionally, renal failure may be non-oliguric.

History and examination should focus on known causes of AKI, such as nephrotoxic drugs and poisons; cardiac failure; diabetes; hypertension; urinary tract obstruction; myeloproliferative disease; autoimmune and connective tissue diseases; trauma or excessive exercise; fluid loss; recent abdominal surgery; and symptoms relating to possible sources of sepsis.

Hypotension and sepsis are important causes of AKI in critically ill patients and so assessment of intra-vascular volume status, together with inspection of possible sites of sepsis, is mandatory. It is important to remember that shock can exist without hypotension and that an apparently 'normal' blood pressure may represent hypotension in a previously hypertensive patient.

Other diagnosis that should be considered

Diagnostic pitfalls in the ICU are inadequate recognition and treatment of hypovolaemia and hypotension, overlooking sepsis, poisoning, nephrotoxic drugs, rhabdomyolysis, an obstructed/infected renal tract, and abdominal compartment syndrome.

Diagnostic investigations

Diagnostic investigations can be simply thought of as those required for the diagnosis of AKI (serum creatinine and hourly urine output) and those to establish the cause:

- serum urea and creatinine (high urea:creatinine ratios favour a prerenal cause)
- serum electrolytes, including calcium; to exclude dehydration, multiple myeloma
- urinary sodium (usually < 20 mmol/l in prerenal causes)
- liver function tests; to exclude hepatorenal syndrome
- amylase; to exclude pancreatitis
- paracetamol; ethylene glycol levels
- creatinine kinase; to exclude rhabdomyolysis
- ultrasound; to exclude obstruction of renal tract, and determine whether kidneys are of normal size
- urinary dipstick; to detect proteinuria (glomerular or interstitial disease), leukocytes and nitrites (infection), and haemoglobinuria or myoglobinuria (rhabdomyolysis)
- urinary microscopy; to detect red blood cells (bleeding within renal tract); dysmorphic red cells or casts (glomerulonephritis); granular casts (tubular necrosis); leukocytes or white-cell casts (urosepsis, pyelonephritis, interstitial nephritis); eosinophils (allergic interstitial nephritis, embolic disease); crystals (uric acid; calcium oxalate indicates ethylene glycol poisoning)
- intra-abdominal pressure (IAP); to exclude abdominal compartment syndrome
- blood film; to exclude haemolytic-uraemic syndrome, thrombotic thrombocytopenic purpura, malaria
- serology (for anti-glomerular basement membrane antibodies, antineutrophil cytoplasmic antibodies, and immune complexes) and renal biopsy have low yield in critically ill patients
- ECG; early changes of hyperkalaemia ($K^+ > 5.5$ mmol/l) include peaked T waves, shortened QT intervals, and ST depression; later changes include widening of the QRS, increased PR intervals, and bundle branch block; ultimately, the P wave disappears and ventricular tachycardia or fibrillation occurs

Prognosis and how to estimate it

AKI is an independent factor for increased mortality in ICU patients, even if renal replacement therapy is not required. Mortality increases with increasing severity; where renal replacement therapy is required, mortality approaches 50%–60%. More than 85% of survivors are free of renal replacement therapy at 1 year and this approaches 100% by 5 years.

Treatment and its effectiveness

AKI frequently occurs in the setting of multiple organ failure; such patients are critically ill and at risk of imminent death. The first step is to instigate resuscitation using the standard Airway, Breathing, Circulation, Disability, and Exposure (ABCDE) approach. In parallel with resuscitation, the underlying diagnosis should be investigated and managed. During this process, reversible factors contributing to the AKI, such as hypoxaemia, hypovolaemia, and, less commonly, urinary tract obstruction, can be corrected.

Hyperkalaemia is definitively managed by renal replacement therapy (RRT). However, temporizing measures include the administration of IV calcium chloride to stabilize the myocardium, along with IV insulin and glucose, sodium bicarbonate, and nebulized beta-2 adrenergic agonists to promote the movement of K^+ from the extracellular to the intracellular space.

During resuscitation, it is crucial that renal perfusion pressure is optimized. If the AKI is volume responsive, it is possible to restore renal function and avert the need for RRT. Typically, a mean arterial pressure (MAP) of ~70 mm Hg is required. Abdominal perfusion pressure (MAP – IAP) less than 60 mm Hg is associated with increased mortality.

Fluid resuscitation is the cornerstone of haemodynamic manipulation; currently, crystalloids are preferred over colloids, and it does not matter whether normal saline (0.9% NaCl) or balanced electrolyte solutions are selected.

If the patient is volume replete but still hypotensive, vasoactive agents such as noradrenaline may be required. Although low-dose dopamine ($< 5 \mu\text{g}/\text{kg min}^{-1}$) can increase urine flow, it does not confer protection from AKI and is no longer recommended.

Furosemide is often used in the setting of AKI but there is no evidence to suggest that mortality or the eventual need for renal replacement is affected by its use. Moreover, Furosemide may cause irreversible deafness and worsen acute tubular necrosis.

Patients with AKI, particularly in the context of MOF, are invariably catabolic; moreover, RRT contributes to nutrient loss, with up to 30 g/day of amino acids being lost in the dialysate. Therefore, nutritional supplementation should be always be given and titrated to the

presence or absence of RRT. Nutritional goals include a total energy requirement of 20–25 kcal/kg day⁻¹. Protein intake should be around 0.6–1.0 g/kg day⁻¹ (no RRT) and up to 2.5 g/kg day⁻¹ (on RRT).

Potentially nephrotoxic drugs must be avoided, while the doses of essential drugs may require modification to avoid toxicity. Contrast-induced nephropathy is a particular concern because diagnostic imaging and other radiological procedures are frequently required. Generally, analysis of the risk–benefit ratio in ICU patients favours the radiological procedure, and prophylactic measures such as adequate volume resuscitation and the administration of acetylcysteine should occur.

Over recent years, intra-abdominal hypertension (IAH) has been increasingly recognized as an important cause of AKI. Measurement of bladder pressure provides an indirect measure of IAP and this can easily be accomplished using a simple manometer. IAH can usually be managed with medical treatments alone, such as, for example, nasogastric and colonic decompression, fluid restriction, or body positioning. Laparostomy may be required for abdominal compartment syndrome when medical treatment has failed (IAP > 20 mm Hg, and new organ failure).

Despite general supportive measures, AKI may fail to improve or may even deteriorate; in these circumstances, RRT may be required. Currently, there is controversy as to the timing and type of RRT that should be used.

Conventional indications for RRT include refractory hyperkalaemia, fluid overload, severe metabolic acidosis, and overt uraemic symptoms such as encephalopathy or pericarditis.

Broadly, there are two types of RRT: continuous RRT (CRRT) and intermittent RRT (IRRT). Currently, there is no data to support the superiority of either of these modalities, and both are commonly used for AKI in the ICU. Doses of RRT that have been associated with increased survival in ICU patients are at least 35 ml/kg hour⁻¹ of haemofiltration or haemodiafiltration, and daily IRRT (dialysis).

152 ICU treatment of sepsis and septic shock

Matt Wise and Paul Frost

Definition of the disease

The Third International Consensus definitions for sepsis and septic shock (Sepsis-3) were published in 2016; sepsis is defined as 'life-threatening organ dysfunction caused by a dysregulated host response to infection' (Singer et al., 2016, p. 801). Organ dysfunction can be assessed using the Sequential Organ Failure Assessment (SOFA) score (see Table 152.1). SOFA utilizes clinical findings, laboratory data, and therapeutic interventions to quantify organ dysfunction in six organ systems (Table 152.1).

Organ dysfunction is indicated by an acute change in the SOFA score of ≥ 2 points consequent to the infection. (The SOFA score is assumed to be 0 in patients without preexisting organ dysfunction.) Patients with suspected infection who are at risk of poor outcomes can be promptly identified at the bedside by the quick SOFA score (qSOFA). The criteria for qSOFA are a respiratory rate of >22 breaths/min; altered mentation; and a systolic blood pressure of ≥ 100 mm Hg. Patients with suspected infection and any two of these three variables are at high risk of death or prolonged intensive care stay.

Septic shock, which is a subset of sepsis, is defined by the presence of particularly profound circulatory, cellular, and metabolic abnormalities and is associated with a greater risk of mortality than sepsis alone. Clinically, septic shock patients are sepsis patients who require vasopressors to maintain a mean arterial pressure (MAP) ≥ 65 mm Hg and have a serum lactate level >2 mmol/l despite adequate volume resuscitation.

Aetiology of sepsis

Bacteria are the most frequent causes of sepsis and septic shock, while viruses, fungi, and parasites are implicated less often. Positive cultures are found in only 60% of cases; this may be the result of previous antibiotic therapy or of inadequate sampling or testing. The aetiology of sepsis is constantly changing; whereas Gram-negative

organisms used to make up the majority of cases, Gram-positive bacteria now predominate. Sepsis due to fungal disease has also seen a dramatic rise. These changes may be explained by alterations in patient demographics, such as an increasingly elderly population with multiple comorbidities; an increased frequency of indwelling catheters or devices; and greater numbers of patients with immunosuppression as a result of disease or drug therapy.

The causative organisms depend on the patient population in question; for example, patients with a haematological malignancy and who have prolonged neutropenia following chemotherapy have a high prevalence of invasive fungal disease. The organism type will also depend on whether the infection is acquired in the community or the hospital setting, where antimicrobial resistance is more common.

In European ICUs, one-third of all patients either present with or develop sepsis; in two-thirds of these cases, the sepsis is present on admission. The commonest sites of infection are lung (68%), abdomen (22%), blood (20%), and urinary tract (14%). The most common microorganisms are *Staphylococcus aureus* (30%), *Pseudomonas* species (14%), and *Escherichia coli* (13%). Roughly half of the *Staphylococcus aureus* organisms identified were methicillin resistant (i.e. MRSA).

Typical symptoms of the disease, and less common symptoms

Symptoms of sepsis and septic shock are protean and depend on the site of infection as well as patient factors such as age, immune status, and presence of comorbidity. Altered mental status, such as anxiety or confusion, is a consistent feature while constitutional symptoms such as malaise, loss of appetite, fatigue, and fever are common. The site of infection may be localized by symptoms such as dysuria and frequency for the urinary tract; cough and purulent sputum for the lung; and diarrhoea and vomiting for bowel infection. Localized symptoms may diminish and constitutional symptoms predominate at extremes of age or if the patient is immunosuppressed.

Table 152.1 The Sequential Organ Failure Assessment (SOFA) score

System	0	1	2	3	4
Respiration					
PaO ₂ /FiO ₂ mm Hg	>400	<400	<300	<200 with respiratory support	<100 with respiratory support
Coagulation					
Platelet $\times 10^3/\mu\text{L}$	≥ 150	<150	<100	<50	<20
Liver					
Bilirubin $\mu\text{mol/L}$	<20	20–32	33–101	102–204	>204
Cardiovascular					
(mm Hg)	MAP ≥ 70	MAP <70	Dopamine <5 or Dobutamine (any dose)*	Dopamine 5.1–15 or adrenaline ≥ 0.1 or noradrenaline ≥ 0.1 *	Dopamine > 15 or adrenaline > 0.1 or noradrenaline > 0.1*
Central nervous System					
Glasgow Coma Score	15	13–14	10–12	6–9	<6
Renal					
Creatinine $\mu\text{mol/L}$	<110	110–170	171–299	300–440	>440
Urine output ml/day				<500	<200

Abbreviations: FiO₂, fraction of inspired oxygen; MAP, mean arterial pressure; PaO₂, partial pressure of oxygen.

*Catecholamine doses are given as micrograms per kilogram per min for at least 1 hour.

Reproduced with permission from J.-L. Vincent, The SOFA (Sepsis-related Organ Failure Assessment) score to describe organ dysfunction/failure, *Intensive Care Medicine*, Volume 22, Issue 7, pp. 707–710, Copyright © 1996 Springer.

Demographics of the disease

One large epidemiological study in the United States analysed hospital discharge data from 1979 to 2000; approximately ten million cases of sepsis were identified from 750 million hospitalizations. During the period of the study, the average age of the patient with sepsis increased; being male and non-white were also relative risk factors. Comorbidities such as cancer, immunosuppression, cirrhosis, renal failure, cardiac failure, and chronic lung disease are also important risk factors for the development of sepsis. Although mortality rates fell during this study, the number of deaths trebled because of an 8.7% annual increase in the incidence of sepsis.

Natural history, and complications of the disease

In a general hospital population, the mortality risk for patients with sepsis is >10%, which increases to >40% for those with septic shock. In European ICUs, the incidence of organ failure in patients with severe sepsis, defined using SOFA, is as follows: cardiovascular, 62.6%; renal, 51.2%; respiratory, 49.8%; CNS, 41.3%; coagulation, 20.1%; and hepatic, 12.2%. Dependence on renal replacement therapy at 1 year can be as high as 20% in survivors. Individuals discharged from hospital have a 50% reduction in life expectancy over the subsequent 5 years, compared to non-septic ICU patients.

Approach to diagnosing the disease

The diagnosis of sepsis requires a documented or suspected infection in association with signs of organ dysfunction (see Table 152.1). Septic shock can be diagnosed when sepsis-induced hypotension persists despite adequate fluid resuscitation. The starting point then is to establish the diagnosis of infection by utilizing a careful history, thorough examination, and appropriate investigations. Clinical examination should be comprehensive and rigorous, as infection may occur in any organ system (Table 152.2). Moreover, some clinical findings are pathognomonic, such as, for example, the petechial rash seen in meningococcal disease.

Clinical signs suggestive of septic shock include a flushed appearance, fever, confusion, tachycardia, a bounding pulse, and hypotension. These signs are consistent with an increased cardiac output. However, if treatment is delayed, then cardiac output may decline and the clinical signs then resemble cardiogenic shock, with cool peripheries, mottled skin, and marked hypotension.

Other diagnosis that should be considered

The differential diagnosis includes:

- hypovolaemic shock: haemorrhagic fluid loss (e.g. gastrointestinal, trauma, retroperitoneal), from diarrhoea, burns, pancreatitis, polyuria, diabetic ketoacidosis, vomiting, or pancreatitis

Table 152.2 Possible signs of infection in each organ system

Organ system	Possible signs of infection
Skin, and soft tissue	Cellulitis, abscess erysipelas, desquamation, necrosis
Locomotor system	Local abscess, draining sinus, pain, pseudoparalysis, bone deformity, swollen joints
Respiratory system	Clubbing, red ear drum, cervical lymphadenopathy, tonsillitis, pharyngitis, stridor, increased respiratory rate, pseudomembranes, cyanosis, bronchial breath sounds, purulent sputum
Cardiovascular system	Pericardial rub, murmurs, dysrhythmia, heart failure, splinter haemorrhages, Osler's nodes, Roth's spots
CNS	Neck stiffness, Kernig's sign, depressed consciousness, confusion, localizing neurological signs
Gastrointestinal system	Bloody diarrhoea, vomiting, abdominal pain, jaundice, hepatosplenomegaly
Genitourinary system	Tenderness in renal angle, rigours, urethral discharge

- cardiogenic shock due to myocardial infarct, myocarditis, acute valve leak, acute ventricular septal defect, or arrhythmia
- obstructive shock due to pulmonary embolus, tension pneumothorax, or cardiac tamponade
- distributive shock: neurogenic, or due to anaphylaxis or Addisonian crisis

It should be remembered that overlap exists between shock states. Infection may precipitate or complicate Addisonian crisis, diabetic ketoacidosis, acute aortic or mitral valve regurgitation, cardiogenic shock, and pancreatitis.

'Gold-standard' diagnostic test

The variables used to diagnose sepsis and septic shock are non-specific (see Table 152.1); accordingly no gold-standard diagnostic test exists for sepsis and septic shock. This fact was recognized by the International Sepsis Definitions Conference (Sepsis-3).

Acceptable diagnostic alternatives to the gold standard

As there is no gold-standard diagnostic test for sepsis and septic shock, there are also no acceptable diagnostic alternatives for a gold-standard test.

Other relevant investigations

Investigations in sepsis and septic shock largely focus on looking for potential sites of sepsis and obtaining microbiological samples or excluding other diagnosis. Blood cultures should be taken in all suspected cases; other samples will be determined by the clinical situation and include urine; sputum or bronchoalveolar lavage; cerebrospinal fluid; pleural fluid; pericardial fluid; ascites; faeces; drain sites; joint effusions; surgically debrided tissue; and abscess fluid.

Imaging is important when looking for occult sources of sepsis and, while plain radiographs of the chest, abdomen, or spine may be diagnostic, other modalities are often required. Ultrasonography has the advantage that it can be performed at the bedside and is particularly useful in identifying collections such as empyema, liver abscesses, abdominal collections, subcutaneous abscesses, and obstruction to the kidneys or biliary tract. CT is employed when other investigations fail to identify a source.

Additional investigations may be helpful with alternative diagnoses and include an ECG; echocardiogram; arterial blood gas, including lactate levels; serum amylase; mast cell tryptase; and CT pulmonary angiography.

Prognosis and how to estimate it

A number of scoring systems are used in intensive care, such as the Acute Physiology and Chronic Health Evaluation (APACHE), the Simplified Acute Physiology Score (SAPS), and SOFA, to define patient outcome. These scoring systems are similar in their predictive accuracy and are best at describing outcome in groups of patients rather than in individuals. For mortality rates for sepsis and septic shock, see 'Natural history, and complications of the disease'.

Treatment and its effectiveness

Resuscitation must be initiated as soon as sepsis or septic shock conditions are recognized and should follow the standard Airway, Breathing, Circulation (ABC) approach, so that immediate threats to life, such as airway compromise or severe respiratory failure, are addressed first.

In a seminal single-centre study published in 2001, early goal-directed therapy (EGDT) aimed at improving tissue oxygenation parameters within the first 6 hours of presentation was shown to increase survival. Resuscitation endpoints of EGDT include a central venous pressure (CVP) of 8–12 mm Hg, an MAP of >65 mm Hg, urine output of >0.5 ml/kg hour⁻¹, and a central venous (superior vena cava) or mixed venous oxygen saturation of >70% or >65%, respectively. IV fluid, red cells, vasopressors, and inotropes were

used to attain these goals. However, subsequent large multicentre trials from the USA, UK, and Australasia were unable to replicate the survival benefits of EGDT, and this approach is no longer recommended. Current therapy for sepsis and septic shock emphasizes source control; early, empirical, broad-spectrum antibiotics; judicious IV fluids (typically 2–3 l for an adult), and vasopressors to maintain an MAP \geq 65 mm Hg. Initially, either a colloid or a crystalloid solution may be given, as there is no evidence to support the selection of one over the other. Balanced electrolyte solutions such as Hartmann's (Ringer's lactate) solution are preferred to normal saline, as the latter can contribute to an undesirable metabolic acidosis.

The quantity of fluid required varies according to the intra-vascular deficit and the severity of the ongoing capillary leak. Fluid requirements are best assessed using a fluid-challenge technique whereby 500 ml of crystalloid is administered over 15 minutes, and its effectiveness assessed against improvements in blood pressure, pulse, and cardiac output. Broadly, fluid administration should continue as long as there is haemodynamic improvement and should be curtailed if filling pressures such as the CVP increase with no concurrent increase in cardiac output. Once resuscitation is completed, IV fluid should be given more sparingly, as cumulative positive fluid balance is associated with increased mortality.

The ability of organs such as the kidneys to autoregulate blood flow is lost below a certain MAP; thus, uncorrected hypotension can lead to ischaemia and organ failure. Vasopressors may be needed to maintain the MAP at around 65 mm Hg. A higher MAP may be required in cases of preexisting hypertension, and a lower MAP may suffice in younger patients without comorbidity. Noradrenaline has predominantly alpha-adrenergic effects and is effective at reversing sepsis-induced vasodilatation. Dopamine has both beta- and alpha-adrenergic effects and increases cardiac output as well as MAP. Before starting either of these agents, it is important that the patient be adequately volume resuscitated.

Catecholamines may have undesirable effects, such as tachyarrhythmias and reduced oxygen delivery. In this context, vasopressin, which can restore vascular tone and blood pressure, has been used as a catecholamine-sparing drug. However, as yet no survival benefits have been demonstrated by this approach.

If, despite restoration of a suitable perfusion pressure and adequate volume resuscitation, there remains evidence of tissue ischaemia, for example, a central venous oxygen saturation (ScvO₂) of <70%, then a dobutamine infusion should be introduced. Dobutamine has predominantly beta-adrenergic effects and increases cardiac output.

Source control, such as surgical debridement, abscess drainage, or removal of infected intra-vascular devices, is mandatory and should not be delayed. Early appropriate antimicrobial therapy is crucially important to survival. The risk of death increases by 7.6% for every hour hypotensive septic patients are without antibiotics. Initial, empiric antibiotic therapy should be broad spectrum, as the causative organism is frequently unknown. After 48–72 hours, antibiotic therapy can be de-escalated and refined according to microbiological results and the patient's response.

IV hydrocortisone (<300 mg/day) may improve blood pressure in patients who remain hypotensive despite fluid and vasopressors. However, this therapy does not translate into a survival benefit, even in those patients who had a reduced response to corticotrophin.

Aside from specific treatment measures, outcomes from sepsis and septic shock are equally dependent on the provision of good general intensive care. Patients should be ventilated using a lung-protective strategy aimed at limiting ventilator-induced lung injury, and sedation should be interrupted daily to minimize the duration of ventilation. Enteral nutrition should be established, and blood glucose levels should be controlled in the range 3.8–8.3 mmol/l. Renal replacement therapy may be required to facilitate the management of fluid balance and metabolic derangements. Thromboprophylaxis

Box 152.1 Surviving sepsis campaign bundles

To be completed within 3 hours

1. Measure lactate level
2. Obtain blood cultures prior to administration of antibiotics
3. Administer broad spectrum antibiotics
4. Administer 30 ml/kg crystalloid for hypotension or lactate > 4 mmol/L

To be completed within 6 hours

5. Apply vasopressors (for hypotension that does not respond to initial fluid resuscitation) to maintain a mean arterial pressure (MAP) \geq 65 mm Hg
6. In the event of persistent hypotension after initial fluid administration (MAP > 65 mm Hg) or if initial lactate was \geq 4 mmol/L, re-assess volume status and tissue perfusion and document findings according to 'Reassessment of volume status and perfusion'.
7. Re-measure lactate if initial lactate elevated.

Reassessment of volume status and perfusion

Document reassessment of volume status and tissue perfusion with:

Either:

Repeat focused exam (after initial fluid resuscitation) including vital signs, cardiopulmonary, capillary refill, pulse and skin findings.

Or two of the following:

- Measure CVP
- Measure ScvO₂
- Bedside cardiovascular ultrasound
- Dynamic assessment of fluid responsiveness with passive leg raise or fluid challenge.

Abbreviations: CVP, central venous pressure; ScvO₂, central venous oxygen saturation. Reproduced with permission Dellinger RP, Levy MM, Rhodes A, et al. Surviving Sepsis Campaign:

International Guidelines for Management of Severe Sepsis and Septic Shock: 2012. Crit Care Med. 2013; 41(2):580–637. Copyright © 2013 the Society of Critical Care Medicine and Lippincott Williams & Wilkins.

with unfractionated or low-molecular-weight heparin should be instigated unless there are contraindications such as bleeding. Stress-ulcer prophylaxis should be provided, using either an H₂ blocker or a proton-pump inhibitor.

Despite improvements in the provision of evidence-based care, the mortality rates of sepsis and septic shock remain unacceptably high. A consortium of international intensive care societies spearheaded by the European Society for Intensive Care Medicine has launched the Surviving Sepsis Campaign in an attempt to reduce mortality from these conditions. A central element in this campaign is the promotion of care bundles, which are defined as groups of disease-process-related interventions that, when implemented together, result in better outcomes than when implemented individually (see Box 152.1).

153 Terminal care in the intensive care unit

Matt Wise and Paul Frost

Introduction

In the UK, around 10%–20% of all patients admitted to the intensive care unit (ICU) do not survive, while in the United States, it has been estimated that 22% of all deaths occur in an ICU. Therefore, terminal or palliative care is as important as any of the life-saving interventions that occur in the ICU. The goal of palliative care is to achieve a good death, described by the US Institute of Medicine as one that is 'free from avoidable distress and suffering for patients, families, and caregivers; in general accord with patients' and families' wishes; and reasonably consistent with clinical, cultural, and ethical standards' (Field et al., 1997, p. 95).

Initiation of palliative care

In the ICU, the switch from care with curative intent to palliation occurs when it becomes obvious that the patient is not responding to treatment. Typically, this is manifest by deteriorating physiology and escalating organ support in the setting of overwhelming disease or injury. Although prognostic models such as the Acute Physiology And Chronic Health Evaluation (APACHE) and the Riyadh Intensive Care Programme (RIP) are available, these can never be 100% accurate and are most appropriately used to assess population risk rather than individual risk. Therefore, it is predominantly expert opinion (consensus amongst treating medical and nursing teams) that determines the point at which the patient is recognized as not responding to treatment and, in fact, dying.

Ethical considerations

The decision to start palliative care is framed by the ethical principles of autonomy (the right of patients to make their own decisions), beneficence (treatment should benefit the patient), non-maleficence (treatment should do no harm), and social justice (treatment resources should be used equitably). Although patient autonomy is of paramount importance, understanding the patient's wishes in the ICU is difficult because only around 5% of critically ill patients retain decision-making capacity. In the UK, ultimate responsibility for the decision to discontinue intensive therapies resides with the medical team. However, these doctors will always strive to act in accordance with the patient's wishes. When the patient cannot express their own wishes, then decision-making occurs with surrogates such as the family. In these circumstances, decisions can be made by the 'substituted-judgement standard', if the patient's relatives' wishes are known or by the 'best-interests standard' if their relatives wishes are unknown. Advance directives (living wills), which are legally binding, can inform this discussion but, as these documents rarely cover every eventuality, their usefulness is limited. In the UK, if there is no family, then the Mental Capacity Act allows for the provision of court-appointed deputies who may make proxy decisions about medical treatment in the patients' best interests.

Where the patient retains capacity, then prognostic information should be carefully communicated so that he or she can make informed choices about treatment. Occasionally, contrary to medical advice, patients may refuse continued life-sustaining treatment; in these circumstances, their autonomy must be respected.

Communication

Good communication is essential for effective palliative care and can reduce subsequent psychological morbidity amongst family members. Generally, more time should be spent listening and

addressing the families concerns during meetings than talking. End-of-life discussions should occur in private, designated interview rooms and be conducted by a senior clinician accompanied by a senior nurse. No external interruptions should be allowed during the meeting, and pagers and mobile telephones should be switched off. Discussion should be sensitive and appropriate to cultural and religious needs, and interpreters may be required. Language should be clear and unequivocal; care should be taken to avoid medical jargon and euphemisms. The family should be told that the patient is dying and that, in the opinion of the medical team, the emphasis of care should shift to palliation rather than persevering with organ support. The transition from full treatment to a palliative approach should not be hurried; the family often need time to digest the prognosis as well as arrange for other family members to be in attendance. It is always reasonable to enquire whether spiritual or religious support is wanted and to offer to arrange this if necessary.

Family disagreement

Occasionally, the family may disagree with the suggested approach and ask that intensive therapies continue. Even though doctors are not legally obliged to continue treatments which they believe to be ineffectual, it is always appropriate to seek consensus with the family before proceeding to a palliative approach. Therefore, every effort should be made to understand and address the family's concerns. An offer of a second opinion or recourse to a hospital ethics committee may be useful. Usually, with the passage of time, agreement with the family can be reached; as a last resort, a court order may be sought.

Organ donation

The issue of organ donation should not be raised, unless by the family, at the initial end-of-life interview. However, in subsequent family meetings, it is appropriate to seek their views on this. It needs to be established whether the family believe that the patient would wish to be an organ donor. The patient may, in fact, be on the donor register. If the family wish that this option be explored, then the transplant coordinator should be contacted to liaise with the family.

Palliative care practicalities

Environment

Once a palliative approach is embarked upon, it is usually unreasonable to move the patient out of the ICU. Such a move is potentially distressing for the patient and the family, who would then have to acquaint themselves with a new environment and staff (although, in some countries, such as New Zealand, patients have been taken to their home to die, for family and cultural reasons). However, the patient may be moved within the ICU in order to optimize privacy and minimize noise.

Symptom control

Symptom control is a defining feature of palliation, and all care should be directed towards ensuring that the patient remains comfortable. Common distressing symptoms include pain, dyspnoea, and delirium.

Over 50% of seriously ill hospital patients report some level of pain and it is important to be vigilant for evidence of this. Usually, the existence and intensity of pain is self-reported but, in the majority

of ICU patients, due to varying degrees of unconsciousness, this is not possible. In the unconscious ICU patient, features suggestive of pain include autonomic responses, such as tears or diaphoresis; facial grimacing, or wincing; and increased muscle tone, particularly on movement.

Care should be taken to avoid iatrogenic causes of pain, such as positioning and turning the patient, tracheal suctioning, and wound, drain, and catheter care. Morphine is the drug of choice for the treatment of pain. In addition to its analgesic effects, it also has additive sedative and potentially beneficial euphoric effects. Undesirable side effects such as pruritus, nausea, and vomiting can be treated with antihistamines and anti-emetics.

Dyspnoea (self-awareness of uncomfortable breathing) in a ventilated patient may be manifest as tachycardia, tachypnoea, accessory muscle activity, nasal flaring, sweating, and agitation. Most commonly, this distressing symptom is dealt with by administering benzodiazepines and morphine. Although these drugs may hasten death, it is ethically acceptable to administer them when the intention is to alleviate distress rather than cause death (the doctrine of 'double effect').

Delirium may be defined as an acute alteration in consciousness with a fluctuating cause, associated with impaired attention, impaired cognition, and increased or decreased psychomotor activity. In a dying ICU patient, the causes of delirium include the underlying illness; sleep deprivation; drug or alcohol withdrawal; medication; pain; and dyspnoea. Delirium can be managed by treating the underlying cause(s), providing a quiet environment, calming nurses and relatives, and using specific drug therapies such as benzodiazepines or neuroleptic drugs (e.g. haloperidol).

Withdrawal of intensive therapies

Symptom control is a prerequisite for withdrawal of intensive therapies; once this is achieved, then organ support can be discontinued. It is important to appreciate that, in these circumstances, there is no legal or philosophical distinction between withholding and withdrawal of treatment. Therefore, inotropes are switched off, renal replacement therapy is stopped, and ventilation and inspired oxygen are reduced. Any exacerbation of distressing symptoms is immediately addressed by titration of sedation and morphine. Monitors are generally switched off, as families can be distracted and distressed by the display of terminal physiological variables. Routine interventions such as blood tests, drug administration, IV fluid, and nasogastric feed are discontinued. If the patient is extubated, then the family are warned that this may be associated with retention of respiratory secretions and noisy breathing. This can be distressing for the family but can usually be addressed by simple airway-opening manoeuvres, positioning, and suction. Where possible, the family should be warned about the likely duration of the dying process, although this can be difficult to predict.

The conscious patient

In the vast majority of cases, the terminally ill ICU patient is deeply unconscious as a consequence of their illness and sedative and analgesic drugs prescribed for their comfort. Rarely, the patient may be wakeful and wish to remain conscious, when therapies such as ventilation are withdrawn, so that they can communicate with their family. This can be accommodated by careful titration of sedation and analgesic drugs to ensure comfort in the very final stages of the illness.

Diagnosing death

Death may be diagnosed after 5 minutes of observed asystole. The absence of the pupillary responses to light, of the corneal reflexes, and of any motor response to supraorbital pressure should be confirmed. The time of death is recorded as the time at which these criteria are fulfilled. Alternatively, where the patient is mechanically ventilated, death may be diagnosed following irreversible cessation of brainstem function. If it accords with the patient's wishes, at this point, organ donation might occur.

Care after death

Following the death, an appointment should be made for the family with the hospital bereavement service. Bereavement advisers not only provide all of the necessary documentation to register the death but can also provide practical information on all aspects of bereavement, including liaison with grief counselling services. Other administrative tasks that should be completed at this time include informing the patient's GP of the death, entering the death into the hospital database and other relevant databases, and following the hospital policy for the property of the deceased.

Many ICUs now offer bereavement follow-up services so that lingering concerns that the family may have about the death can be addressed. Finally, it is important to remember that dealing with death can have a traumatic impact on ICU staff, and appropriate counselling should be readily available.

154 Brain death

Matt Wise and Paul Frost

Definitions

Mechanical ventilation has made it possible for the heart to continue to beat and perfuse other organs even when the brain is dead. This means that death can be diagnosed in two distinct ways: first, in the traditional manner, as permanent cessation of cardiorespiratory function; and, second, while the patient is ventilated, as brain death (BD).

In 1976 the Conference of Medical Royal Colleges and their Faculties in the United Kingdom, in a statement on the diagnosis of BD, recognized the brainstem as the centre of brain activity, without which life was not possible. Brainstem death (BSD) occurs when there is complete, irreversible loss of brainstem function, that is, irreversible loss of the capacity for consciousness, coupled with irreversible loss of the capacity to breathe. In the UK, the terms BD and BSD are used interchangeably and are legally synonymous with somatic death.

Aetiology of the disease

In adults, severe head injury accounts for 50% of cases of BSD; 30% occur following subarachnoid or intra-cerebral haemorrhage, and 20% occur as a result of cerebral anoxia, for example, following cardiorespiratory arrest, hanging, or strangulation.

Natural history, and complications of the disease

Cerebral injury following trauma, haemorrhage, or infection causes the brain to swell (cerebral oedema). Usually, deleterious rises in intracranial pressure are prevented by compensatory reductions in CSF and intracranial blood volumes. However, following severe injury, these mechanisms are exhausted, and intracranial pressure rises, often exponentially. This causes a deteriorating cycle of further cerebral ischaemia, neuronal injury, and oedema. In these circumstances, brain tissue is displaced downwards towards the foramen magnum. Ultimately, the cerebellar tonsils may be forced through the foramen magnum (tonsillar coning), compressing the brainstem and causing BSD.

Crucial functions of the brainstem include control of consciousness via the reticular activating system, and control of cardiorespiratory homeostasis. Additionally, all sensory and motor tracts pass through the brainstem and cranial nerves 3–12 emerge from it. Therefore, clinical signs of coning include coma; apnoea; cardiovascular instability and absence of reactivity; movement; and brainstem reflexes.

Following BSD, characteristic pathophysiological changes arise. These include hypotension; cardiac arrhythmias; pulmonary oedema; diabetes insipidus (DI) and other endocrine disturbances; disseminated intra-vascular coagulopathy (DIC); and hypothermia.

Cardiovascular instability occurs in around 80% of brain dead patients; its causes are multifactorial and include loss of sympathetic tone; vasodilatation; and myocardial depression.

The mechanism of myocardial depression is uncertain but is characterized by evidence of myocardial ischaemia and even infarction.

Pulmonary oedema may arise as a result of myocardial dysfunction secondary to massive sympathetic over activity, occasionally seen at the onset of BSD (neurogenic pulmonary oedema).

Following BSD, production of antidiuretic hormone is low to non-existent; consequently, DI occurs in up to 65% of affected

patients. DI is characterized by a high urinary output, hypernatraemia (serum sodium >150 mmol/l), plasma hyperosmolality (typically >310 mOsm/kg), and urinary hyposmolality (typically <300 mOsm/kg). Pituitary failure also leads to reductions in circulating thyroid hormones, and these reductions may contribute to myocardial dysfunction.

DIC is common and may be related to the release of tissue thromboplastin from dead brain tissue.

Finally, hypothermia arises as a result of hypothalamic failure; increased heat loss related to vasodilatation; and decreased heat production associated with a reduced metabolic rate.

BSD is always followed by asystolic cardiac arrest; typically, this happens after a few days. Rarely, in countries where the concept of BSD is not recognized and intensive care is continued, cardiac arrest has taken weeks to occur. There has never been a verified report of recovery of brainstem function in these circumstances.

Approach to diagnosing the disease

Before clinical examination for BSD can proceed, the following preconditions must be met. The aetiology of the coma must be established and be irreversible, all reversible causes of coma must be excluded, and the patient must be apnoeic on mechanical ventilation.

Often, the aetiology of the brain damage is immediately self-evident and irreversibility is easy to establish, for example, following a massive intra-cerebral bleed or severe head injury. However, for other conditions, such as cerebral hypoxic ischaemic injury following cardiac arrest, a longer period of observation may be required to increase diagnostic and prognostic certainty.

A number of conditions can confound the clinical examination for BSD and have first to be ruled out. These include hypothermia, drugs, and circulatory, metabolic, and endocrine disturbances.

At the time of BSD, death testing the core temperature must be >34°C as, occasionally, impaired consciousness has been associated with core temperatures of 32°C–34°C.

Anaesthetic drugs such as barbiturates, benzodiazepines, and opiates are routinely used in the management of severely head-injured patients. These drugs and their active metabolites can have persistent effects, particularly if their elimination is reduced because of hepatic or renal failure. Therefore, sufficient time needs to be given to allow clearance of these agents so that they do not confound the clinical examination for signs of BSD. Occasionally, it is helpful to measure drug concentrations, for example, of thiopental, or administer antagonists, for example, to opiates and benzodiazepines, so that confounding influences of these agents can be excluded.

BSD testing should not proceed if thiopental levels are >5 mg/l or if midazolam levels are >10 µg/l.

Neuromuscular blocking agents can mimic coma and respiratory failure and it is important to exclude their presence. This can be done by demonstrating the presence of deep tendon reflexes or by using a nerve stimulator.

Metabolic disturbances and circulatory instability that arise as a direct consequence of brainstem injury should be distinguished from similar, primary disturbances that may cause coma. Hypernatraemia may occur as a consequence of DI complicating BSD or be due to gross dehydration, unrelated to BSD. It is important to emphasize that the establishment of an unequivocal, irreversible cause of the coma outweighs any contribution that minor deviations from normal homeostasis might theoretically make to the comatose state.

Nonetheless, as far as it is possible, metabolic, endocrine, and circulatory contributions to the internal milieu must be normalized prior to BSD testing. So, profoundly abnormal electrolyte levels, for example, sodium <115 mmol/l or >160 mmol/l, potassium <2 mmol/l, and hypoglycaemia (<3 mmol/l) and hyperglycaemia (>20 mmol/l) should be corrected. Additionally, the mean arterial pressure should be >60 mm Hg, and blood gases should be normal.

Rarely, myxoedema, thyroid storm, and Addisonian crisis can present with coma, and appropriate hormone assays should be requested if there is any suspicion that these conditions are present.

Several neurological disorders, for example, acute inflammatory polyneuritis, cause profound neuromuscular weakness resembling loss of brainstem reflexes. Although it would be extremely unlikely for such conditions to coexist with the primary, known cause of irreversible brain damage, nonetheless, these conditions should be considered and excluded. Finally, in the context of traumatic coma, it is essential to exclude a high cervical spinal injury, as this could cause quadriparesis and invalidate the apnoea test.

Once the preconditions have been fulfilled, BSD can be confirmed by clinical examination. In the UK, this examination is undertaken by two doctors, experienced in the procedure, who have been registered for at least 5 years, one being a consultant. These clinicians must confirm the absence of all brainstem reflexes as follows:

- pupils are fixed in diameter and do not respond to light
- no response (i.e. eyelid movement) to direct stimulation of the corneas (corneal reflex)
- no eye movements following direct stimulation of the tympanic membranes with iced water (vestibulo-ocular reflex)
- there should be no motor response in the cranial or somatic distribution to supraorbital pressure
- no contraction of the soft palate when the uvula is stimulated (gag reflex)
- no response to tracheal suctioning as far as the carina (cough reflex)
- no respiratory response to an apnoea test; this means that no breathing movements should be seen following disconnection of the patient from the ventilator; when the partial pressure of carbon dioxide (PaCO_2) is above the threshold for maximal stimulation of the respiratory centres in the medulla oblongata (i.e. $\text{PaCO}_2 > 6.65$ kPa); during this time, hypoxaemia is prevented by the provision of oxygen at 5 l/min via a catheter placed down the endotracheal tube

In order to reassure the family and remove the risk of observer error, the BSD tests are carried out twice. In the UK, there is no prescribed interval between tests.

Other diagnoses that should be considered

The 'locked-in' syndrome usually arises as a result of destruction of the base of the pons, for example, following haemorrhage, infarction, or trauma. Characteristically, these patients are cognitively intact, retain vertical eye movements, but are otherwise totally paralysed.

Guillain–Barré syndrome involving all of the peripheral and cranial nerves could mimic BSD.

It is vitally important to appreciate that adherence to the preconditions prior to clinical examination will always protect against the misdiagnosis of BSD.

'Gold-standard' diagnostic test

Clinical neurological examination remains the gold-standard method for diagnosing BD.

Other relevant investigations

Various neurophysiological and imaging tests are available that can be helpful in the diagnosis of BSD. EEG shows electrocerebral silence, and somatosensory evoked potentials show loss of all cortically generated components. Imaging, such as magnetic resonance angiography, four-vessel angiography, and CT angiography will all demonstrate absence of intracranial blood flow. All of these tests require further validation studies before they can be recommended as a routine part of the diagnosis of BSD. Until that time, the diagnosis remains a clinical one.

Treatment and its effectiveness

Following the diagnosis of BSD, the grim news is imparted to the family. During this time, it is always reasonable to consider whether the patient is eligible to be an organ donor. In addition to the benefits for organ recipients, grieving families often report some comfort resulting from this act of altruism. If organ donation is not an option, then the patient should be disconnected from the ventilator.

PART 6

Disorders of the kidney and urinary tract, and electrolyte and metabolic disorders

155 Normal renal function

Aron Chakera, William G. Herrington, and Christopher A. O'Callaghan

Introduction

The kidney is a vital organ with multiple functions. Without kidney function, death will occur in a matter of days. Fortunately, several forms of effective renal replacement therapy are available.

Urinary tract structure

There are normally two kidneys that are 9–11 cm in length, and each weigh about 150 g. They lie in the retroperitoneum below the levels of the liver and spleen, respectively (see Figure 155.1) The blood supply to the kidneys comes from the renal arteries, which are branches of the aorta. The kidneys receive 20% of cardiac output (approximately 1100 ml/min), and blood is first delivered to the glomeruli in the outer part of the kidney. Inflow to the glomerulus is via the afferent arteriole, with outflow through the efferent arteriole, which then supplies blood to the tubules. Blood then returns to the renal veins, which drain into the inferior vena cava. The glomerulus, tubules, and collecting ducts make up the functional unit of the kidney: the nephron (see Figure 155.2). Each kidney contains approximately 1 million nephrons. Urine is formed by a process of filtration,

Figure 155.1 CT demonstrating the urinary system. Please see colour plate section.

image courtesy of Nigel Cowan.

as blood passes through the glomerulus. The filtrate (urine) is modified along the course of the tubules, where substances may be reabsorbed or secreted. Urine present at the end of the nephron drains into the renal pelvis and from there passes down the ureters to the bladder, leaving through the urethra.

Kidney function

The kidneys have several important functions:

- they are organs of **excretion**: they remove metabolic products such as urea, organic acids, and unwanted electrolytes
- they are critical to **homeostasis**: they regulate body water content, as well as blood electrolyte and acid–base balance
- they have **endocrine** functions: they sense hypoxia and produce **erythropoietin** in response, promoting red blood cell formation; they are also responsible for **vitamin D** activation by hydroxylation and thus have a central role in calcium, phosphate, and bone metabolism; lastly, they secrete **renin** in response to decreased blood flow, thus activating the renin–angiotensin system, which regulates the salt and water balance; the kidneys are thus central to blood pressure control

The kidneys do not act in isolation. A careful balance of hormones released from other organs act on the kidneys to maintain the body's fluid and electrolyte balance. These include aldosterone, vasopressin, parathyroid hormone, and atrial natriuretic peptide.

Glomerulus function

Each glomerulus is composed of a network of capillaries, supplied by muscular arterioles. The amount of vasoconstriction in the afferent and efferent arterioles determines the pressure within the glomerulus. This intra-glomerular pressure drives filtration of water and solutes through the glomerular filtration barrier, which is composed of three layers: the fenestrated capillary endothelial cells, the basement membrane, and a layer of epithelial cells with foot processes (podocytes) (see Figure 155.3). The epithelium makes up the Bowman's capsule and continues as the tubules. The three layers of the filtration barrier act to limit the passage of large proteins, but allow water and solutes to pass freely. Blood leaves the glomerular capillaries through the efferent arteriole. By modifying tone in the afferent and efferent arterioles, intra-glomerular pressure and, therefore, glomerular filtration rate and the production of urine are regulated. Angiotensin II acts predominantly on the efferent arterioles to cause vasoconstriction, which increases intra-glomerular pressure and filtrate formation.

Tubular function

The tubular system can be divided into four main parts on the basis of function: the proximal tubes, the loop of Henle, the distal tubules, and the collecting ducts.

Proximal tubules

The proximal tubules perform the bulk of the reabsorption. Significant amounts of water and solutes are returned to the blood from the filtrate. This is the main site of glucose and amino acid reabsorption. These cells are highly metabolically active and are thus susceptible to hypoxic damage (acute tubular necrosis).

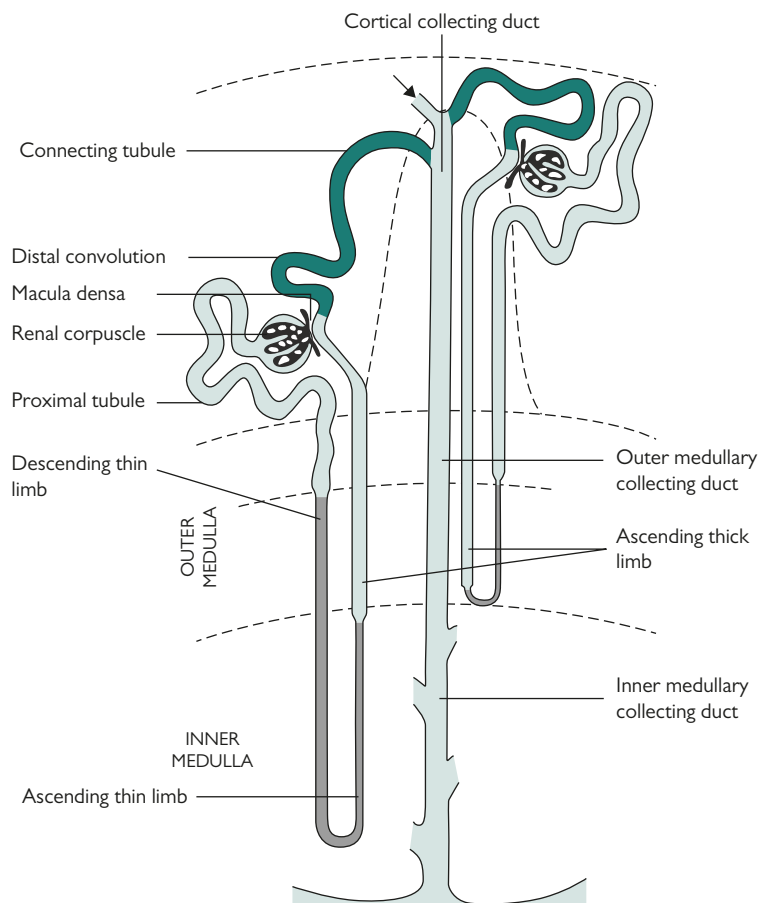

Figure 155.2 The basic organization of short-looped (cortical) and long-looped (juxtamedullary) nephrons; note that the early distal tubule of each type of nephron is in contact with the afferent arterioles of its own glomerulus.

Loop of Henle

The loop of Henle plays a critical role in concentrating urine through the countercurrent system, which depends on the differing permeability of parts of the loop to water and electrolytes.

Distal tubules

The distal tubules fine tune the urinary acid and electrolyte composition, influenced by the actions of aldosterone.

Please see colour plate section. image courtesy of Ian Roberts

Collecting ducts

Collecting ducts modify urinary water content (and therefore osmolality) in response to vasopressin.

Assessment of kidney function

The main assessment of kidney function is by measurement of the serum creatinine. This can be used to provide an estimate of the glomerular filtration rate. This is discussed in detail in Chapter 157.

Natural history of kidney function

Kidney function may deteriorate with age. On average, there is a fall of 1 ml/min year⁻¹. However, this is extremely variable. A mild

degree of renal impairment in the elderly is, thus, very common and may not require investigation. However, associated cardiovascular risk factors should still be addressed.

156 Diagnosis in suspected renal disease

William G. Herrington, Aron Chakera, and Christopher A. O'Callaghan

Introduction

Renal dysfunction can be easily and, in most cases, unambiguously diagnosed from an elevation in serum creatinine and/or abnormal urinalysis. The clinical challenges lie in first suspecting that renal dysfunction is present and therefore requesting the appropriate test (e.g. serum creatinine/urine analysis), and then identifying the underlying aetiology. A major clue to renal dysfunction in the hospitalized patient can be a reduction in urine output. Therefore, urine output should be carefully monitored in those patients who are at risk, which includes most significantly ill hospitalized patients.

Aetiology

The likely causes of renal dysfunction arising *de novo* in the hospital and community settings are quite distinct. Renal dysfunction arising in hospital is often predictable and caused by a combination of underlying comorbidities, the current illness, and treatment or interventions, such as drugs. For example, septic or post-operative patients are at high risk of hypotensive acute renal failure. In contrast, renal dysfunction arising in the community has a much wider differential diagnosis, which ranges from common causes such as diabetes and hypertension, to rarer primary renal diseases such as glomerulonephritis.

Traditionally, renal dysfunction is arbitrarily divided into acute kidney injury (AKI) and chronic kidney disease (CKD). The key difference is that, in AKI, there is a rapid and potentially reversible fall in kidney function, characterized by a reduction in glomerular filtration rate (GFR). CKD is characterized by long-standing (>3 months) loss of kidney function, which is often, but not always, progressive and is often irreversible due to the presence of fibrotic change within the kidneys.

AKI in hospital is usually divided into:

- prerenal causes, which account for about 60% of hospital-acquired AKI; often, there are multiple contributory factors which may act synergistically, for example, sepsis; with some hypotension during surgery; volume depletion; older age; and diabetes
- intrinsic renal causes, which account for about 20% of hospital AKI and can be further divided into interstitial nephritis, vasomotor nephropathy, toxic tubular injury, and glomerulonephritis
- post-renal causes, which account for about 10% of hospital AKI

In the community setting, obstruction is surprisingly a more common cause of AKI, largely due to prostatic disease (see Figure 156.1).

Figure 156.1 Causes of acute kidney injury in a community-based survey.

Box 156.1 Pulmonary renal syndromes

Without alveolar haemorrhage

- acute or chronic kidney disease with pulmonary oedema, due to fluid overload
- pneumonia with renal failure (e.g. legionella)
- heart failure with pulmonary oedema and secondary renal impairment
- poisoning (e.g. with organic solvents or paraquat)

With alveolar haemorrhage

- anti-glomerular basement membrane disease (Goodpasture's disease)
- systemic vasculitis
 - microscopic polyangiitis
 - Wegener's granulomatosis (granulomatosis with polyangiitis)
 - Churg–Strauss syndrome

There are many different causes for CKD, as outlined in Chapter 163. Often kidney failure occurs in conjunction with failure of other organs. Various autoimmune conditions cause a pulmonary–renal syndrome (see Box 156.1)

Symptoms

Renal impairment *per se* is typically asymptomatic until very near to end-stage renal disease. Presenting symptoms may relate to an underlying predisposing condition (see Table 156.1). For example, shortness of breath in cardiac disease, and rashes in autoimmune diseases, such as SLE. Rarely, renal disease presents directly, as, for example, peripheral oedema in nephrotic syndrome, frank haematuria and loin masses in renal malignancy, or uraemic symptoms in end-stage renal disease, such as fatigue, itching, poor appetite, malaise, and nausea.

Importantly, in the hospitalized patient, it is often difficult to tell the non-specific symptoms of kidney failure apart from the underlying illness. Often, kidney failure in this setting is picked up early with frequent blood tests, and managed effectively before the symptoms of advanced AKI can be manifest. However, this is not always the case, and such symptoms may be manifest (see Box 156.2).

Table 156.1 Presentations of renal diseases

Prerenal	Renal	Post-renal
Diarrhoea/vomiting	Haematuria (GN)	Anuria
Sepsis	Rash (SLE/vasculitis/interstitial nephritis)	Obstructive lower urinary symptoms
Hypotension	Arthralgia (SLE/vasculitis)	Dysuria
Haemorrhage	Myalgia (rhabdomyolysis/GN)	Renal colic
Severe heart failure	Neuropathies (amyloid/cryoglobulinaemia)	Frank haematuria
Liver failure	ENT symptoms (Wegener's)	Renal mass
	Eye symptoms (vasculitis/SLE/TINU/others)	Palpable bladder
	Oedema (GN/NS)	
	Frothy urine (NS)	

Abbreviations: ENT, ear, nose, and throat; GN, glomerulonephritis; NS, nephrotic syndrome; SLE, systemic lupus erythematosus; TINU, tubulointerstitial disease with uveitis.

Box 156.2 Features of uraemia and an estimated glomerular filtration rate <15 ml/min per 1.73 m² body surface area

- Anorexia and malnutrition
- Nausea and vomiting
- Tiredness
- Fluid overload with oedema, breathlessness, and orthopnoea
- Anaemia
- Pruritus
- Mental apathy and depression
- Muscle twitching, restless legs, and cramps
- Bleeding tendency; haematemesis, epistaxis
- Sexual dysfunction, loss of libido, and impotence
- Cardiac-pericarditis

Reproduced with permission from the Oxford Textbook of Medicine (5th edition), Warrell, Cox and Firth (Eds), Published by Oxford University Press 2012)

Demographics

CKD guidelines have been designed to highlight patients at risk of developing renal dysfunction. Renal disease may affect any age group. However certain primary renal diseases do have sex, age, and racial predilections. Myeloma, amyloidosis, and vasculitis are more common in older patients. Lupus is more common in younger women, and patients of black African ethnicity. Minimal change disease is more common in younger patients. Membranous nephropathy is more common in older patients. Renal impairment from obstructive uropathy, secondary to prostatic disease, should always be considered in older men.

In the community setting, the older the patient, the greater the chance of CKD. In the hospital setting, this holds true and, in addition, the more unwell the patient is, the higher the probability is that AKI will be superimposed. It is sensible to consider all hospitalized patients as being at risk of renal dysfunction and to check renal function regularly in patients whose specific illnesses or treatments might increase this risk (e.g. drugs, fluid loss, and sepsis).

Natural history, and complications

Most intrinsic renal diseases are progressive without appropriate treatment. However, some conditions, such as membranous nephropathy, can relapse and remit over time.

Prompt and appropriate management of AKI minimizes both the absolute loss of renal function, and the time period over which this loss occurs. Such intervention lessens the need for renal replacement therapy (dialysis) in the short term, and improves prognosis. Many (but not all) patients with AKI return to their baseline kidney function following treatment.

Renal failure due to obstruction is one of the more benign forms of kidney injury and, once treated successfully, many patients return to a good level of kidney function. Even if renal function does not improve after the relief of obstruction, there is much less chance of progression to end-stage renal failure than there is with intrinsic renal diseases.

Approach to diagnosing the disease

Patients with suspected renal disease should be assessed in the usual manner, with a full history, examination, and appropriate renal investigations. Specific issues to address with suspected renal disease include the following:

- predisposing factors: age is probably the most important predisposing factor, followed by past medical/surgical history (e.g. hypertension, diabetes mellitus, evidence of microvascular complications, or kidney stones)
- family history of heritable kidney diseases (e.g. Alport syndrome, or polycystic kidney disease)
- smoking (a risk factor for renal arterial disease)

- drugs, including analgesics, over-the-counter medications, and herbal/traditional medicines (causes of renal damage)
- symptoms of prostatic disease (which can cause urinary tract obstruction)
- rashes (which may signify a systemic disease, such as SLE, or an allergic response, indicating an interstitial nephritis)
- joint problems (which may signify a systemic disease, such as SLE)
- sinus symptoms (which may indicate granulomatosis with polyangiitis)
- weight loss, or fatigue (indicating a systemic disease; fatigue may indicate anaemia due to erythropoietin deficiency in advanced kidney disease)
- urine (look for blood, discolouration, frothiness, dysuria; see Chapter 157); frank haematuria occurring with upper respiratory infections can indicate IgA nephropathy)
- nocturia (which can indicate prostatic disease or poor urine-concentrating capacity, which can arise with advanced renal disease)
- shortness of breath (indicating fluid retention with pulmonary oedema, or lung involvement in a systemic disease)
- swelling/oedema (indicating fluid retention)

The examination should be thorough. Do not forget to check weight, and assess fluid status. This is particularly important in AKI, as volume depletion and heart failure are both common causes. Always measure heart rate (tachycardia may indicate severe dehydration), check blood pressure, and look for a postural drop (indicating either dehydration or autonomic neuropathy, which is common in diabetes). It is important to examine for peripheral oedema and to assess the heart, paying particular attention to the jugular venous pressure, the heart size (clinically and radiologically), and the presence of any murmurs or a third heart sound.

Careful inspection of the skin can be informative (e.g. livedo reticularis, purpura, photosensitive rash, digital infarcts). Palpate for the kidneys, bladder, and masses. Perform a rectal exam for prostate disease. Assess the peripheral vasculature for signs of insufficiency, such as bruits or absent pulses (suggesting renovascular causes for kidney injury). Fundoscopy may reveal changes consistent with hypertension or diabetes mellitus. Always perform dipstick urinalysis.

Standard investigations that may be helpful in suspected renal disease are given in Table 156.2.

Differential diagnosis

There are several standard presentations of renal disease; these can be considered under the following headings:

- asymptomatic haematuria (see Chapter 55)
- asymptomatic proteinuria (see Chapters 55, 161, 164, and 163)
- chronic slowly progressive renal damage (see Chapter 163)
- nephritic syndrome (see Chapter 159)
- acute rapidly progressive renal damage (see Chapter 162)
- nephrotic syndrome (see Chapter 161)

Table 156.2 Standard investigations that may be helpful in suspected renal disease

Prerenal	Renal	Post-renal
Creatinine and urea	CRP	Urine tract ultrasound
Liver function	Myeloma screen	PSA
ECG	ANCA/ANA/complement/anti-GBM	+/- Urine cytology
Bone chemistry	Urine microscopy	IgG4 levels (IgG4-related disease such as retroperitoneal fibrosis)
CRP	albumin: creatinine ratio or protein: creatinine ratio	
Septic screen	TSH	
Full blood count and clotting	Blood film (particularly looking for haemolytic-uraemic syndromes)	
	Albumin	

Abbreviations: ANCA, antineutrophil cytoplasmic antibody; ANA, antinuclear antibody; ECG, electrocardiography; GBM, glomerular basement membrane; PSA, prostate-specific antigen; TSH, thyroid-stimulating hormone.

Asymptomatic low-grade proteinuria can be caused by many different diseases. These include all the causes of nephrotic syndrome, as well as benign causes. In the absence of other features, proteinuria is not usually investigated with a renal biopsy if it is less than 1 g/day.

'Gold-standard' diagnostic test

The gold-standard diagnostic test for renal dysfunction is the measurement of the GFR by clearance of radioisotopes (e.g. ^{51}Cr -labelled EDTA). However, in routine clinical practice, the diagnosis of renal dysfunction is made on the basis of urinalysis for protein content, and a standardized serum creatinine assay, which is used to calculate an estimated GFR (eGFR). The eGFR is calculated from serum creatinine on the basis of age, gender, and ethnicity.

Other relevant investigations

A small number of patients have structural renal diseases (e.g. horseshoe kidney) that may only be evident on radiological investigation. The clinical context of a patient in whom renal disease is suspected may invoke a number of laboratory or radiological tests (see Chapter 157). The final common test in many cases is a renal biopsy.

Prognosis and how to estimate it

This depends on the nature of the underlying disease. As a generalization, AKI is reversible, whereas CKD, due to intrinsic disease, is slowly but inexorably progressive.

Treatment and effectiveness

Both treatment and its effectiveness will depend on the nature of the underlying disease.

157 Investigation in renal disease

William G. Herrington, Aron Chakera, and Christopher A. O'Callaghan

Introduction

Renal physicians use a combination of tests to diagnose and monitor renal disease. These include urine, blood, and imaging investigations.

Urine

Appearance

Normal urine is clear to yellow in colour. Conjugated jaundice causes dark yellow urine. Cloudy urine suggests leucocytes. An offensive odour suggests bacterial infection. Frothy urine suggests heavy proteinuria. Frank haematuria causes red- or cola-coloured urine.

Urinalysis

Urine dipstick analysis is an indispensable bedside test. It can be used to detect proteinuria, haematuria, leucocyte levels, nitrate levels, glycosuria, and ketone levels; it is also used to measure specific gravity and pH.

Proteinuria

Proteinuria analysis via a dipstick measures predominately albumin. It does not detect all tubular secreted protein or immunoglobulins/light chains. Urine albumin secretion is <20 mg/day in normal kidneys. Dipsticks cannot reliably detect <300 mg/day of albuminuria (microalbuminuria). A dipstick is semi-quantitative (if concentrated); however, formal quantification is done via the albumin-creatinine ratio (ACR) or the protein-creatinine ratio (PCR).

Haematuria

Haematuria is reliably excluded by a negative dipstick. False positives can occur with myoglobinuria or haemoglobinuria. Microscopy is required to differentiate myoglobinuria, glomerular bleeding, and urinary tract bleeding.

Leucocyte levels

Dipsticks detect an enzyme (leucocyte esterase) produced by leucocytes. A positive result usually indicates bacterial urinary tract infection. If the culture is negative, a cause of sterile pyuria should be sought. This includes infection with a fastidious organism (e.g. *Chlamydia* spp.), prostatitis, tubulointerstitial nephritis (eosinophiluria), renal stone disease, renal tract tumours, papillary necrosis, or renal tract tuberculosis (requires three early morning urine samples).

Nitrite levels

Nitrites are an indicator of nitrate-reducing bacteria, and are best detected after a 4-hour bladder dwell. Nitrites are 98% specific but only 53% sensitive, as many bacteria, including *Pseudomonas* spp. and *Streptococcus faecalis*, do not reduce nitrates. Leucocytes and nitrites are good predictors of infection, if both are positive. Urine culture remains the 'gold-standard' test to exclude an infection.

Glycosuria

Glycosuria is detectable in the urine in hyperglycaemia when reabsorption is overwhelmed, and in proximal tubular disease when reabsorption is impaired. There is large inter-individual variation in the threshold for glycosuria, so it is an insensitive screening test for diabetes.

Ketone levels

Ketones are readily detectable, and useful in diagnosis of diabetic and alcoholic ketoacidosis. They may also be positive in starvation,

volume depletion, and isopropyl alcohol poisoning (hand rubs and de-icers).

Specific gravity

The term 'specific gravity' refers to the density of urine compared to distilled water and is a measure of solute content. Concentrated urine has a high specific gravity. Specific gravity normally ranges between 1.005 and 1.035. It is useful to know the specific gravity when trying to estimate degree of proteinuria from a dipstick. Recurrent stone formers can use a dipstick specific gravity, to ensure they are maintaining dilute urine.

pH

The pH of urine ranges from 4.5 to 8.0. Measuring urine pH is useful in the workup for metabolic acidosis. Failure to decrease urine pH below 5.5 in the face of acidosis, suggests renal tubular acidosis. A low urine pH predisposes to uric acid stones. Alkaline urine predisposes to calcium phosphate stones.

Urinary chemical analysis

Urinary chemical analysis can be used to determine osmolality.

Osmolality

Osmolality is more accurate than specific gravity and is used to assess polyuric states, and disorders of sodium balance (see Chapter 174).

Protein-creatinine ratio

The protein-creatinine ratio has replaced 24-hour urinary collections. These collections are inconvenient for patients and are often inaccurate due to timing mistakes. The validity of the ratio relies on the assumption that creatinine excretion remains roughly constant at 10 mmol/day. The test is best performed on concentrated early morning urine. The protein-creatinine ratio detects albumin and tubular secreted protein. The albumin-creatinine ratio is a more sensitive test of glomerular proteinuria. It is preferred for detecting early glomerular renal disease, especially in diabetes mellitus. Thus, although often almost equivalent in practice, the protein-creatinine ratio and the albumin-creatinine ratio are not strictly interchangeable. (see Table 157.1).

Bence Jones proteins

Bence Jones proteins are urinary free light chains secreted by a plasma cell dyscrasia. They are not detected by a standard urine dipstick. They precipitate on heating to 60°C, and redissolve at 90°C. The test for them should be requested in parallel with a serum protein electrophoresis, and serum free light chains as part of a paraprotein screen.

Urinary catecholamines

Urinary catecholamines are indicated when screening for a pheochromocytoma. Three 24-hour collections of acidified urine are required to reliably exclude the diagnosis.

Urine microscopy

Urine microscopy can be used to detect crystals, cells, and casts.

Crystals

Crystals can be seen by light microscopy, and may display birefringence under polarized light. They aid stone diagnosis, and occasionally indicate a cause for acute renal failure kidney injury (e.g. calcium oxalate crystals in ethylene glycol poisoning, and uric acid crystals in tumour lysis syndrome (see Chapter 166)).

Table 157.1 Converting dipstick albumin–creatinine ratios to 24-hour proteinuria				
Dipstick	ACR (mg/mmol) (UK units)	ACR (mg/g) (US units)	24-Hour proteinuria (g/day)	Diagnosis
Negative	<2.5	<30	<0.03	Normal
Trace	3.0–30.0	30–300	0.03–0.30	Microalbuminuria
+	30.0	300	0.30	Overt proteinuria
++	100.0		1.00	
+++	350.0		3.50	Nephrotic range proteinuria
++++	1000.0		10.00	

Abbreviations: ACR, albumin–creatinine ratio.

Cells

Microscopy can identify red cells, white cells, renal tubular epithelium, urothelium, urethral squamous epithelium, and organisms in urine. Finding more than two red cells per high-powered field is significant. Glomerular bleeding damages red cells through the stress they undergo when passing through the filtration barrier and the highly osmotic environment of the tubules. The red cells become dysmorphic with blebs and buds (see Figure 157.1). Red cells from elsewhere in the urinary tract retain normal morphology. Neutrophils usually represent bacterial infection. The number of large, oval renal tubular epithelial cells increases in acute tubular damage but these cells are not diagnostically useful. Urothelial cells are examined by cytologists to screen for malignancy.

Casts

Casts can be cellular or non-cellular. Hyaline casts (Figure 157.2A) are plugs of Tamm–Horsfall mucoprotein from renal tubules and are abundant in concentrated urine. They are not thought to be pathological. Granular casts (see Figure 157.2B) are cellular remnants embedded in hyaline material, and are non-specific for glomerular and tubular disease. Cellular casts are much more useful (Table 157.2). Red cell casts are virtually diagnostic of a glomerulonephritis (confirming the

presence of blood from within the nephron). White-cell casts occur in urinary tract infection and tubulointerstitial nephritis. Epithelial cell casts contain sloughed tubular cells and, like granular casts, are non-specific, occurring in glomerular disease and tubular disease (Figure 157.3). When these epithelial cells are heavily lipid laden, they have a Maltese cross appearance and denote nephrotic syndrome.

Urine culture

The urine culture is deemed significant if there is a pure growth of a single type of organism, at a concentration of 10^5 colony-forming units per millilitre.

Glomerular filtration rate

The normal range of the glomerular filtration rate (GFR) is 90–125 ml/min, depending on the age of the patient. GFR is used to direct renally excreted drug dosing. Serial measurements enable progression of kidney disease to be monitored. GFR can be determined by administering a purely filtered exogenous molecule and then measuring its clearance, or by measuring levels of endogenously produced and filtered molecules such as creatinine and cystatin C.

Figure 157.1 Microscopic haematuria. (A) Isomorphic red cells. Isomorphic red cells are seen in non-glomerular haematuria. (B) Dysmorphic red cells. Dysmorphic red cells are seen in glomerular haematuria, but may also be found in non-glomerular and tubulointerstitial disease. Please see colour plate section.

Estimated GFR

Creatinine is convenient and cheap to measure. When it is in steady state, renal excretion is balanced with production from skeletal muscle. The steady-state concentration for a given GFR will thus vary with an individual's creatinine production. Factors determining production include sex, age, and size. Equations utilizing these variables are used to convert serum creatinine into an estimation of GFR (eGFR). The conventional units for GFR are millilitres per minute; however, eGFR reports the GFR as a function of body surface area. The units for eGFR are thus millilitres per minute per 1.73 m². eGFR is now routinely reported together with serum creatinine; although it requires four variables for calculation (serum creatinine, age, gender, and ethnicity: the four-variable MDRD formula), it has superseded the Cockcroft–Gault equation, as it does not require a patient's weight. The MDRD formula is based on data derived from a population with chronic kidney disease. Above a GFR of 60 ml/min, the eGFR is less reliable. More recently, an updated formula, the CKD-EPI equation, has been used for reporting eGFR; this equation is more accurate than the MDRD formula, particularly at higher levels of renal function. Like the MDRD formula, it uses creatinine, age, gender, and ethnicity to produce an eGFR.

Creatinine clearance

Creatinine clearance can be measured directly by a timed urine (or peritoneal dialysate) collection (see Box 157.1). It is a reasonable measurement of GFR if collection is accurate (usually over 24 hours).

However, it is seldom used in practice, as it is frequently not possible to obtain an accurate collection of urine samples.

Urea

Urea is a less reliable as a marker of renal function. It is synthesized by the liver as a means of ammonium excretion and undergoes variable tubular reabsorption. However, these facts can be useful diagnostically. Urea can be increased by a gastrointestinal bleed, high dietary protein intake, or a catabolic state. Conversely, liver disease or a low-protein diet reduces urea production. In hypovolaemia, renal perfusion falls, reducing GFR. Creatinine and urea levels thus rise. However, urea reabsorption is increased from the tubules, to increase the peak urine osmolality in the loop of Henle to preserve water. Urea thus rises disproportionately compared to creatinine, in prerenal renal failure.

Isotopic GFR

Isotopic GFR is expensive and thus rarely performed. The radiolabelled marker ⁵¹Cr-EDTA is injected and serial venous measurements taken over time.

Renal imaging

Ultrasonography

A renal ultrasound should be performed in acute kidney injury within 24 hours to exclude obstruction and measure kidney size; 10–11 cm is

	Prerenal	Acute tubular necrosis	Glomerular nephritis	Post-renal	Acute interstitial nephritis	Nephrotic syndrome
Specific gravity	High: >1.020	Iso-osmotic: 1.010	Normal: 1.010–1.020	Iso-osmotic: 1.010	Iso-osmotic: 1.010	Normal: 1.010–1.020
Protein on dipstick	–	–	+	+/-	+/-	+++
Blood on dipstick	–	–	+	+/-	+/-	+/-
Microscopy	Hyaline casts	Renal tubular epithelial cells Granular casts	Dysmorphic red cells Red cell casts	Normal red cells	Eosinophils White-cell casts	Fatty casts

Figure 157.3 (A) Red cell cast; inset: haemoglobin cast. Red cell casts are typically seen in glomerulonephritis. (B) Epithelial cell casts may be seen in glomerular and tubular disease. (C) White cell cast; individual white cells (arrows) are clearly seen. White cell casts may be seen in pyelonephritis and tubulointerstitial disease. Please see colour plate section.

normal and suggests an acute cause. An 8–9 cm kidney (+/– acquired cysts) suggests chronic kidney disease. Remember, hydronephrosis may not develop for 48 hours after acute obstruction or in partial obstruction.

Kidney–ureter–bladder imaging

A kidney–ureter–bladder CT scan is a very useful investigation. It does not require IV contrast. It will identify stones, confirm hydronephrosis, and delineate the site and cause of obstruction.

The use of contrast is indicated if a plain scan does not delineate obstruction, or to assess suspicious cysts or renal masses. Performing further CT images after a delay allows time for contrast to be excreted. The ureters can then be imaged. This is called a CT urogram. The presence of fat suggests a benign angiomyolipoma. Enhancing masses greater than 3 cm in diameter, with thick irregular walls, and areas of necrosis are suspicious of malignancy.

Box 157.1 Formula for the calculation of creatinine clearance from a urine collection

Creatine clearance (in millilitres per minute) may be calculated from the following formula:

$$\text{creatinine clearance} = \frac{[\text{creatinine}]_{\text{urine}} \times \text{urine volume}}{[\text{creatinine}]_{\text{plasma}} \times \text{collection time}}$$

where urine volume is in millilitres, and collection time is in minutes.

Nuclear medicine

^{99m}Tc-DMSA imaging can be used for assessment of split kidney function. An MAG3 scan with furosemide excretion is useful for the assessment of obstruction and reflux.

Magnetic resonance angiography and CT angiography

Magnetic resonance angiography and CT angiography are used to assess the renal arteries. In expert hands, duplex ultrasound with Doppler and nuclear scans can identify reduced perfusion, but CT angiography or magnetic resonance angiograms are the best screening investigations. However, they may overestimate the degree of stenosis or miss distal stenosis and thus digital subtraction angiography remains the gold-standard investigation for assessment of renal artery disease.

Immunology in renal practice

Immunology is used to assess both chronic and acute renal failure. The standard screen for immunological renal disease includes tests for antinuclear antibody (ANA), complement proteins, and antineutrophil cytoplasmic antibody (ANCA). Additional tests may also be indicated.

Immunoglobulin testing and serum protein electrophoresis

Immunoglobulin testing and serum protein electrophoresis are very commonly requested. In people over 50 years of age with renal disease, a serum and urinary electrophoresis (Bence Jones proteins) should be considered. A free light chain assay is now available to detect light chains in the serum. The interpretations of these tests are summarized in Table 157.3.

Table 157.3 Immunoglobulins/protein electrophoresis interpretation

Test	Diagnosis
Positive serum IgG, IgA, or IgD monoclonal band +/- immunoparesis	Plasma cell dyscrasia (MGUS or myeloma)
Positive serum IgM monoclonal band	Waldenström's macroglobulinaemia
Urinary free light chains (Bence Jones proteins)	Plasma cell dyscrasia (MGUS or myeloma) Waldenström's macroglobulinaemia B-cell lymphomas and leukaemias AL amyloidosis
Raised serum IgA	Associated in 50% of IgA nephropathy cases
Polyclonal gammaglobulinaemia	Very non-specific: connective tissue disorders (including lupus) Vasculitis HIV infection Tubulointerstitial nephritis +/- uveitis
Hypogammaglobulinaemia	Multiple causes, including nephrotic syndrome

Abbreviations: AL, amyloid light chain; MGUS, monoclonal gammopathy of unknown significance.

ANCA

ANCA is requested urgently when a rapidly progressive glomerulonephritis is suspected. ANCA is associated with small vessel vasculitides. There are two different ANCA appearances on immunofluorescence: cytoplasmic (cANCA) and perinuclear (pANCA). The target antigen for cANCA is proteinase 3 (PR3), and for pANCA is myeloperoxidase (MPO). PR3 specificity is associated with granulomatosis with polyangiitis (Wegener's granulomatosis), and MPO specificity with microscopic polyangiitis. Both can cause a focal segmental necrotizing (pauci-immune) glomerulonephritis.

Anti-glomerular basement membrane antibody

An anti-glomerular basement membrane antibody (anti-GBM) test is also requested urgently in rapidly progressive glomerulonephritis. It is highly specific for anti-GBM disease.

ANA

ANA is non-specifically associated with many autoimmune conditions. Elderly patients often have a weakly positive ANA titre. A positive result in the young, however, is more significant. Specific nuclear antigen assays that are useful in nephrology practice include anti-double-stranded DNA (lupus); anti-Scl70 and anti-RNA polymerase (systemic sclerosis); and anti-Ro and anti-La (Sjögren's syndrome).

Complement

Complement proteins are reduced in certain renal diseases where there are high levels of circulating immune complexes (and in other diseases as well). Complement proteins are useful diagnostic pointers, but rarely diagnostic in themselves (see Table 157.4).

Virology

Hepatitis B/C and HIV status are required for haemodialysis patients for infection control purposes. These viruses are associated with several renal diseases (see Chapter 170).

Rheumatoid factor and cryoglobulins

Rheumatoid factor and cryoglobulins are not routinely screened for, but may be indicated where there is a low C4 level, a hepatitis C infection, or a history of rash and peripheral neuropathy. Cryoglobulins precipitate at <37°C and so need to be kept warm after sampling. Type 1 cryoglobulins are monoclonal IgMs or IgGs and are associated with lymphoproliferative diseases. Type 2 mixed essential cryoglobulinaemia is characterized by the presence of a monoclonal IgM with rheumatoid factor function, and polyclonal IgG. It is strongly associated with hepatitis C.

Antiphospholipid antibodies

Antiphospholipid antibodies are indicated with a history of recurrent venous or arterial thrombosis, recurrent miscarriage, livedo reticularis, or a prolonged activated partial thromboplastin time that does not correct. Tests for lupus anticoagulant and anti-cardiolipin antibodies should be requested.

Table 157.4 Complement proteins C3 and C4 in renal diseases

	C3	C4
Lupus nephritis	↓	↓
Post-infective glomerulonephritis	↓	↓/↔
Infective endocarditis	↓	↓
Mesangiocapillary glomerulonephritis type 1 without cryoglobulins	↓	↓
Mesangiocapillary glomerulonephritis type 1 With mixed essential cryoglobulinaemia	↔	↓
Mesangiocapillary glomerulonephritis type 2 (dense deposit disease)	↓	↔

Renal biopsy

Renal biopsy is essential for the diagnosis and estimation of prognosis in many kidney diseases.

Indications

Indications for a biopsy include unexplained acute kidney injury, chronic kidney disease with normal sized kidneys, heavy proteinuria (in adults), assessment of disease cause, assessment of disease activity (e.g. in SLE), and an acute deterioration in renal transplant function. A risk of bleeding is associated with a biopsy, and this should be balanced against the possible diagnostic and prognostic benefit.

Contraindications

Contraindications need to be included in the risk–benefit assessment (see Table 157.5).

Technique

Renal biopsy is now routinely performed as a day case, with real-time ultrasound guidance. CT guidance is reserved for the obese. Local anaesthetic is required. Either kidney can be biopsied, but the left is preferred. In native kidneys, the lower pole is biopsied. The upper part (usually still the lower pole) is biopsied in a transplant, due to the position of the transplant in the pelvis. The mid pole is avoided because of the presence of large vessels. Two cores are taken, usually with a spring-loaded gun. Patients are required to lie flat for 6 hours afterwards. The risk of bleeding falls after 48 hours. Biopsies are processed for light microscopy, immunofluorescence, and electron microscopy.

Complications

Bleeding is the most concerning complication: about 2% of renal biopsy patients experience macroscopic haematuria or a capsular haematoma. Angiography and embolization is indicated for rapid

Table 157.5 Renal biopsy contraindications

Relative contraindications	Caution
Hypertension (>160/90 mm Hg)	Small kidneys
Abnormal clotting (INR/APTT _r >1.3)	Multiple cysts
Thrombocytopenia (platelet count < 100)	Uncooperative patient
Hydronephrosis	Single kidney
Urinary tract infection	Antiplatelet therapy within 5 days
Suspected renal tumour	Morbid obesity

Abbreviations: APTT_r, activated partial thromboplastin time ratio; INR, international normalized ratio.

blood loss or persistent bleeding. Rarely, a nephrectomy is required (0.1%) and hence dialysis should be part of informed consent, particularly in a solitary kidney or advance renal failure.

Genes and the kidney

Polycystic kidney disease is the commonest inherited kidney disorder. There are a number of other inherited diseases with characterized genes (see Chapter 169). However, genetic analysis is rarely requested in clinical nephrology, as the diagnosis is often confirmed by clinical findings and imaging. This may change when treatments to alter the course of these diseases are found and early treatment is necessary. Research is also ongoing into susceptibility genes for chronic kidney diseases.

158 Urinary tract infection

William G. Herrington, Aron Chakera, and Christopher A. O'Callaghan

Definition of the disease

A urinary tract infection (UTI) is defined as present when urine culture results in the growth of a single organism at greater than 10^5 colony-forming units/ml of urine.

Etiology

Organisms causing UTI are listed in Table 158.1. Bowel flora are the commonest cause. *Escherichia coli* accounts for 80% of infections. *Klebsiella* spp., *Proteus mirabilis*, *Enterococcus faecalis*, and *Staphylococcal saprophyticus* account for most of the remaining 20%. *Staphylococcus aureus* culture is usually catheter related or secondary to haematogenous spread.

Host vulnerability factors include urinary tract obstruction, urinary stasis (e.g. incomplete bladder emptying), foreign bodies (e.g. stones or stents), sexual intercourse, diabetes mellitus, and immunosuppression.

Lower UTIs are more common. They represent superficial uncomplicated infection and will respond to a short course of treatment. Upper tract involvement is more serious as it represents deep tissue infection.

Symptoms

Symptoms classically correlate to the site of infection (see Box 158.1). Urethritis causes dysuria. Cystitis irritates the bladder trigone, resulting in suprapubic discomfort, urinary frequency, and urgency. Pyelonephritis may not have associated lower urinary tract symptoms. The usual presentation is a young female with a high fever and renal angle discomfort or tenderness. Renal capsular stretch results in vagal stimulus and can induce nausea and vomiting. Septicaemia is suggested by high fever,

Box 158.1 Common symptoms of lower urinary tract infection

- Severe dysuria, often described as 'scorching' or 'like peeing barbed wire', worse towards the end of or immediately after micturition
- Increased urinary frequency
- Urgency—the sensation of a strong desire to pass urine
- Strangury—the feeling of needing to pass urine despite just having done so
- Offensive-smelling urine, often described as 'strong' or 'fishy'
- Macroscopic haematuria
- Urge incontinence—leakage of urine associated with the desire to pass urine
- Constant lower abdominal aching, not just in the genital area but also in the back, flanks, and lower abdomen
- Nonspecific malaise, aching all over; nausea, tiredness, irritability, and cold sweats

Reproduced with permission from Warrell, Cox and Firth, Oxford Textbook of Medicine, Fifth Edition Oxford University Press, Oxford, UK, Copyright © 2010

rigours, and hypotension and can be life-threatening. In the elderly, the presentation of a UTI may be non-specific, with pyrexia, loss of mobility, and confusion. Prostatitis can give pain on defaecation and a tender prostate on digital rectal examination.

Demographics

Females have a 50% lifetime risk of UTI, and 5% will have recurrent infections. The peak incidence is in sexually active females. Elderly females are also at increased risk, due to a rise in vaginal pH. Males are at low risk of UTI due to a longer urethra and distance of the meatus from the anus. The incidence of UTI in males increases with age, probably as a result of prostatic disease. A UTI in a male should always prompt investigation for an underlying urological cause.

Natural history, and complications

Most UTIs are uncomplicated and can be treated with a short course of antibiotic appropriate for the likely causative organisms (Box 158.2). Asymptomatic bacteriuria can lead to symptomatic infection, but can usually be safely left untreated. The exception to this is in pregnancy and in patients with anatomical abnormalities of their renal tract or renal transplants. Pregnancy is associated with a 5% incidence of bacteriuria. Because of progestogen-mediated ureteric smooth muscle relaxation, the risk of upper UTI is increased, and asymptomatic infections are treated.

Box 158.2 Organisms commonly causing uncomplicated urinary tract infection

- *Escherichia coli*
- *Klebsiella pneumoniae*
- *Proteus*
- *Pseudomonas*
- *Enterococcus*
- *Staphylococcus saprophyticus* (in sexually active females)

This article was adapted from Urinary tract infections in adults, Hooton T. in *Comprehensive clinical nephrology*, Johnson RJ, Feehally J (eds), Table 53.1, p. 695 Copyright Elsevier 2003.

Complicated infections data from: Nicolle LE. A practical guide to the management of complicated urinary tract infection. *Drugs* 1997; 53: 583–592.

An adult with appropriately treated acute pyelonephritis will usually have an uncomplicated recovery. However, an obstructed and infected urinary system is an emergency that requires urological drainage.

Recurrent cystitis can eventually result in a sterile inflammation and ulceration of the bladder, termed 'interstitial cystitis'. Treatment of the resultant chronic pain can be difficult but may respond to tricyclic antidepressants.

UTI in children was believed to cause renal scarring. However, it is unclear to what extent the infections contribute to the loss of renal function. The infection itself may simply be an indicator of underlying vesicoureteric reflux, which may itself be injurious. Vesicoureteric reflux affects 1% of newborns, but is present in 50% of children presenting with a UTI. Reflux usually stops at puberty, when the bladder base thickens. After the age of 7, the kidney seems to be resistant to new scarring. The resultant scarred kidney from reflux is termed 'reflux nephropathy' or 'chronic pyelonephritis'. Reflux nephropathy is still responsible for 7% of new dialysis patients.

Approach to diagnosing the disease

Diagnosis is from the history and urinary findings. Urinalysis, plus urine and blood cultures, is a routine screening test in sepsis. Dipstick detection of leucocytes and nitrites is highly sensitive. Blood and protein may also be present. On microscopy of a fresh urine specimen, the presence of >10 white cells per high-power field, or of any bacteria, is significant (Box 158.1 and Figure 158.1). A white-cell count and C-reactive protein and procalcitonin levels may be useful indicators of infection severity. Pitfalls include missing the diagnosis in the elderly, where the presentation may be non-specific, and missing associated urinary tract obstruction or stones.

Differential diagnosis

The differential of renal angle pain is renal stones, renal malignancy, or infection. A renal ultrasound is indicated if there is doubt about the diagnosis (marked loin pain/deterioration in creatinine/history of stones or renal colic/male/elderly/atypical urinalysis).

Figure 158.1 Urinary bacteria (rods). Please see colour plate section.

Reproduced with permission from Davidson et al, *Oxford Textbook of Clinical Nephrology*, Third Edition, Oxford University Press, Oxford, UK, Copyright © 2005.

The differential of dysuria includes a *Chlamydia trachomatis* or *Neisseria gonorrhoeae* urethritis. These infections are usually accompanied by a urethral discharge.

'Gold-standard' diagnostic test

The gold-standard diagnostic test for UTI is urine culture, with a finding of $\geq 10^5$ colony-forming units/ml. However, this threshold may miss up to 30% of infections, and a threshold of 10^4 colony-forming units/ml is suggested in the context of symptoms of pyelonephritis or in children, while 10^3 colony-forming units/ml may be significant in men.

Other relevant investigations

An ultrasound is indicated in a second attack of pyelonephritis or in suspected obstruction. Early morning urines are indicated in sterile pyuria with risk factors for tuberculosis.

In older males, an assessment of the prostate, together with cystoscopy and an ultrasound to assess bladder emptying, may be necessary to identify predisposing prostate or bladder disease.

CT scans are useful in severe cases of pyelonephritis or where there is associated stone/obstructive disease.

Children with a UTI may need a renal ultrasound scan to look for anatomical abnormalities. A ^{99m}Tc -DMSA nuclear scan can be used to detect renal scarring. Micturating cystograms are not routinely used but may be helpful under certain circumstances.

Prognosis and how to estimate it

Most UTIs resolve with simple antibiotic treatment.

Treatment and effectiveness

Increased fluid intake is advised. Antibiotics are usually indicated. Empirical choice of antibiotic is directed by local microbiological sensitivities. Treatment duration is an important consideration (Table 158.2).

There are several special situations. A UTI in combination with obstruction can cause rapid renal scarring and is a urological emergency. Decompression is achieved by percutaneous nephrostomy or retrograde stenting.

In children with reflux or recurrent infection, long-term prophylactic antibiotics were previously advocated. However, there is little evidence that such treatment alters prognosis. Surgery probably offers no long-term benefit over prophylactic antibiotics.

Catheter-related infection is common. Treatment is rarely effective without catheter removal or exchange. Treatment is thus reserved for local symptoms or systemic upset.

Table 158.2 A typical protocol for empirical treatment of a single urinary tract infection; protocols will vary with local patterns of antibiotic sensitivity

Diagnosis	Treatment
Asymptomatic bacteriuria	Well: No treatment Pregnant: 7–10 days oral
Uncomplicated lower urinary tract infection	3–7 days oral nitrofurantoin 50 mg four times per day 3–7 days of co-amoxiclav 375 mg three times per day, or cefalexin 500 mg three times per day in renal impairment
Complicated urinary tract infection	Acute pyelonephritis: 14-day course of oral ciprofloxacin 500 mg twice per day, or co-amoxiclav 625 mg three times per day Septicaemia: Inpatient management with IV co-amoxiclav 1.2 g three times per day +/- stat dose of gentamicin +/- IV fluids Male: 4–6 weeks oral ciprofloxacin 500 mg twice per day, to clear deep prostate infection Recent urinary instrumentation: consider adding vancomycin 1 g IV

Recurrent UTIs are defined by greater than four proven infections within a year. Treatment advice includes increasing fluid intake, double voiding, and avoiding nylon underwear. Prophylactic use of cranberry juice is supported by randomized trials. Cranberry juice contains proanthocyanidins that appear to inhibit the attachment of pathogens to uroepithelium. Between 200 and 750 ml per day of cranberry (or lingonberry) juice can reduce recurrent infection by 12%–20%. Refractory cases may benefit from a year of monthly rotating, low-single-dose antibiotic prophylaxis. In postmenopausal females, oestrogen creams may improve associated atrophic vaginitis. In sexually active women, post-coital voiding and a post-coital dose of antibiotic can be helpful.

159 Glomerulonephritis

William G. Herrington, Aron Chakera, and Christopher A. O’Callaghan

Definition of the disease

Glomerulonephritis (GN) is inflammation of the glomerulus. It can be caused by many different underlying conditions and can present in a range of ways. The key features, however, are evidence of renal dysfunction (clinical and investigative) with associated glomerular disease—the latter is often initially suspected from urine dipstick examination (Chapter 157), and may then be confirmed by a renal biopsy.

Etiology

There are many causes of GN (Table 159.1). Immunological damage to the glomerulus can arise from direct binding of an antibody to the glomerular basement membrane (anti-GBM disease; also known as Goodpasture’s disease). In a number of other glomerular diseases, immune mechanisms are implicated, but the exact pathogenesis is not clear.

Symptoms and clinical features

Acute nephritis is characterized by hypertension, fluid retention causing peripheral oedema, and microscopic haematuria and proteinuria. There may also be non-specific systemic features such as fevers, weight loss, anorexia, malaise, myalgias, or arthralgias. Other symptoms may indicate a specific underlying diagnosis (see ‘Approach to diagnosing the disease’ and ‘Other diagnoses that should be considered’). Rapidly progressive GN (RPGN) is an acute destructive GN with renal failure developing over days; typically, features of nephritic syndrome are present. Nephrotic syndrome is defined by the presence of heavy proteinuria (>3.5 g/day), resulting in hypoalbuminaemia and peripheral oedema and is discussed in Chapter 161 (also see Table 159.2). GN may be asymptomatic and detected by abnormal urinalysis on incidental testing.

Some common symptoms of different GNs

Antineutrophil cytoplasmic antibody-positive vasculitis

Antineutrophil cytoplasmic antibody (ANCA)-positive vasculitis affects small vessels. It can be asymptomatic (until uraemia develops) or associated with non-specific systemic upset (fevers, weight loss, anorexia, malaise, myalgias, arthralgias). There may be a vasculitic rash, ocular, or

ENT involvement. Granulomatosis with polyangiitis (Wegener’s granulomatosis) is characteristically associated with upper respiratory tract involvement, with nasal crusting, epistaxis, sinusitis, or otitis media.

Nephritis in SLE

Nephritis can occur with SLE. There may be features of systemic lupus such as Raynaud’s phenomenon, serositis, skin changes including a butterfly rash, alopecia, CNS involvement, or haematological derangements (thrombocytopenia, haemolysis, leucopenia). It may be associated with antiphospholipid syndrome.

Henoch–Schönlein purpura and IgA nephropathy

Henoch–Schönlein purpura (HSP) and IgA nephropathy share similarities. IgA nephropathy classically presents with macroscopic haematuria, often associated with upper respiratory tract infections. HSP is characterized by systemic symptoms that include palpable purpura, diffuse abdominal pain which may be worse after meals (bowel ischaemia), and symmetrical polyarthralgia. In adults, HSP predominately affects the kidney.

Rarer causes of GN

Anti-GBM disease (Goodpasture’s disease)

Anti-GBM disease (Goodpasture’s disease) can be asymptomatic. Renal failure often occurs very rapidly. Macroscopic haematuria or ‘cola’ urine may be reported. A cough, dyspnoea, and haemoptysis suggest pulmonary haemorrhage.

Mesangiocapillary GN

Mesangiocapillary GN can present in a variety of ways ranging from asymptomatic urine abnormalities to a rapidly progressive GN. It can be associated with cryoglobulinaemia or with partial lipodystrophy.

Postinfectious GN

Postinfectious GN can follow any infection, including streptococcal sore throat, infective endocarditis, abscesses, and tropical infections.

Demographics

IgA nephropathy is the commonest cause of GN worldwide. In the Far East, it is responsible for almost half of all cases of glomerular

Table 159.1 Etiology of glomerulonephritis

	Rapidly progressive glomerulonephritis	Acute nephritis	Nephrotic syndrome	Asymptomatic microscopic haematuria +/- proteinuria*
Immune complex	Henoch–Schönlein purpura (IgA nephropathy) Mesangiocapillary glomerulonephritis	IgA nephropathy Lupus nephritis Postinfectious GN Mesangiocapillary glomerulonephritis	Membranous nephropathy	IgA nephropathy Mesangiocapillary glomerulonephritis
Antibody dependent	Anti-glomerular basement membrane disease			
Pauci-immune	ANCA-positive vasculitis (granulomatosis with polyangiitis (Wegener’s) and microscopic polyangiitis) Polyarteritis nodosa: does not typically cause glomerulonephritis, but arterial inflammation can cause renal ischaemia and necrosis Churg–Strauss syndrome	Thrombotic microangiopathy [†]	Minimal-change disease Focal segmental glomerulosclerosis	

* With normal urological investigations.

[†]Thrombotic microangiopathy is often considered to be a disparate group of systemic disorders rather than a glomerulonephritis.

Histology	Number of children ^a (%)	Number of adults ^b (%)
Minimal-change nephrotic syndrome	76	17
Mesangiocapillary glomerulonephritis	8	3
Focal segmental glomerulosclerosis	7	17
Proliferative (including diffuse mesangial proliferation)	2	0
Membranous	2	30
Other	5	9
Systemic lupus erythematosus	–	8
Amyloid	–	7
Diabetes	–	9

disease. It is also common in Europe. Black and Asian people have a higher prevalence of lupus nephritis.

Vasculitis is rare in all populations. The prevalence of ANCA-positive vasculitis and anti-GBM disease are 20 and 0.5 per million population, respectively.

Mesangiocapillary GN, lupus nephritis, and Henoch–Schönlein purpura tend to affect the young (10–40 years of age). ANCA-positive vasculitis peaks between the ages of 55–70. Anti-GBM disease can affect any age, but the full syndrome with pulmonary haemorrhage is more common in younger patients. The younger patients are more commonly male, and older patients are more commonly female. Lupus nephritis affects ten times as many women as men.

Natural history, and complications

The progression rate varies with disease. For example, renal survival is 80% at 20 years in IgA nephropathy, while untreated ANCA-positive vasculitis carries a 90% 2-year mortality. Pulmonary haemorrhage is a serious complication of ANCA-positive vasculitides and anti-GBM

disease. The risk is increased by pulmonary oedema and cigarette smoking.

Complications of treatment are largely related to immunosuppression.

Approach to diagnosing the disease

GN is easily missed. A thorough history may elicit suspicion. Non-specific systemic upset with a combination of fevers, weight loss, anorexia, malaise, myalgias, or arthralgias is common with autoimmune and infective diseases and should prompt further assessment. In any patient with hypertension, peripheral oedema, or impaired renal function urine dipstick testing should be performed.

Urinary abnormalities or abnormal renal function should initiate further investigations to identify the cause and, when indicated, to prepare for a renal biopsy. Often, knowledge of the demographics of the relevant diseases and a thorough history and examination will narrow the diagnosis.

Other diagnoses that should be considered

Microscopic haematuria can be caused by urinary tract stones or tumours and sometimes infections. Alport's syndrome and thin basement membrane disease also present with microscopic haematuria alone and thus resemble IgA nephropathy. They are hereditary nephropathies with urine abnormalities but no inflammation and are thus not strictly GNs. Thin basement membrane disease has a good prognosis and rarely causes renal impairment. Alport's causes a progressive decline in renal function and high-tone sensorineural deafness. End-stage renal failure usually occurs around 20 to 30 years of age. Staining for type IV collagen is negative on biopsy. It is most important to differentiate the conditions causing benign abnormalities on urinalysis from RPGN, which requires urgent investigation and treatment.

'Gold-standard' diagnostic test

The gold-standard diagnostic test is renal biopsy (see Table 159.3 and Figures 159.1 and 159.2). In benign disorders, it may not be indicated.

Table 159.3 Renal biopsy findings in glomerulonephritis

Disease	Light microscopy	Immunofluorescence	Electron microscopy
ANCA-positive vasculitis	Focal and segmental necrotizing glomerular lesions +/- arteritis +/- crescents	Pauci-immune (negative)	
Anti-glomerular basement membrane disease	Diffuse global necrotizing lesions +/- Bowman's capsule rupture with crescents	Linear IgG+ C3+	
Mesangiocapillary glomerulonephritis	Basement membrane duplication + mesangial hypercellularity	Type 1: C3+ IgG+	Sub-endothelial immune complex deposits
Lupus nephritis	I: Normal II: Mesangial hypercellularity III: Focal endocapillary proliferation (<50% glomeruli) IV: Diffuse endocapillary proliferation (>50% glomeruli); can be segmental or global V: Glomerular basement membrane thickening with sub-epithelial 'spikes' on silver staining VI: Advanced sclerosis	IgA/IgG/IgM+ C3/C1q+ (Full house)	All: mesangial electron-dense deposits +/- sub-endothelial (Class III/IV) +/- sub-epithelial (Class V)
Postinfectious GN	Acute proliferative glomerulonephritis Intra-capillary neutrophils	C3+ IgG+/-	Sub-epithelial electron-dense deposits ('humps') Endocapillary swelling with widening of endothelial spaces
Thrombotic microangiopathy	Glomerular capillary fibrin thrombi and sub-endothelial oedema Ischaemic changes	Negative	Capillary fibrin thrombi Endocapillary swelling + injury
Henoch–Schönlein purpura/IgA nephropathy	Mesangial hypercellularity +/- increased mesangial matrix +/- endocapillary proliferation +/- segmental sclerosis +/- tubular atrophy +/- crescents	IgA +	Mesangial electron-dense deposits +/- sub-endothelial deposits

Figure 159.1 Histology of renal biopsy. (A) IgA nephropathy showing mesangial hypercellularity in which there are at least four mesangial cells in a peripheral mesangial area (periodic acid-Schiff stain). (B) Postinfectious glomerulonephritis showing endocapillary hypercellularity, in which the capillary lumina are filled with infiltrating leucocytes (hematoxylin and eosin stain (H&E)). (C) Antiglomerular basement membrane disease, showing extracapillary proliferation (a cellular crescent), in which there is partial tuft collapse and proliferation of cells within Bowman's space (H&E and silver). (D) ANCA-associated vasculitis, showing necrosis with capillary wall rupture and fibrin exudation (H&E and silver). (E, F) Membranoproliferative pattern, showing a lobular appearance of the glomerular tuft, with mesangial hypercellularity and thickened capillary walls, with glomerular basement membrane duplication evident on the silver stain (H&E and silver). Please see colour plate section.

Acceptable diagnostic alternatives to the gold standard

Other investigations in GN are adjuncts to diagnostic biopsy material. If RPGN is suspected, a rapid ELISA test can demonstrate anti-PR3, anti-myeloperoxidase, and anti-GBM antibodies within hours.

Other relevant investigations

With GN, urine microscopy may demonstrate dysmorphic red cells with or without red-cell casts—a sign of glomerular bleeding. Other

standard investigations include renal function, liver function, bone chemistry, and a nephritic screen (antinuclear antibody (ANA), complement, ANCA, anti-GBM, immunoglobulins, serum, and urine electrophoresis, hepatitis virus serology, and C-reactive protein). Tests for infection such as anti-streptolysin O and anti-DNase B titres are requested if postinfectious GN is suspected. Diarrhoea and thrombocytopenia should prompt a request for a blood film, haemolysis screen, and stool culture to assess for a thrombotic microangiopathy (see Chapter 170). In vasculitis, a chest X-ray and test to determine the diffusion constant for carbon monoxide (as this constant is elevated with pulmonary haemorrhage) are usually requested.

Figure 159.2 Immunofluorescence of renal biopsy. (A) Linear glomerular basement membrane (GBM) positivity for IgG in anti-GBM disease. (B) Granular capillary wall positivity for IgG in membranous nephropathy. (C) Mesangial positivity for IgA in IgA nephropathy. (D) Mesangial and capillary wall positivity for C3 in C3 glomerulonephritis. (E) Mesangial and tubular basement membrane positivity for kappa light chains in light chain deposition disease. (F) Positivity for lambda light chains in tubular casts in light chain cast nephropathy. Please see colour plate section.

Membranous nephropathy, which often presents as nephrotic syndrome, is secondary to systemic diseases, drugs, or malignancy in only a minority of cases. There are geographical differences in the prevalence of secondary causes, and these should be considered carefully for each patient. Important secondary causes are SLE in younger women, and chronic hepatitis B infection, especially in East Asia (Box 159.1). It has recently been shown that the majority of patients with idiopathic membranous nephropathy have circulating antibodies against the M-type phospholipase A2 receptor, but such antibodies are typically absent in secondary membranous nephropathy.

Renal biopsy requires a full blood count, a coagulation screen, a negative urine culture, and a renal ultrasound. If polyarteritis nodosa

is suspected (because of prominent myalgias, neuropathy, hepatitis B infection, or livedo reticularis), a formal renal angiogram should be performed to exclude microaneurysms before biopsy (see Chapter 170).

Clues in screening investigations are as follows:

Clues indicating ANCA-positive vasculitis: Granulomatosis with polyangiitis (Wegener's granulomatosis) is typically associated with a positive cANCA titre and an elevated PR3 titre. Microscopic polyangiitis typically has a positive pANCA titre and an elevated myeloperoxidase titre.

Clues indicating anti-GBM disease: Anti-GBM disease is indicated by a positive anti-GBM antibody titre.

Box 159.1 Conditions associated with membranous nephropathy**Autoimmune diseases**

Clues indicating Churg–Strauss syndrome: The patient may be pANCA positive and has an associated eosinophilia.

Clues indicating mesangiocapillary GN: Type 1 mesangiocapillary GN with essential mixed cryoglobulinaemia is indicated by low C4 with positive rheumatoid factor and cryoglobulin. Look for hepatitis C co-infection. Type 2 mesangiocapillary GN (characterized by dense deposits in the glomerular basement membrane on electron microscopy) is indicated by low C3. Look for a C3 nephritic factor.

Clues indicating lupus nephritis: Lupus nephritis is associated with positive ANA and anti-double-stranded DNA antibody titres with low complement titres. Look for antiphospholipid antibodies.

Clues indicating postinfectious GN: Postinfectious GN has a low C3 with normal C4 and evidence of recent or ongoing infection.

Clues indicating Henoch–Schönlein purpura/IgA nephropathy: In Henoch–Schönlein purpura and IgA nephropathy, 50% of cases have a raised IgA, and skin biopsy demonstrates IgA.

Prognosis and how to estimate it

Prognosis is difficult to individually predict. Renal and patient survival is affected by age and the degree of renal impairment at diagnosis. Patients who are dialysis dependent at presentation have a high mortality rate. Progression in those with renal survival can be predicted by extrapolation a plot of the eGFR over time. Anti-GBM disease does not typically relapse, but most other GNs can have a relapsing–remitting pattern over time. Each active phase of GN can leave behind significant chronic damage. Chronic damage with fibrosis and atrophy of the renal tubules on a renal biopsy is a marker for progression, as is significant proteinuria.

Treatment and effectiveness

Treatment can be divided into general measures and disease-specific immunosuppression.

General measures

Fluid overload is treated with salt and water restriction, and diuretic therapy or dialysis. Hypertension should be treated.

Immunosuppression

Immunosuppression is often given as a short, intense course of high-dose immunosuppression (induction) followed by low-dose, long-term therapy (maintenance). The aim is to balance toxicity with efficacy. All drugs predispose to infection as well as other drug-specific toxicities. Specific regimes have been designed for each disease. As many of the diseases are rare, the evidence base for treatment is often weak. This and the potential toxicity of any therapy should be explained to the patient.

Commonly used immunosuppression and drug-specific side effects are given in Table 159.4.

Induction therapy for ANCA-positive vasculitis and anti-GBM disease involves high-dose immunosuppression, typically with cyclophosphamide and steroids. If the creatinine is over 500 $\mu\text{mol/l}$ or there is pulmonary haemorrhage, plasma exchange may be helpful. Maintenance therapy after 3 months of induction is usually with azathioprine.

Lupus nephritis is treated if there is histological evidence of risk of progression (International Society of Nephrology Grades III and IV). Steroids, in combination with high-dose oral mycophenolate

Table 159.4 Commonly used immunosuppression and drug-specific side effects

Drug/treatment	Uses	Toxicity	Prophylaxis	Monitoring
Corticosteroids	Induction (high dose) Maintenance (low dose)	Weight gain and glucose intolerance Osteoporosis Gastric toxicity Insomnia Cataracts	Bone Gastric	Blood sugars
Cyclophosphamide	Induction	Leucopaenia Infertility Premature menopause Haemorrhagic cystitis Urothelial cancer	PJP (TB if at risk) Mesna (if IV)	White-cell count
Azathioprine	Maintenance	Leucopaenia Hepatic toxicity Skin tumour		White-cell count Liver function
Mycophenolate mofetil	Induction (high dose) Maintenance (low dose)	Leucopaenia Diarrhoea Teratogenicity		White-cell count
Rituximab	Induction/maintenance	Rare: anaphylaxis PML Autoimmunity: ITP, and thyroid disease		
Plasma exchange	Induction	Line-related infection		

Abbreviations: ITP, immune thrombocytopenia; PJP, pneumocystis jiroveci pneumonia; PML, progressive multifocal leukoencephalopathy; TB, tuberculosis.

mofetil or cyclophosphamide, have been shown to be useful in inducing remission. Maintenance therapies include mycophenolate and azathioprine. Trials are also underway to assess the effectiveness of new biological agents, such as rituximab, for these conditions.

Some GNs do not require immunosuppression. Postinfectious GN tends to resolve spontaneously with clearance of the infection. There is no convincing evidence that immunosuppression is helpful with IgA nephropathy or mesangiocapillary GN. However, mesangiocapillary GN, in conjunction with hepatitis C infection, may respond to interferon alfa and ribavirin to reduce viral load.

160 Interstitial renal disease

William G. Herrington, Aron Chakera, and Christopher A. O'Callaghan

Definition of the disease

Tubulointerstitial renal diseases affect the renal tubules and/or the supporting interstitial tissue around them. The glomeruli are typically spared in early disease. Acute interstitial nephritis is characterized by an inflammatory infiltrate (often containing eosinophils). Chronic tubulointerstitial nephritis (TIN) is characterized by extensive tubular atrophy and interstitial fibrosis. The processes are clinically distinct but a prolonged acute interstitial nephritis will develop into chronic disease.

Etiology

There are many different causes of tubulointerstitial renal damage. Acute interstitial nephritis is an important cause of acute kidney injury. In 90% of cases, it is caused by drugs. It is rarely caused by infections (including leptospirosis, legionella, or TB).

Chronic TIN is a slower fibrotic process. An untreated, drug-associated interstitial nephritis may develop into tubulointerstitial fibrosis. There are many other specific causes (see Table 160.1). Tubulointerstitial fibrosis is the end result of tissue ischaemia and is, therefore, a non-specific finding in nearly all causes of chronic kidney disease.

Causes of tubulointerstitial damage include drugs and toxic substances; multiple myeloma; renal infiltration; kidney cysts; renal ischaemia; autoimmune disease; and crystal formation.

Drugs and toxic substances

Drugs commonly associated with interstitial renal disease include proton-pump inhibitors, NSAIDs, antibiotics (e.g. trimethoprim, penicillins, cephalosporins, and rifampicin), and allopurinol. Analgesic nephropathy was previously reported with phenacetin (a prodrug of paracetamol), but is not seen now. Long-term lithium use can cause renal damage, but most patients with renal damage can safely be managed with a lithium alternative. If lithium must be used, levels should be kept below 1 mmol/l and continued only if necessary. Lithium also causes a nephrogenic diabetes insipidus. Chinese herb nephropathy and Balkan nephropathy are caused by ingestion of aristolochic acid and are associated with rapidly progressive disease and late urothelial tumours. Endemic Balkan nephropathy is very similar and probably also caused by aristolochic acid ingestion.

Multiple myeloma

Multiple myeloma can cause renal impairment via several mechanisms. These include cast nephropathy (30%–60%), light chain amyloidosis (20%), light chain deposition disease (10%), hyperuricaemia, and hypercalcaemia. Cast nephropathy is caused by tubular blockage and inflammation caused by casts consisting of urinary light chains and tubular Tamm–Horsfall protein. On renal biopsy, these casts can

Figure 160.1 Cast nephropathy. Please see colour plate section. Reproduced with permission from Turner et al, *Oxford Textbook of Clinical Nephrology*, Fourth Edition, Oxford University Press, Oxford, UK, Copyright © 2015.

be characteristically fractured and may be surrounded by multinucleated giant cells (see Figure 160.1).

Renal infiltration

Lymphoma and leukaemia can infiltrate the kidney and can be typed by immunohistochemistry on biopsy. Tuberculosis can infiltrate the kidney and causes granulomas. The differential of granulomatous interstitial nephritis includes tuberculosis, sarcoidosis, Sjögren's syndrome, and drugs.

Kidney cysts

Kidney cysts can be macroscopic (polycystic kidney disease) or microscopic (nephronophthisis and medullary cystic kidney disease). These are discussed in Chapter 169.

Renal ischaemia

Sickle cell erythrocytes may obstruct flow in the relatively hypoxic medullary capillaries. Recurrent ischaemic damage results in tubulointerstitial fibrosis. Papillary necrosis can occur and cause loin pain and macroscopic haematuria.

Autoimmune disease

In the autoimmune disease tubulointerstitial nephritis with uveitis syndrome (TINU), tubulointerstitial damage is associated with anterior uveitis, but the eye and kidney inflammation do not necessarily occur at the same time. There is often evidence of systemic upset, with

Table 160.1 Causes of chronic tubulointerstitial disease

Vascular/ischaemic	Drug related	Occupational	Neoplastic	Immunological	Infectious	Metabolic	Disease related	Other causes
Hypertensive nephrosclerosis	NSAIDs	Lead	Myeloma	Sjögren's syndrome	Chronic pyelonephritis	Hypercalcaemia	Polycystic kidney disease	Obstructive uropathy
Atheroembolic disease	Analgesic nephropathy	Mercury	Lymphoma	Sarcoidosis	Tuberculosis	Hypokalaemia	Nephronophthisis	Balkan nephropathy
Sickle cell anaemia	Lithium Ciclosporin Chinese herb nephropathy	Cadmium	Leukaemia	Tubulointerstitial nephritis with uveitis syndrome		Oxalosis Hyperuricaemia Cystinosis	Medullary cystic kidney disease Medullary sponge kidney	

weight loss, a raised erythrocyte sedimentation rate (ESR), abnormal liver function, and anaemia.

Crystal formation

Hypercalcaemia and oxalosis are examples of crystals that can precipitate in the tubules and interstitium. Oxalosis is most commonly caused by small bowel resection, which affects gut oxalate absorption. It is also seen in hereditary hyperoxalosis. Hyperoxalosis also occurs acutely with ethylene glycol poisoning.

Symptoms

An acute interstitial nephritis can present with rash, arthralgias, and systemic upset. Renal function is abnormal and there may be an eosinophilia. These features, however, can be entirely absent.

In contrast, chronic TIN is often asymptomatic. Polyuria and nocturia can occur due to loss of urine concentrating ability or due to salt wasting. There may be symptoms from the underlying condition causing the TIN. Proximal tubular disease can lead to excess urinary loss of bicarbonate, sodium, potassium, phosphate, and glucose. The patient has a normal anion gap acidosis, with hypokalaemia, hypouricaemia, and hypophosphataemia. Disease of the more distal nephron can cause distal renal tubular acidosis. Late disease is associated with glomerular fibrosis and the usual manifestations of chronic kidney disease.

Demographics

Acute interstitial nephritis peaks in the late middle age and has no sex predilection. Tubulointerstitial disease demographics are dictated by the underlying etiology. TINU predominately affects young females.

Natural history, and complications

Most cases of acute interstitial nephritis resolve spontaneously with withdrawal of the causative drug. Between 10% and 20% of patients entering dialysis in the developed world have end-stage renal disease due to one or another of the tubulointerstitial diseases. However, the rate of renal progression is very variable. There is an increased risk of urothelial malignancy with analgesic nephropathy, Chinese herb nephropathy, and Balkan endemic nephropathy. Annual urine dipstick testing and cytology is recommended.

Approach to diagnosing the disease

The diagnosis is usually made on the basis of history, examination, and a series of screening tests. The classic triad of rash, eosinophilia, and arthralgias are present in only 10% of acute interstitial nephritis. Acute interstitial nephritis may occur more than a year after the first prescription of the offending drug.

Urinalysis can be normal or exhibit a sterile pyuria, glycosuria, or low-grade proteinuria. The urinary protein:creatinine ratio is generally less than 100 mg/mmol. If there is salt wasting due to an impairment of tubular function, then hypertension is typically absent. The key blood tests include electrolytes, creatinine, and bone and liver chemistry. Urine microscopy may find eosinophils.

Depending on the clinical context, specific investigations may be indicated. These may include a paraprotein screen (urinary free light chains, and serum protein electrophoresis) and an autoimmune screen, which may include an ESR test; tests for rheumatoid factor and antinuclear, anti-Ro, and anti-La antibodies; a test to measure serum angiotensin-converting enzyme; and collection of early morning urine samples ($\times 3$) to look for acid-fast bacilli.

Ultrasound scanning in chronic tubulointerstitial disease usually demonstrates small kidneys. Multiple small simple cysts in small

kidneys are common. Large encysted kidneys suggest polycystic kidney disease. Kidneys that are of normal size despite evidence of significant chronic renal impairment may suggest infiltrative disease or myeloma.

'Gold-standard' diagnostic test

The diagnosis of tubulointerstitial disease is confirmed on renal biopsy. The biopsy may indicate the underlying cause (see Figure 160.2).

Acceptable diagnostic alternatives

A biopsy is also not always necessary in the presence of a suitable clinical finding. However, it is usually performed in the acute setting. It is also recommended in a suspected chronic TIN if there is diagnostic doubt or a course of potentially toxic treatment is to be recommended (e.g. corticosteroids).

Prognosis and how to estimate it

Inflammation is reversible and, hence, acute interstitial nephritis often exhibits some recovery on removal of the causative insult. Progression of chronic TIN can be predicted from a plot of $1/\text{creatinine}$ or the estimated glomerular filtration rate against time, once the cause has been treated.

Treatment and effectiveness

The aim is to identify the causative agent and remove further exposure. Drug-associated acute interstitial nephritis may recover more quickly with steroids, and many nephrologists will prescribe a course. There is no reliably designed randomized control trial. Specific causes should be treated appropriately.

161 Nephrotic syndrome

William G. Herrington, Aron Chakera, and Christopher A. O'Callaghan

Definition of the disease

Nephrotic syndrome is a clinical syndrome of heavy proteinuria (greater than 3.5 g per 24 hours), oedema, and hypoalbuminaemia, which is associated with hyperlipidaemia and a procoagulant state.

Etiology of nephrotic syndrome

The glomerular filtration barrier restricts proteinuria to around 30 mg/day (of which albumin is around 10 mg). The barrier consists of fenestrated endothelium (negatively charged), glomerular basement membrane, and a slit diaphragm of interdigitating podocyte foot processes. Loss of normal podocyte function and morphology is associated with albumin leakage through the barrier. Various factors contribute to sodium retention. For example, plasminogen is amongst the proteins lost in the urine and is cleaved by urokinase in the distal tubule to plasmin. Plasmin activates the epithelial sodium channel, driving salt and water retention, and oedema. In addition, there is activation of the renin–angiotensin–aldosterone system, which drives sodium and water retention. Lipids, smaller immunoglobulin molecules (IgG mainly), and anticoagulant clotting factors are also lost in the urine.

Causes of nephrotic syndrome are traditionally classified by their histopathological descriptions. In most cases, the histological picture can have a primary (idiopathic) or secondary cause. Minimal change, membranous nephropathy, and focal segmental glomerulosclerosis account for over 60% of cases.

Primary causes of nephrotic syndrome

Minimal change disease

The pathogenesis of minimal change disease remains unclear. The disease may be triggered by viral infections, NSAIDs, and, rarely, malignancy. Oedema is often massive, with periorbital swelling, pleural effusions, and ascites.

Membranous nephropathy

Membranous nephropathy (see Chapter 159) is associated with autoantibodies directed against the M-type phospholipase A2 receptor (PLA2R) in ~70% of cases. Secondary causes include malignancies (breast, lung, colon, renal cell, and lymphoma), particularly in the >65 age group, and drugs such as gold, D-penicillamine, and captopril. Infective causes include hepatitis B and C and other chronic infections. Lupus nephritis (type V) can have histological features of membranous nephropathy.

Focal segmental glomerulosclerosis

A circulating factor is implicated in idiopathic focal segmental glomerulosclerosis. Focal segmental glomerulosclerosis can also be secondary. Causes include HIV, hyperfiltration induced by reduced nephron numbers (e.g. renal dysplasia, reflux nephropathy, renovascular disease), and morbid obesity.

Mesangiocapillary glomerulonephritis

Mesangiocapillary glomerulonephritis is also known as membranoproliferative glomerulonephritis. Type 1 mesangiocapillary glomerulonephritis is characterized by immune complex deposition, and activation of the classical complement pathway. It is more common in the developing world, where it is associated with recurrent infections. It can be associated with cryoglobulins and a hepatitis C infection. Type 2 mesangiocapillary glomerulonephritis is now referred to

as 'dense deposit disease' and is caused by abnormal activation of the alternative complement pathway.

Secondary causes of nephrotic syndrome

Glomerulosclerosis

Glomerulosclerosis caused by diabetes can sometimes result in proteinuria severe enough to cause nephrotic syndrome, but symptoms are usually not marked. (see Chapter 164).

Renal amyloidosis

Renal amyloidosis usually occurs as part of systemic amyloid deposition. Ninety per cent of patients with amyloid have kidney involvement; 60% have nephrotic-range proteinuria (see Chapter 170).

Monoclonal deposition diseases

Monoclonal deposition diseases are a heterogeneous group of conditions caused by plasma cell dyscrasias where the deposits are fibrils that do not organize into discrete fibrils and are therefore Congo red negative. Only 30% will have a detectable monoclonal paraprotein. Assessment of serum free light chains may assist in monitoring the underlying disease.

Symptoms

Patients present with progressive weight gain with peripheral oedema and often orthopnoea. Urine may be frothy. Creatinine is often normal (at least initially).

Demographics

Minimal change disease is the dominant cause of childhood nephrotic syndrome. It also represents 25% of adult nephrosis. Membranous nephropathy and focal segmental glomerulosclerosis are the commonest causes of nephrotic syndrome in the developed world. Nephrotic syndrome is rare before 35 years of age and peaks in the fifth and sixth decades. Black patients with nephrotic syndrome have focal segmental glomerulosclerosis in two-thirds of cases.

Complications of the disease

Large fluid shifts associated with hypoalbuminaemia or treatment can cause acute kidney injury with acute tubular necrosis. There is an increased risk of thrombosis. Loin pain, haematuria, and increasing creatinine may herald renal vein thrombosis (screen with a magnetic resonance venogram) (see Figure 161.1). Infections with capsulated organisms are increased due to low immunoglobulin levels. Long-standing proteinuria predisposes to progressive loss of renal function.

Approach to diagnosing the disease

Diagnosis can be delayed if a patient with oedema does not have a urine dipstick analysis performed. Nephrotic-range proteinuria will show up as at least 3+ protein on urinalysis. The diagnosis is confirmed by a protein–creatinine ratio over 300 mg/mmol, and hypoalbuminaemia. In adults, renal biopsy is the diagnostic test. Minimal change disease classically presents with rapid onset gross peripheral and facial oedema, and haematuria is usually absent. Demographics and associated findings may be pointers. A peripheral neuropathy may be associated with amyloidosis or a cryoglobulinaemia.

Standard investigations are used to help with diagnosis, assess severity, and prepare for a renal biopsy. A urinary PCR, renal function,

Figure 161.1 CT scan demonstrating renal vein and inferior vena cava thrombus.

Image courtesy of Nigel Cowan.

fasting lipids, and albumin confirm nephrotic syndrome. A renal biopsy requires a full blood count, coagulation screen, renal ultrasound, urine microscopy, and culture. Tests to aid the diagnosis of the etiology include a liver function test; a bone chemistry blood test; tests for antinuclear antibody, complement proteins C3 and C4, and

antineutrophil cytoplasmic antibody, as well as an immunoglobulins test; serum and urine electrophoresis; anti-PLA2R antibodies; hepatitis virus serology; and a C-reactive protein test. In mesangiocapillary glomerulonephritis, an isolated low C4 may indicate the presence of cryoglobulins. An isolated low C3 may indicate the presence of C3 nephritic factor.

Differential diagnosis

Causes of hypoalbuminaemia without nephrotic-range proteinuria are frequently confused with nephrotic syndrome. These include liver failure, acute and chronic inflammatory states, malnutrition, and malabsorption.

'Gold-standard' diagnostic test

Histological findings in nephrotic syndrome are given in Table 161.1; also see Figure 161.2.

Acceptable diagnostic alternatives

In children, a renal biopsy is rarely performed, as minimal change disease dominates the cause. Instead, children are given a trial of corticosteroid.

Treatment

Treatment is divided into general supportive measures applicable to all nephrotic syndrome causes, and disease-specific measures.

General measures

General measures are as follows:

Salt and water restriction: Aim for 0.5 to 1.0 kg weight loss a day until oedema is controlled. This is partially achieved by restricting salt (3 g a day if possible) and fluid (as low as 500 ml a day, if required).

Diuretics: Large doses of diuretics are often required. If 250 mg of furosemide is insufficient, metolozone (a thiazide diuretic) is added. Amiloride may have a specific role in treatment through blockade of the epithelial sodium channel. Close monitoring of

Table 161.1 Histological findings in nephrotic syndrome

Disease	Light microscopy	Immunofluorescence	Electron microscopy
Minimal change disease	Normal	Negative	Podocyte foot-process effacement
Membranous nephropathy	Glomerular basement membrane thickening with sub-epithelial 'spikes' on silver staining	IgG positive C3 positive	Sub-epithelial electron-dense deposits (often with foot-process effacement)
Lupus nephritis (type V)	Glomerular basement membrane thickening	IgA/IgG/IgM positive C1q/C3/C4 positive (full house)	Sub-epithelial and mesangial electron-dense deposits (often with foot-process effacement)
Focal segmental glomerulosclerosis	Focal (some glomeruli are spared) segmental (only some parts of glomeruli are affected) mesangial matrix expansion with sclerosis Collapsing glomerular tufts suggest HIV	IgM positive C3 positive	
Mesangiocapillary glomerulonephritis	Capillary-wall thickening with basement membrane duplication +/- mesangial hypercellularity	Type 1: granular IgG positive C3 positive Type 2: C3 positive only	Type 1: Sub-endothelial immune complex deposits Type 2: Linear, dense deposits with glomerular basement membrane +/- mesangial hypercellularity
Diabetic glomerulosclerosis	Mesangial expansion Nodular glomerulosclerosis (Kimmelstiel-Wilson disease)	Negative	Glomerular basement membrane thickening
Renal amyloidosis	Amorphous pale hyaline deposits in glomeruli and arteries with positive Congo red stain	AL: Light chain positive (75% lambda) AA: -S-AA +	8-10 nm amyloid fibrils
Light chain deposition disease	Nodular glomerulosclerosis; negative for Congo red	AL: light chain positive (65% kappa)	Electron-dense material along glomerular and tubular basement membranes

Abbreviations: AA, AA protein-related renal amyloidosis; AL, amyloid light chain amyloidosis.

Note: Renal biopsy is the 'gold-standard' investigation in adults.

Table 161.2 Commonly used immunosuppression, and drug-specific side effects

Drug/treatment	Uses	Toxicity	Prophylaxis	Monitoring
Corticosteroids	Induction (high dose) Maintenance (low dose)	Weight gain and glucose intolerance Osteoporosis Gastric toxicity Insomnia Cataracts	Bone Gastric	Blood glucose
Cyclophosphamide	Induction	Leucopenia Infertility Premature menopause Haemorrhagic cystitis Urothelial cancers	PJP (TB if at risk) Mesna (if IV)	White-cell count
Ciclosporin	Induction Maintenance	Nephrotoxicity Tremor/hirsutism/gum hypertrophy Dyslipidaemia Hypertension		Drug levels Renal function

Abbreviations: IV, intravenous; PJP, *Pneumocystis jiroveci* pneumonia; TB, tuberculosis.

fluid balance and electrolytes is required, as the response can be profound.

Angiotensin-converting enzyme inhibition: Angiotensin-converting enzyme inhibitors should be used; alternatively, angiotensin II receptor blockers can be used in the long term.

Blood pressure control: The current recommended target for blood pressure in the presence of heavy proteinuria is $\leq 130/80$ mm Hg.

Anticoagulation: Inpatients should receive prophylactic heparin; long-term anticoagulation with warfarin may be advisable with severe nephrotic syndrome and when the albumin is consistently below 20 g/dl.

Lipid-lowering therapy: Dietary modification, together with a statin-based regimen, should be used.

Specific treatments

Treatment of a secondary cause often successfully treats the nephrotic syndrome. This is, however, not usually the case in diabetic nephrosclerosis. Primary causes also have specific treatments.

Treatment of minimal change disease

Minimal change disease will remit within 3 months in 90% of cases with a course of high-dose corticosteroids. Treatment-resistant cases may be focal segmental glomerulosclerosis that was not detected on biopsy due to a sampling error. Relapse is common. Frequent relapsing, and steroid-dependent disease, can be treated with ciclosporin or a course of cyclophosphamide (see Table 161.2).

Treatment of membranous nephropathy

Membranous nephropathy treatment is reserved for disease associated with a poor prognosis. Up to a third of cases spontaneously improve. Indications of poor prognosis include persistent nephrosis for a year, proteinuria greater than 10 g per day, and falling renal function. The modified 'Ponticelli regime' is a 6-month course of alternating corticosteroid with oral cyclophosphamide and may be preferable

to the traditional alternative ciclosporin. Rituximab, and tacrolimus are sometimes used. A suggested screen for associated malignancy includes a chest X-ray, mammogram, a prostate-specific antigen test, and endoscopy if faecal occult blood tests are positive.

Treatment of focal segmental glomerulosclerosis

Focal segmental glomerulosclerosis can be treated with a 6-month course of high-dose corticosteroids. HIV-associated nephropathy is effectively treated with antiretroviral agents.

Treatment of mesangiocapillary glomerulonephritis

Mesangiocapillary glomerulonephritis has a poor prognosis, as there is no proven therapy other than general measures. End-stage renal disease occurs in 50% at 10 years and it frequently recurs following transplantation.

Treatment of diabetic glomerulosclerosis

Diabetic glomerulosclerosis is treated with intensive blood pressure and glycaemic control.

Treatment of renal amyloidosis and monoclonal deposition diseases

Renal amyloidosis and monoclonal deposition diseases are managed by treatment of the underlying chronic disease or plasma cell dyscrasia.

162 Acute kidney injury

Aron Chakera, William G. Herrington, and Christopher A. O’Callaghan

Definition of the disease

Acute kidney injury (also referred to as acute renal failure) refers to a rapid decrease in renal function; it is reflected by an increase in blood urea and creatinine and is often associated with oliguria (a urine volume of less than 400 ml/24 hours). It usually develops over days to weeks. Acute kidney injury has been variously classified, but the current classifications are based on the glomerular filtration rate (or creatinine), looking at changes from baseline, and the presence of oliguria or anuria. The KDIGO (Kidney Disease: Improving Global Outcomes) staging system is shown in Table 162.1. In this classification system, acute kidney injury is indicated by one or more of the following:

- an increase in creatinine by $\geq 26.5 \mu\text{mol/l}$ within 48 hours
- an increase in creatinine to ≥ 1.5 times baseline, known or presumed to have occurred within the prior 7 days
- urine volume $< 0.5 \text{ ml/kg h}^{-1}$ for 6 hours

Etiology of the disease

The potential etiologies of acute kidney injury are usually considered anatomically under the headings prerenal, renal (intrinsic), and post-renal (Table 162.2). Relative frequencies of the major causes of acute kidney injury in hospitalized patients are given in Figure 162.1.

Typical symptoms of the disease, and less common symptoms

Due to the large physiological reserve of the kidneys, many cases of acute kidney injury are initially asymptomatic. Oliguria often precedes significant increases in urea and creatinine. Prerenal causes can be associated with low blood pressure, postural hypotension, and signs of sepsis or cardiac failure, whereas intrinsic renal diseases may cause haematuria or proteinuria (which may be noted as frothy urine) or there may be an associated rash or respiratory tract involvement, as can occur with vasculitis (see Chapters 140 and 247). Postrenal

	Serum creatinine	Urine output
1	1.5–1.9 times baseline Or $\geq 26.5 \mu\text{mol/l}$ increase	$< 0.5 \text{ ml/kg/h}$ for 6–12 hours
2	2.0–2.9 times baseline	$< 0.5 \text{ ml/kg/h}$ for ≥ 12 hours
3	3.0 times baseline Or Increase to $\geq 353.6 \mu\text{mol/l}$ Or Initiation of renal replacement therapy	$< 0.3 \text{ ml/kg/h}$ for ≥ 12 hours Or Anuria for ≥ 12 hours
Loss	Persistent ARF (complete loss of kidney function) > 4 weeks	
ESRD	ESRD > 3 months	

Abbreviations: ARF, acute renal failure; ESRD, end-stage renal disease.

Table 162.2 Causes of acute kidney injury

Prerenal	Hypotension Sepsis Medications Cardiac failure Hypovolaemia Haemorrhage Dehydration Impaired glomerular haemodynamics Angiotensin-converting enzyme inhibitors NSAIDs Vascular disease Renal artery stenosis Embolization Renal arteriole obstruction in haemolytic-uraemic syndrome Renal vein thrombosis Small vessel obstruction from accelerated phase hypertension
Prerenal/renal	Hepatorenal syndromes Pulmonary-renal syndromes
Renal (intrinsic)	Glomeruli Antiglomerular antibodies Antibody-antigen complex deposition Tubules Drug-induced tubulitis Antibiotics Contrast agents Chemotherapy agents Acute tubular necrosis (usually provoked by prerenal causes) Acute cortical necrosis (usually provoked by prerenal causes) Obstruction with casts, stones Interstitial Infection Granulomatous diseases
Postrenal	Ureteral obstruction Stones Tumours Sloughed papillae Clots Bladder outflow obstruction Benign prostatic hypertrophy Gynaecological malignancy Neurogenic bladder Urethral obstruction Strictures Intra-renal crystaluria

causes may present with abdominal or loin pain and, in males, there is often a history of prostatic symptoms. Late presentations may be associated with electrolyte disturbances, especially hyperkalaemia (see Chapter 173), as well as confusion, a metallic taste, or pericardial and pleural effusions from uraemia.

Figure 162.1 Relative frequencies of the major causes of acute kidney injury in hospitalized patients; ATN, acute tubular necrosis; TIN, tubulointerstitial nephritis.

Demographics of the disease

Acute kidney injury occurs in up to 10% of patients admitted to hospital, with an increased incidence in the elderly and patients in critical care settings. Patients with preexisting renal impairment or cardiovascular disease are particularly vulnerable. There is no racial or gender bias. The demographics follow the causes (Table 162.3).

Natural history, and complications of the disease

In hospitalized patients, the development of acute kidney injury is associated with a mortality of up to 50% in some series. Early diagnosis and correction of significant electrolyte abnormalities, together with optimization of fluid balance, are essential to minimize the incidence of complications. Death is usually from cardiac arrhythmias or pulmonary oedema. As acute kidney injury in hospital is usually the consequence of the conditions leading to hospitalization (rather than the cause), the natural history is highly dependent on the management of these condition (e.g. sepsis, cardiac failure). If treated early, many prerenal causes may be rapidly reversible; however, if treatment is delayed, and acute tubular necrosis results, a period of established renal failure lasting weeks may occur. If the renal insult is more profound, acute cortical necrosis may occur which may not be reversible.

Approach to diagnosing the disease

Unless there are prior results available, all elevations in urea and creatinine should be assumed to represent acute kidney injury. Potential causes can be considered anatomically and divided into prerenal, renal, and postrenal (see Chapter 156 for further details). A thorough medication history (including documentation of any herbal remedies and over-the-counter preparations taken) as well as a detailed family history should be elicited. Males should be directly questioned regarding symptoms of prostatic disease.

As many systemic diseases affect the kidneys, a complete examination should be performed, including fundoscopy (hypertensive changes, Roth's spots, and cholesterol emboli), inspection of the skin for rashes (SLE, IgA nephropathy, vasculitis, sepsis), palpation of the bladder and, where indicated, digital rectal examination in males. Dipstick urinalysis, ideally from a non-catheter specimen, is an essential part of the workup, with active urinary sediment (containing blood, protein, and/or leukocytes) being consistent with intrinsic renal disease. As patients with acute kidney injury may be unwell and unable to give a full history or cooperate with examination, it is essential to review any available notes. This includes operation and anaesthetic records, as the majority of cases of acute kidney injury developing in hospital have an easily recognizable cause, such as a period of perioperative hypotension or the prescription of a nephrotoxic drug.

Table 162.3 Causes of development of acute impairment of renal function in 2216 consecutive medical and surgical admissions

Cause	Number of patients
Acute tubular necrosis

Other diagnoses that should be considered

Acute renal impairment in hospitalized patients is usually prerenal in aetiology, so particular attention should be given to assessing cardiac function and fluid balance. A rough heuristic is that the ratio of the creatinine ($\mu\text{mol/l}$) to urea ($\mu\text{mol/l}$) should be $\sim 20:1$ (i.e. someone with a urea of $20 \mu\text{mol/l}$ would be expected to have a creatinine of $\sim 400 \mu\text{mol/l}$). Significant elevations of this ratio (e.g. urea of $35 \mu\text{mol/l}$ with a creatinine of $400 \mu\text{mol/l}$) should raise the suspicion of dehydration (necessitating optimization of fluid balance) or gut haemorrhage. Syndromes associated with acute kidney injury are given in Table 162.4.

'Gold-standard' diagnostic test

The gold-standard diagnostic test is measurement of the serum urea and creatinine, demonstrating an acute deterioration in renal function. Oliguria often precedes changes in creatinine and urea.

Acceptable diagnostic alternatives to the gold standard

A variety of biomarkers are under investigation to improve the early identification of acute kidney injury (e.g. cystatin C, neutrophil gelatinase-associated lipocalin, and kidney injury molecule-1). Currently, these are not generally available for clinical use.

Other relevant investigations

It is essential to ensure that the patient is not dangerously hyperkalaemic. An ECG should be performed and the patient placed onto cardiac monitoring. If there are diagnostic ECG changes, initial treatment should be commenced while awaiting laboratory results (see Chapter 173).

Renal tract ultrasonography can provide information on renal size and morphology (which may support the presence of some preexisting renal impairment), identify obstruction, and, in most cases, comment on renal blood flow and perfusion. If there is rhabdomyolysis, serum creatinine kinase is usually substantially elevated.

Where intrinsic renal disease is suspected from systemic causes, immunological tests, including tests to detect anti-double-stranded DNA antibodies, antinuclear antibodies, antineutrophil cytoplasmic antibodies, anti-glomerular basement membrane antibodies, and complement proteins C3 and C4, may be indicated, as may viral serology, and assessment for a paraprotein with urine and plasma electrophoresis or free light chain quantification. Often, a definitive diagnosis of the underlying cause requires a renal biopsy.

Table 162.4 Syndromes associated with acute kidney injury

Acute kidney injury and a rash	Vasculitis Infective endocarditis Cryoglobulinaemia Sepsis SLE Henoch–Schönlein purpura/thrombotic thrombocytopenic purpura
Acute kidney injury and jaundice	Hepatorenal syndrome Infections (e.g. leptospirosis, EBV, CMV) Drugs (e.g. anaesthetic agents) Sickle cell disease Severe sepsis
Acute kidney injury and hypercalcaemia	Myeloma Malignancy Milk-alkali syndrome Sarcoid
Acute kidney injury and lung involvement	Pneumonia with ATN (or TIN) Systemic vasculitis SLE Goodpasture's disease
Acute kidney injury and joint involvement	Systemic vasculitis SLE Amyloidosis
Acute kidney injury and haemolysis	Haemolytic–uraemic syndrome/thrombotic thrombocytopenic purpura Accelerated hypertension Scleroderma Pre-eclampsia

Abbreviations: ATN, acute tubulointerstitial nephritis; CMV, cytomegalovirus; EBV, Epstein–Barr virus; SLE, systemic lupus erythematosus; TIN, tubulointerstitial nephritis.

Particularly in older patients, routine testing of thyroid function may be worthwhile, as subclinical hypothyroidism can cause significant elevations in creatinine.

Prognosis and how to estimate it

The prognosis of acute kidney injury is largely dependent on the underlying aetiology. The poor outcome of acute kidney injury in hospitalized patients largely reflects significant comorbidities in this population, with these having led to the renal impairment. When the inciting agent(s) are removed or the underlying cause treated, many patients with acute kidney injury due to prerenal causes can

be expected to recover to their baseline level of renal function, even should they reach the point of temporarily requiring renal replacement therapy. Where intrinsic renal disease is suspected, a renal biopsy may provide some information regarding prognosis (e.g. percentage of sclerosed glomeruli and degree of tubular atrophy).

Treatment and its effectiveness

Therapy in acute kidney injury is initially directed at managing any immediate life threats (e.g. hyperkalaemia or pulmonary oedema) before identifying and treating any underlying causes.

Management of prerenal renal impairment aims to improve renal perfusion, by optimizing fluid balance and blood pressure and stopping any offending medications, such as angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, or NSAIDs. When assessment of intravascular fluid status is difficult, insertion of a central line for central venous pressure monitoring and/or an arterial line for accurate measurement of blood pressure, and considering the use of inotropic agents to improve renal perfusion, may be indicated.

Postrenal causes are managed by relieving the obstruction, by catheterization or insertion of a nephrostomy tube. (Note that unilateral obstruction should not cause an elevation in the urea or creatinine, provided the unaffected kidney is normal.)

Management of intrinsic kidney injury is directed at the underlying abnormality where possible, for example, cessation of medications that may be responsible for interstitial nephritis, or commencement of immunosuppression in autoimmune diseases. Where appropriate, dialysis may be instituted (either haemodialysis or, less commonly, peritoneal dialysis) to support patients through the acute illness, with the hope of eventual renal recovery. For patients who are haemodynamically unstable, haemofiltration is often preferred to haemodialysis. This is a slower therapy that minimizes rapid fluid and electrolyte shifts; it is used by most intensive care units. Up to 10% of patients will remain dialysis dependent following the development of acute kidney injury.

163 Chronic kidney disease

William G. Herrington, Aron Chakera, and Christopher A. O'Callaghan

Definition of the disease

Chronic kidney disease (CKD) is defined as abnormalities of kidney structure or function, where the abnormalities have been present for >3 months and have implications for health. It is characterized by a reduced estimated glomerular filtration rate (eGFR) or other renal abnormalities. CKD is staged according to the eGFR (see Table 163.1) or the degree of albuminuria (see Table 163.2). The KDIGO (Kidney Disease: Improving Global Outcomes) criteria for CKD is either an eGFR that is <60 ml/min 1.73 m⁻² and has been present for >3 months, or one or more markers of kidney damage, when these have been present for >3 months. The accepted markers of kidney damage are:

- albuminuria (albumin excretion rate ≥30 mg/24 hours; albumin-creatinine ratio ≥3 mg/mmol)
- urine sediment abnormalities
- electrolyte and other abnormalities due to tubular disorders
- abnormalities detected by histology
- structural abnormalities detected by imaging
- history of kidney transplantation

The staging uses the eGFR to produce a 'G' stage (Table 163.1), and albuminuria to produce an 'A' stage (Table 163.2). These are combined so that a patient will have both a 'G' and an 'A' stage (e.g. G4, A3). Stage G5 is often referred to as end-stage renal disease. This staging does not incorporate information on the precise diagnosis, on comorbidities, or on the historical rate of renal decline, all of which may be important in assessing the significance of CKD for an individual patient.

Etiology of CKD

There are many causes of CKD, but the most common are diabetes, hypertension, and renovascular disease. Diabetes mellitus is the commonest cause of end-stage renal disease in developed countries and accounts about a quarter of new dialysis patients in the UK (see Figure 163.1).

Symptoms

The biochemical and physiological derangements of CKD occur much earlier than the clinical manifestations (Table 163.3). Therefore, most patients with CKD are asymptomatic. The subtle and late

Table 163.1 KDIGO (Kidney Disease: Improving Global Outcomes) estimated glomerular function rate, or 'G', staging system for chronic kidney disease

GFR or G stage	Description
G1	eGFR >90 ml/min 1.73 m ⁻² with markers of kidney damage
G2	eGFR 60–89 ml/min 1.73 m ⁻² with markers of kidney damage
G3A	eGFR 45–59 ml/min 1.73 m ⁻²
G3B	eGFR 30–44 ml/min 1.73 m ⁻²
G4	eGFR 15–29 ml/min 1.73 m ⁻²
G5	eGFR <15 ml/min 1.73 m ⁻² or on dialysis

Abbreviations: eGFR, estimated glomerular function rate.

Table 163.2 KDIGO (Kidney Disease: Improving Global Outcomes) albuminuria, or 'A', staging system for chronic kidney disease

Albuminuria or A stage	AER (albumin excretion rate)	ACR (albumin-creatinine ratio)
A1	<30 mg/24 hours	<3 mg/mmol
A2	30–300 mg/24 hours	30–300 mg/mmol
A3	>300 mg/24 hours	>30 mg/mmol

Reproduced with permission from Kidney Disease: Improving Global Outcomes (KDIGO) Acute Kidney Injury Work Group. KDIGO clinical practice guideline for acute kidney injury. Kidney Int Suppl. 2012 Mar;2(1):1–138.

symptomatology of CKD accounts for late presentations and a large untreated population with early disease. Unfortunately, it is not uncommon for a patient's first contact with renal services to be for the initiation of dialysis.

Polyuria and nocturia can arise if there is a loss of renal tubular concentrating ability. Oedema and hypertension present later and can reflect either a defect in the regulation of body salt and water content associated with raised renin levels or, in the later stages, a loss of ability to excrete salt and water. Renal anaemia causes tiredness. The classic 'uraemic' symptoms, including persistent nausea and vomiting, anorexia, malaise, and itching, are uncommon until there is severe renal impairment with an eGFR usually well below 15 ml/min 1.73 m⁻². Renal replacement therapy is often started on the basis of these 'uraemic' symptoms before there is an absolute biochemical need.

Demographics of CKD

The prevalence of CKD depends on the definition used. The prevalence of CKD Stages 3–5 as defined in Table 163.1 may be as high as 10% in Western developed populations. Renal function declines with age, so most CKD occurs in the elderly. However, in the elderly, progression of CKD Stage 3 and non-proteinuric CKD Stage 4 to end-stage renal disease is rare. A fatal cardiovascular event is much more common. Consequently, the prevalence of CKD Stage 5 is perhaps as low as 0.2%. The rising prevalence of obesity and diabetes, and the growing elderly population, are, however, increasing the numbers of patients on renal replacement therapy by up to 6% per annum.

Figure 163.1 Causes of kidney disease in new maintenance renal replacement therapy patients.

data from United Kingdom Renal Registry 2007.

Table 163.3 Physical features indicating the etiology and chronicity of chronic kidney disease		
System	Feature	Comment
General	Pallor	Anaemia is a common feature of advanced CKD
	Pigmentation, scratch marks, brown nails	Indicate long-standing CKD
Cardiovascular/ respiratory	Blood pressure	Hypertension is a common association (but uncommon cause) of CKD
	Elevated jugular venous pressure, enlarged heart, gallop rhythm, mitral regurgitant murmur, pulmonary crackles, peripheral oedema	Manifestations of fluid overload caused by CKD and/or cardiac failure associated with hypertension or 'uraemia'
	Aortic systolic murmur	Valvular calcification is more common in CKD
	Peripheral pulses, vascular bruits	Absence of pulses and/or presence of bruits increase the likelihood of renovascular disease as the cause of CKD
Abdominal	Palpable kidneys	Likely to indicate adult polycystic kidney disease in this context
	Palpable bladder, malignant-feeling prostate on digital examination	Consider urinary obstruction as cause of CKD
	Hernias	Require repair if peritoneal dialysis otherwise preferred as RRT
Neurological	Peripheral neuropathy	Indicates long-standing CKD
	Proximal myopathy	Indicates long-standing CKD
Rheumatological	Arthritis	Gout and pseudogout are associated with CKD
	Carpal tunnel syndrome	
Ocular fundi	Features of hypertension	

Abbreviations: CKD, chronic kidney disease; RRT, renal replacement therapy.

Natural history and complications of CKD

CKD progresses at a different rate in different patients. Factors associated with accelerated decline are listed in Box 163.1. Some of these factors are modifiable and provide the basis for current treatment.

Proteinuria is one of the most important factors associated with chronic kidney damage. It can arise with glomerular damage and raised intra-glomerular pressures. Large amounts of proteinuria are thought to be toxic to the tubules, inducing interstitial inflammation that progresses to fibrosis. With each gram increase in daily proteinuria, there is a significant increase in risk of progression (see Figure 163.2). Proteinuria is an independent marker of cardiovascular risk. It is readily quantifiable on a spot urine protein-creatinine ratio or spot albumin-creatinine ratio and can often be reduced by controlling hypertension and inhibiting the renin-angiotensin system.

CKD is remarkable in that usually more than 90% of renal function is lost before renal replacement therapy is required. However, significant complications begin earlier.

Cardiovascular risk

A reduced eGFR is associated with an increased risk of cardiovascular events (see Figure 163.3). This continues on dialysis, where cardiovascular disease is the leading cause of death. A 20-year-old on dialysis has the same cardiovascular risk as an 80-year-old in the general population. An elderly patient with an eGFR less than 60 ml/min 1.73 m⁻² has a 1% annual chance of progression to end-stage renal disease but a 10% risk of death.

Box 163.1 Factors that have been associated with the rapid progression of chronic kidney disease

- raised blood pressure
- poor glycaemic control
- persistent primary renal disease activity
- persistent proteinuria
- family history of progression
- recurrent urinary tract infections
- obesity
- smoking
- hyperfiltration states
- dyslipidaemia

The increased cardiovascular risk with CKD arises largely because key risk factors such as age, hypertension, and diabetes mellitus predispose to both CKD and cardiovascular disease. However, CKD does increase cardiovascular risk directly through left ventricular hypertrophy (secondary to renal-induced hypertension, chronic fluid overload, and anaemia), proteinuria, dyslipidaemia, accelerated atherosclerosis, accelerated vascular calcification, oxidative stress, inflammation, and endothelial dysfunction. Management of cardiovascular risk in CKD thus involves more than the control of blood pressure and lipids.

Mineral and bone disorders

The term 'renal osteodystrophy' has now been replaced by the term 'chronic kidney disease-mineral and bone disorders' (CKD-MBD). The kidney excretes phosphate and activates vitamin D, so renal impairment can cause hyperphosphataemia and

Figure 163.2 Examples of rate of glomerular filtration rate decline, stratified by degree of proteinuria or disease; ΔGFR, change in glomerular filtration rate.

Figure 163.3 Age-standardized risk of cardiovascular events by estimated glomerular filtration rate; eGFR, estimated glomerular filtration rate. Adapted from data by Go et al. 2004.

lead to insufficient levels of active vitamin D. As a consequence, parathyroid hormone levels rise to maintain plasma ionized calcium. This hyperparathyroidism can become autonomous (tertiary hyperparathyroidism) and result in abnormal turnover of bone. In extreme cases, cystic resorption of bone (osteitis fibrosa cystica) occurs. Abnormalities of bone in renal disease can also include the changes of osteomalacia and osteoporosis. Low-turnover bone disease can arise with overzealous suppression of parathyroid hormone with vitamin D treatment and may be linked to accelerated vascular calcification. CKD patients are at higher risk of fracture from all these bony abnormalities.

Biochemical markers of bone turnover are used to direct treatment. A raised alkaline phosphatase and parathyroid hormone level indicate high bone turnover. A low parathyroid hormone level indicates possible low turnover.

Overt bone disease is, however, infrequent in renal practice. Vascular calcification, however, is two to five times greater in CKD patients than age-matched controls with coronary artery disease. Vascular smooth muscle cells can transform to osteoblast-like cells, which lay down a bone-like matrix in blood vessel media. This then calcifies in the setting of a high calcium–phosphate product. The result is increased arterial stiffness. This may explain part of the increased vascular risk in renal patients.

Renal anaemia

Deficiency of erythropoietin secretion results from the atrophy of peritubular interstitial fibroblasts. It typically can occur below an eGFR of 30 mL/min/1.73 m² (<45 in diabetics). Other causes of anaemia, especially iron deficiency, should be excluded and, occasionally, it is helpful to measure erythropoietin levels. Uraemia reduces dietary intake of iron, impairs intestinal absorption, and increases capillary fragility/platelet dysfunction, promoting gastrointestinal blood loss.

Hyperkalaemia

The kidney excretes potassium. A decreased eGFR reduces delivery of sodium to the aldosterone-mediated distal tubular Na⁺/K⁺ exchanger, causing potassium retention. Drugs targeting the renin-angiotensin system exacerbate this effect. Extracellular shifts of potassium are encouraged by concomitant acidosis and poor glycaemic control. Refractory hyperkalaemia is an indication for dialysis.

Acidosis

The kidneys regulate acid excretion. The accumulation of organic acids in CKD impairs bone turnover, promotes hyperkalaemia and protein catabolism, and exacerbates uraemic symptoms. Refractory acidosis is an indication for dialysis.

Fluid overload

The kidney excretes salt and water, so salt and water retention is common with renal impairment. This can cause hypertension and oedema and should be managed with diuretics and salt restriction. Occasionally, predominant tubulointerstitial disease can cause tubular salt wasting with hypotension, but this is uncommon.

Nutrition

Dietary modification is important to avoid electrolyte disorders. Potassium, phosphate, and sodium intake must be reduced. With severe disease, fluid intake may need to be reduced. However, it is important to maintain good nutrition in CKD despite dietary restrictions.

Uraemic pericarditis and encephalopathy

These are very rare and only occur with severe uraemia. They are both indications for urgent dialysis. Pericarditis requires careful heparin-free dialysis. Encephalopathy requires careful short and slow dialysis to allow re-equilibration of uraemic small molecules across the blood brain barrier.

Approach to diagnosing the disease

A raised creatinine should be considered to be acute kidney injury unless there are grounds for believing otherwise. CKD is confirmed by longitudinal follow-up of creatinine results. It is also suggested by the finding of small kidneys on an ultrasound scan (bipolar length of less than 8 cm). Exceptions include polycystic kidneys, infiltrative diseases such as amyloid or lymphoma, and occasionally diabetes mellitus.

'Gold-standard' diagnostic test

The gold-standard diagnostic test for CKD is longitudinal follow-up of creatinine and eGFR (see Table 163.1). Although total proteinuria is often measured, measurement of albuminuria is now regarded as the gold-standard test for assessing urinary protein loss.

Other relevant investigations

Dipstick urinalysis is important in the assessment of CKD. The absence of proteinuria or microscopic haematuria reduces the likelihood of a significant glomerular disease. Microscopic haematuria or proteinuria greater than 0.5 g/day suggests glomerular disease. Diagnosis relies on an autoimmune screen and renal biopsy. In patients above 50, isolated microscopic haematuria could arise from a urinary tract tumour, and this should be excluded in this age group.

Causes of non-proteinuric CKD include renovascular disease, ischaemic/hypertensive nephropathy, structural kidney diseases, obstructive kidney disease, and tubulointerstitial disease. Patients older than 45 years could be screened for paraproteinaemia by serum protein electrophoresis and free light chain analysis. Additional investigations include ultrasonography, magnetic resonance angiography, and, occasionally, renal biopsy. The renal biopsy is the best test to establish the cause of acute kidney injury. It is seldom of use in advanced CKD, as the biopsy is likely to show non-specific fibrotic changes. Biopsy is also often unnecessary if the diagnosis is obvious from the history, examination, or investigations.

Prognosis and how to estimate it

The progression of CKD can be predicted from a plot of $1/\text{creatinine}$ or eGFR against time. These graphs are commonly a straight line, and the time to dialysis can therefore be estimated by extrapolation. A change in the rate of decline may indicate a new renal insult, such as prostatic obstruction. Renovascular disease may progress in a stepwise fashion with long intervening periods of stability (see Figure 163.2).

Baseline proteinuria is a strong predictor of future progression, with >1 g/day associated with progression.

Treatment and its effectiveness

Treatment is divided into prevention of progression, modification of cardiovascular risk, and management of complications. In practice, many of the interventions used to reduce progression of CKD also reduce cardiovascular risk. Later in the disease, preparations for renal replacement therapy are made.

Prevention of progression

Specific renal diseases may require specialist treatment of the underlying condition. However, regardless of the underlying condition, it is important to control modifiable risk factors for progression (Box 163.1).

Blood pressure control is critical. An accepted target is 130/80 mm Hg, although some guidelines recommend higher or lower targets. For example, if proteinuria is greater than 1 g/day, the target may be lowered further (AASK/MDRD trials). Angiotensin-converting-enzyme (ACE) inhibitors are the first-line antihypertensives, but renal function should be checked within 2 weeks of introduction or a dose change. Commonly used second-line agents include furosemide, beta blockers, alpha-blockers, and calcium-channel blockers. The choice may be dictated by coexisting medical problems.

Proteinuria is minimized by blood pressure control. ACE inhibitors have an additional benefit beyond that of blood pressure control (REIN study). The dose should be titrated against proteinuria. Angiotensin II receptor blockade is similarly efficacious but adds no further benefit (IDN/RENALL trials).

Glycaemic control should be optimized (DCCT/UKPDS trials).

The SHARP study demonstrated that intensive lowering of LDL cholesterol reduces risk of major atherosclerotic events in CKD patients, but does not have any meaningful effect on renal progression.

Dietary protein restriction does not significantly improve progression (MDRD trial). Obesity and smoking are associated with progression and are important causes of mortality. Salt restriction and a diet high in fruit and vegetables reduce blood pressure (DASH study). Exercise 3–5 times a week is advocated.

Hyperuricaemia is independently associated with progression and can be reduced with allopurinol. However, no trial has demonstrated it slows renal progression.

Correction of acidosis with oral sodium bicarbonate may have beneficial effects, including slowing renal progression.

Acute renal insults should be minimized. Physicians should consider renal dose reduction and renal toxicity for any new medications. Patients should be advised that NSAIDs are contraindicated. It is also helpful to ask patients to stop ACE inhibitors in acute illnesses associated with hypovolaemia. Radio-opaque contrast agents should be used where there is no alternative.

Table 163.4 Suggested target ranges for CKD patients

	Target
Haemoglobin or erythropoietin (g/dl)	10–12 g/dl
Phosphate	0.9–1.5 mmol/l
Calcium–phosphate product	<4.8 mmol ² /l ²
Parathyroid hormone	1–2 times normal range, for Stage 4 CKD 2–9 times normal range, for Stage 5 CKD
Bicarbonate	22–26 mmol/l

Abbreviations: CKD, chronic kidney disease.

Management of complications

There is no hard clinical endpoint trials which show that correcting anaemia, acidosis, and calcium–phosphate balance slows CKD progression, but these factors are considered important in their own right.

Renal anaemia is corrected by optimizing iron stores, often with IV iron, before administering subcutaneous erythropoietin. Reversing anaemia reduces left ventricular hypertrophy, improves quality of life, and reduces the requirement for blood transfusion. The target haemoglobin is generally between 10 and 12 g/dl (see Table 163.4). Overcorrection is associated with possible increased cardiovascular events (CHOIR/CREATE/TREAT trials). Some IV iron preparations have been associated with allergic reactions. Erythropoietin can increase blood pressure.

Parathyroid hormone levels are controlled by optimizing phosphate levels and using vitamin D replacement therapy. Phosphate levels are controlled by dietary restriction and, if necessary, with phosphate binders. These agents (e.g. calcium carbonate, calcium acetate, sevelamer, and lanthanum) are taken with food and bind dietary phosphate, preventing absorption. Vitamin D suppresses parathyroid hormone secretion, and preparations include alfacalcidol and calcitriol. With tertiary hyperparathyroidism, parathyroidectomy may be necessary. Cinacalcet is a ‘calcimimetic’ drug and is an alternative for patients unfit for parathyroidectomy. It binds the calcium-sensing receptor on the parathyroid gland and so inhibits parathyroid hormone secretion.

Acidosis is controlled with oral sodium bicarbonate.

Modification of cardiovascular risk

Applying evidence from the general population, all patients with CKD with a history of myocardial infarction, stroke, or peripheral vascular disease should be prescribed aspirin, an ACE inhibitor, a beta blocker, and a statin-based regimen (unless contraindicated).

Preparation for renal replacement therapy

Preparation for dialysis or transplantation requires multiple timely interventions to deal with both medical and psychosocial aspects of care. All progressing patients should be vaccinated against hepatitis B and helped to make an informed decision on dialysis modality in time to arrange formation of an arteriovenous fistula or insertion of a peritoneal dialysis catheter. Referral for transplant assessment should occur within 6 months of estimated date of dialysis. Ideal renal replacement therapy in those fit for surgery is a pre-emptive, live-related transplant.

164 Diabetic renal disease

William G. Herrington, Aron Chakera, and Christopher A. O'Callaghan

Definition of the disease

Diabetic nephropathy is kidney damage occurring as a result of diabetes mellitus. Overt diabetic nephropathy is defined as proteinuria greater than 0.5 g/day.

Etiology of diabetic nephropathy

Diabetic nephropathy has a complicated pathogenesis including glomerular hypertension with hyperfiltration and advanced glycation end products. Poor glycaemic control is associated with progression to microalbuminuria and overt diabetic nephropathy. The lifetime risk is fairly equivalent for type 1 and type 2 diabetes mellitus.

Symptoms

Early disease is usually asymptomatic. Hyperglycaemia causes an osmotic diuresis and, thus, diabetes can present with polyuria. Hypertension develops with microalbuminuria; oedema indicates abnormal sodium and water retention and, occasionally, the development of nephrotic syndrome. Patients with diabetes, perhaps due to accompanying cardiac disease, are particularly susceptible to fluid overload and uraemic symptoms. End-stage renal disease can occur as early as when the estimated glomerular filtration rate (eGFR) is 15 ml/min 1.73 m².

Demographics of diabetic nephropathy

Diabetes mellitus affects 6%–9% of the UK population, and the incidence of type 2 diabetes is increasingly annually affecting > 30% of over 60 year olds where obesity is common, such as North America. The peak age of diagnosis of type 2 diabetes mellitus is between 60 and 65 years of age; 25% of these patients will develop overt diabetic nephropathy over 20 years. Only a proportion of patients will, thus, live long enough to develop end-stage renal disease. However, type 2 diabetes mellitus is still the commonest cause of end-stage renal disease in the developed world, with type 2 diabetics representing over 20% of the dialysis population. Type 1 diabetes now accounts for as little as 3% of all cases of diabetes mellitus. After 20 years,

type 1 diabetics have a 40% incidence of overt diabetic nephropathy. Susceptibility to diabetic nephropathy differs between populations and individuals and may have a genetic basis. Pima Indians are particularly at risk, with a 40% progression to end-stage renal disease 10 years after developing microalbuminuria.

Natural history of diabetic nephropathy

The degree of hyperglycaemia correlates with the development of microalbuminuria and overt nephropathy (UKPDS/DCCT trials). Hyperglycaemia is also more likely with hypertension or a genetic predilection. Very strict glycaemic control reduces progression to nephropathy, but once overt proteinuria is established, it does not greatly alter prognosis.

The natural history of nephropathy in type 1 diabetes has been divided into five stages (see Figure 164.1):

- Stage 1 is transitory functional kidney changes, which decrease with correction of hyperglycaemia
- Stage 2 is hyperfiltration and increased glomerular filtration rate (GFR) due to activation of the renin–angiotensin system
- Stage 3 is the development of microalbuminuria (30–300 mg/day), which is often accompanied by hypertension; this amount of proteinuria is below the threshold for a standard urinary dipstick, is detected by elevations of the albumin–creatinine ratio (ACR), and is a powerful predictor of future overt nephropathy
- Stage 4 is overt diabetic nephropathy with dipstick-positive proteinuria and an accompanying progressive fall in GFR
- Stage 5 is end-stage renal disease

Complications of the disease

Diabetic nephropathy usually progresses to end-stage renal disease if the patient does not die from the associated vascular disease.

Approach to diagnosing the disease

Diagnosis is usually on clinical grounds and on exclusion of other diagnoses. It requires at least a 5-year history of diabetes mellitus

Figure 164.1 The stages of diabetic nephropathy; GFR, glomerular filtration rate.

Adapted from www.EdRen.org with permission from Professor Neil Turner.

(although, in type 2 disease, the onset of hyperglycaemia is difficult to date and typically precedes the formal diagnosis of diabetes by many years). The commonest first presentation is microalbuminuria detected on routine screening during diabetic follow-up. Diabetic neuropathy and retinopathy support the diagnosis, but nephropathy can occur in their absence.

Gold-standard diagnostic test

A renal biopsy is the gold-standard diagnostic test for diabetic renal disease. It is useful where there is diagnostic doubt but, in practice, is infrequently performed because the chance of finding anything other than diabetes is very small. A biopsy might be considered in:

- rapidly increasing proteinuria, particularly with a preserved GFR
- rapidly falling GFR
- microscopic haematuria with microscopic evidence of dysmorphic red cells or red-cell casts
- absence of retinopathy (approximately one-third of biopsied diabetic patients without retinopathy have an alternative glomerular disease)
- short history of diabetes (particularly in type 1 diabetics)
- symptoms of a multisystem disorder
- a positive paraprotein or autoimmune screen

Early histology reveals glomerular basement membrane thickening. Mesangial expansion begins about 5 years after disease onset. This expansion enlarges into intercapillary nodules with glomerulosclerosis (Kimmelstiel–Wilson disease; see Figure 164.2).

Other relevant investigations and differential diagnosis

A dipstick revealing microscopic haematuria in a patient over 50 should prompt a urological referral to exclude urinary tract malignancy, but haematuria can occur in late diabetic nephropathy. Ultrasonography excludes obstructive renal disease. Diabetic kidneys are frequently enlarged, and so asymmetrical or small kidneys may suggest concomitant renovascular disease. This can be confirmed by magnetic resonance angiography.

Diabetics are also predisposed to other renal diseases. These include urinary tract infections and autonomic bladder dysfunction. They also have increased susceptibility to acute insults like radioopaque contrast nephropathy.

Figure 164.2 Renal biopsy demonstrating nodular (indicated by 'N') glomerulosclerosis. Please see colour plate section.

Reproduced with permission from Turner et al, *Oxford Textbook of Clinical Nephrology*, Fourth Edition, Oxford University Press, Oxford, UK, Copyright © 2015.

Prognosis and how to estimate it

As with other cases of chronic kidney disease, prognosis is predicted by extrapolation from a plot of $1/\text{creatinine}$ or eGFR against time. However, once diabetic nephropathy has developed, there is usually a continuous steady decline in GFR, despite treatment. People with diabetes also have significantly increased risk of vascular disease. Mortality in those with nephropathy is 25-fold greater, compared to that in other diabetics. Diabetics are also high-risk dialysis patients and transplant recipients. On average, those with diabetes on dialysis have a 30% 2-year mortality (twice the rate of the non-diabetic dialysis population).

Treatment and its effectiveness

Treatment can be divided into prevention of nephropathy, slowing progression of nephropathy, and preparation for renal replacement therapy.

Prevention of nephropathy

Diabetic patients should have their urine screened for microalbuminuria at least once a year. A spot urine (preferably early morning) ACR can be used to estimate daily albuminuria. Multiplying the ACR by 10 gives an approximation of daily albumin excretion (Table 164.1).

Primary prevention measures include controlling glycaemia and blood pressure. Intensive glycaemic control reduces the onset of nephropathy. Newer agents slow nephropathy in type 2 diabetes. For example, sodium-glucose co-transporter-2 inhibitors offer renoprotection, probably through a non-glycaemic mechanism. Glucagon-like peptide receptor antagonists may also be renoprotective. Patients should not smoke and should ideally adhere to a healthy lifestyle.

Management of microalbuminuria/overt nephropathy

Blood pressure should ideally be maintained below 130/80 mm Hg, and even lower blood pressure may have cardiovascular benefits. It is, unknown if intensive blood pressure lowering is more renoprotective than standard blood pressure control.

Angiotensin-converting enzyme (ACE) inhibitors are the first-choice antihypertensive. They reduce progression to dialysis and death, compared to other antihypertensives. Angiotensin blockade similarly reduces dialysis and death, compared to other antihypertensives. Halving proteinuria with these agent nearly halves the kidney risk (IDNT/RENAAL trials).

Angiotensin blockers, however, afford no added renoprotection above ACE inhibitors. A combination of ACE inhibitor and angiotensin blockade may modestly reduce proteinuria further, but increases the risk of hyperkalaemia and acute kidney injury, and trials have not shown improved renal outcomes.

It is thought that strict glycaemic control may not affect the rate of progression once overt nephropathy has developed. However, biopsy studies from pancreatic transplant recipients have shown resorption of glomerular nodules and normalization of basement membrane thickness after 10 years of true euglycaemia.

If metformin is used for diabetic control, the dose should be dose reduced at eGFR of 60 ml/min 1.73 m^{-2} and probably stopped at an eGFR of 20 ml/min 1.73 m^{-2} . Short-acting sulfonylureas (e.g. gliclazide) are preferred to long-acting versions. Pioglitazone is an option if fluid overload is not a problem. Dipeptidyl peptidase 4 inhibitors are increasingly being used for glycaemic control in patients with advanced renal failure, and linagliptin does not need dose adjustment with renal impairment and might delay the need for insulin. Insulin is partially excreted by the kidney, and insulin doses may need to be reduced as GFR falls. CREDENCE is a large ongoing diabetic kidney disease trial testing if sodium-glucose co-transporter-2 inhibition reduces cardiovascular mortality or kidney disease progression.

Salt restriction improves blood pressure control and may also reduce proteinuria and improve oedema.

Hypercholesterolaemia is associated with progressive nephropathy. There is no evidence that reducing it alters the rate of renal

Table 164.1 Interpretation of albumin–creatinine ratio

albumin–creatinine (mg/mmol)	24-hour albuminuria	Standard dipstick for protein	Stage
<2.5	<30 mg/day	Negative	1 + 2
2.5–300	30–300 mg/day	Negative/trace	3 (Microalbuminuria)
>300	>300 mg/day	Positive	4 + 5 (Overt diabetic nephropathy)

deterioration. However, lipid control is an important in its own right to reduce the risk of cardiovascular disease.

Renal replacement therapy

Preparation for renal replacement therapy should begin early in diabetics. Uraemia occurs earlier, and preparation for transplantation often requires cardiac and peripheral vascular investigations. There is no difference between peritoneal and haemodialysis in terms of survival. Type 1 diabetics can be temporarily ‘cured’ by a combined pancreas and kidney transplant.

165 Urinary tract obstruction

William G. Herrington, Aron Chakera, and Christopher A. O’Callaghan

Definition of the disease

The urinary tract can become obstructed by various disease processes, including tumours. Obstruction at any level of the urinary tract can impair the free flow of urine and may be partial or complete, and unilateral or bilateral.

Etiology

There are many causes of obstruction. Bilateral obstruction usually occurs at the level of the bladder or lower. Retroperitoneal fibrosis and extrinsic compression of both ureters by a malignancy are exceptions. The probability of a specific cause typically varies with the anatomical location of the obstruction and the age of the patient (see Table 165.1). Children are affected by congenital vesicoureteric junction (VUJ) or pelvi-ureteric junction (PUJ) obstruction. Young adults suffer stone disease. The elderly are prone to urothelial cancers, and older men to bladder outflow obstruction. Retroperitoneal fibrosis is an inflammatory condition that typically affects men over 50 years of age. Diagnosis should be confirmed by biopsy to exclude a lymphoma or malignancy.

Symptoms

Bilateral obstruction is more likely to cause easily detectable renal impairment. Complete bilateral obstruction causes anuria. Acute obstruction is often very painful, with colicky pain and sometimes nausea and sweating (see Chapter 166). Chronic obstruction is more subtle. PUJ obstruction may be asymptomatic apart for loin pain, which is worse after drinking a large volume or consuming alcohol, which can trigger a diuresis. Bladder outflow obstruction usually progresses slowly and the bladder capacity may increase to over 2 l. Bladder outflow obstruction is often accompanied by characteristic obstructive and irritative lower urinary tract symptoms. Obstructive prostatic disease can cause hesitancy, poor flow, and terminal dribbling. Bladder distension induces detrusor instability characterized by urgency and frequency. A significant residual volume after voiding predisposes to infection. Obstruction can also cause reflex activation of the renin-angiotensin system resulting in hypertension.

Demographics

Table 165.1 summarizes how age predicts likely cause of obstruction.

Natural history, and complications

Renal recovery in complete obstruction will usually occur if the obstruction is relieved promptly. However, recovery seldom occurs after more than 3 months of obstruction. Chronic partial obstruction is less predictable with the majority of any recovery occurring within 7 to 10 days of treatment. An infected obstructed renal tract is a urological emergency. It can cause rapid irreversible loss of renal function and severe septicæmia.

Approach to diagnosing the disease

Obstruction is often suggested by a history of obstructive lower urinary symptoms or loin pain. Examination of a patient with renal impairment must always include palpation for an enlarged bladder. A renal tract ultrasound is an important screening tool and should be included in the assessment of all cases of acute and chronic renal failure. It should be performed promptly with any acute deterioration in renal function.

Differential diagnosis

If obstruction is detected, a cause must be identified and treated. Ultrasound will demonstrate hydronephrosis in 90% of cases of obstruction. The remaining cases may develop hydronephrosis over the next 72 hours. Partial obstruction can cause a rise in creatinine without obvious hydronephrosis. Anuric obstructed kidneys will not develop hydronephrosis. Chronic hydronephrosis may persist after the cause is removed, due to prolonged stretch of the renal pelvis (a ‘baggy system’). Similarly, chronic reflux may leave a large dilated ‘megaureter’. Delayed excretion on a MAG3 renogram or intravenous pyelogram/computed tomography urography can help define any ongoing functional obstruction. In some cases, a trial of decompression by nephrostomy or stenting is necessary to establish whether this improves renal function.

‘Gold-standard’ diagnostic test

The gold-standard for diagnosing obstructive urinary tract disease is CT scanning. Most hydronephrosis is detected by ultrasound examination (see Figure 165.1A, B), but an unenhanced CT kidney-ureter-bladder can confirm hydronephrosis and identify the level and cause of obstruction (Figure 165.1C).

Table 165.1 Common causes of obstruction

Level of obstruction	Infants/children	Adult	Middle aged/elderly
Kidney	Pelvi-ureteric junction obstruction	Late-presenting pelvi-ureteric junction obstruction Stones (staghorn)	Urothelial tumours Stones
Ureter	Vesicoureteric junction obstruction	Stones	Urothelial tumour Retroperitoneal fibrosis Malignant extrinsic compression (e.g. lymphadenopathy/pelvic tumours)
Bladder		Neuropathic bladder (e.g. from diabetes, or spinal cord damage)	Bladder tumour Clot retention
Bladder neck, or urethra	Congenital urethral valves	Urethral stricture	Prostate disease

Figure 165.1 (A) Moderate hydronephrosis on ultrasound; C, cortex; H, hydronephrosis. (B) Severe hydronephrosis with loss of cortical thickness. (C) CT scan showing bilateral ureteric stenosis (arrow) due to retroperitoneal fibrosis on CT.

Other relevant investigations

A DMSA/MAG3 with diuretic can help confirm obstruction when in doubt.

A nephrostogram (dye instilled down a nephrostomy tube) or retrograde pyelogram (dye instilled into the ureter during cystoscopy) are alternatives to a urogram to assess ureteric obstruction (see Figure 165.2A).

Digital rectal examination and a prostate specific antigen (PSA) test should be undertaken in men with haematuria or obstruction.

A prostate biopsy may be indicated if the PSA and examination findings are unable to differentiate between benign prostatic hypertrophy and cancer.

Prognosis and how to estimate it

If obstruction is treated early, any associated renal impairment will usually improve. A creatinine taken 10 days after treatment is likely to represent the new baseline kidney function.

Figure 165.2 (A) Vesicoureteric junction obstruction. (B) Successful treatment of vesicoureteric junction obstruction with a JJ stent.

Treatment and effectiveness

Ureteric obstruction is often treated initially with a percutaneous nephrostomy followed by a ureteric stent inserted percutaneously at the same time as the nephrostomy or placed retrogradely per urethra (see Figure 165.2B). PUJ obstruction (often detected in utero or perinatally) can be managed by pyeloplasty. Stones may require lithotripsy or operative intervention.

Treatment of retroperitoneal fibrosis requires relief of the initial obstruction (often with JJ stents) and cessation of any suspected medications. Medical therapies include corticosteroids and immunosuppressant medications such as azathioprine and tamoxifen. Definitive surgery involves ureterolysis and omental wrapping.

Bladder outflow obstruction is initially treated by urinary catheterization. The collapse of a distended bladder and the rapid refilling of veins can result in bleeding with frank haematuria. Some advocate clamping a catheter after drainage of a litre of urine. Prostate cancer is treated surgically, hormonally, or with radiotherapy. Benign prostatic hypertrophy can be treated with alpha blockade. Tamsulosin has the least orthostatic hypotensive effect. A 5-alpha reductase inhibitor

such as finasteride is an alternative. A transurethral resection of prostate is the definitive treatment for failed medical therapy, and long-term catheterization is required in those unfit for surgery.

A diuresis is common following the relief of any obstruction. This occurs because the previously obstructed kidney has a reduced capacity to concentrate urine. If there is renal impairment, it may reflect an osmotic diuresis from retained osmotically active metabolites (e.g. urea). Careful attention to fluid balance is important—it may be necessary to provide fluid replacement at half the urinary volume to prevent dehydration without driving a diuresis.

166 Renal calculi

William G. Herrington, Aron Chakera, and Christopher A. O'Callaghan

Definition of the disease

Nephrolithiasis is the presence of kidney stones, which are also known as 'renal calculi'.

Etiology of the disease

Renal calculi arise when urine becomes supersaturated with insoluble components. This may occur when there is excessive production of these components, a decrease in factors maintaining their solubility (e.g. citrate), or a reduction in urine volume (leading to increased concentration). Infection may play a significant role in the initiation of renal calculus formation, by creating a nidus for further crystal growth (see Figure 166.1). Renal calculi are usually classified into two categories: those containing calcium (80%), and non-calcareous calculi (20%; see Table 166.1).

Typical symptoms of the disease, and less common symptoms

Passage of renal calculi into the ureter causes severe, often colicky pain which is often described as 'worse than childbirth' and classically radiates from loin to groin. Calculi in the renal pelvis cause loin pain, due to obstruction and dilatation of the renal capsule. Calculi that remain within the renal parenchyma or that are too large to pass through the ureter may be asymptomatic. There is usually no fever, and the presence of an increased temperature should raise the suspicion of infection. Calculi that pass into the bladder are usually asymptomatic, but can cause complete anuria if they obstruct the urethra at the bladder outlet. This may be positional, occurring on standing. Patients with calculi anywhere in the urinary tract occasionally present with haematuria.

Demographics of the disease

The lifetime incidence of renal calculi is ~10% for men, and 5% for women, but varies greatly between countries, and is increased in hot climates. Peak incidence occurs between the third and fifth decades, and the overall incidence appears to be increasing. Up to half of all people with a renal calculus will suffer from a recurrence.

Natural history, and complications of the disease

The majority of renal calculi are relatively small (<5 mm), and pass spontaneously. Approximately 20% of patients fail to pass the calculus, or develop infections that necessitate hospitalization. The major complications are urinary system obstruction, which can occur anywhere between the kidney and urethra, leading to hydronephrosis and impaired renal function (note that, if only one kidney is affected, the urea and creatinine may not increase), and infection. Infections, particularly those proximal to an obstruction, can be serious and necessitate surgical intervention to prevent urosepsis, abscess formation, and permanent loss of kidney function.

Once renal calculi have formed, they tend to increase in size with time, potentially leading to obstruction

Approach to diagnosing the disease

The diagnosis is often suspected from the history (many patients will have had previous renal calculi), and examination, especially when

the classic loin-to-groin colicky pattern of pain is present. A urine dipstick should be performed to assess for any evidence of infection (note that, if the infection is above an obstructing calculus, the urinalysis may be normal), and serum electrolytes and chemistry should be checked to determine renal function, and to identify secondary causes. Imaging of the urinary tract should be performed, to identify the location, number, and size of any calculi.

Other diagnoses that should be considered

Differential diagnoses that should be considered include abdominal aortic aneurysms, ectopic pregnancies, appendicitis, and testicular torsion in males.

The classical pain and radiological appearance of renal calculi may be mimicked by sloughed papillae or clots.

'Gold-standard' diagnostic test

Non-contrast CT KUB (kidneys, ureter, and bladder) (see Chapter 157) is currently the diagnostic test of choice. This technique provides excellent visualization of the kidneys and urinary tract; it may identify anatomical abnormalities that can predispose to calculus formation (medullary sponge kidney, horseshoe kidneys) and reveal other pathologies (see 'Other diagnoses that should be considered') that may be part of the differential diagnosis.

Acceptable diagnostic alternatives to the gold standard

An IV urogram is an acceptable alternative to CT KUB. As contrast is routinely given, some assessment of renal function may be made at the same time. Plain-film KUB X-ray should not be done if non-contrast CT KUB is available for diagnosis, but is useful for follow-up (see Figure 166.2).

Ultrasonography may be used in pregnant patients to avoid radiation exposure, as may MRI. Both techniques are less sensitive than CT. Ultrasonography is highly user dependent.

Other relevant investigations

Urinalysis should be performed to identify any coexisting infection. Renal function should be assessed, particularly if there is a concern that obstruction may be present. If any calculi are passed, they should be collected, and sent for analysis.

As increasing fluid intake and reducing dietary sodium significantly reduces the likelihood of further calculus formation (by reducing the concentration of calculus-promoting factors), many units will not perform further investigations, unless there are atypical features present, or there have been recurrent calculi. In these cases, serum calcium, phosphate, urate, and parathyroid hormone levels should be measured, as well as urinary pH (ideally, on a pH meter in the clinic; otherwise, samples should be collected under oil), calcium, citrate, cysteine, urate, phosphate, and oxalate levels (24-hour collection).

Prognosis and how to estimate it

The prognosis after an isolated renal calculus is good, although the risk of further calculi is high. Where large calculi have caused prolonged obstruction, there can be significant permanent loss of renal function.

Figure 166.1 Types of crystals found in the urine in association with renal stones: (A) urate crystals, (B) calcium oxalate crystals, (C) calcium phosphate crystals, and (D) triple phosphate (struvite) crystals.

Images by Giovanni B. Fogazzi reproduced with permission from the Oxford Textbook of Clinical Nephrology, edited by Davison et al, Published by Oxford University Press 2005.

Treatment and its effectiveness

Management of calculi depends primarily on their size and location. Calculi that are likely to pass spontaneously can be managed conservatively with analgesia, and by encouraging fluids. Where there is obstruction or infection present, intervention may be required. Conservative treatments include:

- analgesia: as pain is primarily mediated by prostaglandin, NSAIDs are particularly effective; opioids may be used for additional pain relief, or if NSAIDs are contraindicated

- encouraging calculus expulsion: calcium-channel blockers and adrenergic blockers decrease ureteric spasm, and encourage passage of the calculus down the ureter; an oral steroid is often added for several days to decrease inflammation
- antibiotics: should be commenced if there is evidence of infection; usually, a broad-spectrum penicillin (e.g. amoxicillin or fluoroquinolone) is appropriate

Obstructed patients, or those with ongoing pain, should be referred to the urology service. Options for calculus removal include extracorporeal shock wave lithotripsy, percutaneous

Type	Major constituents	Risk factors for formation	Shape of crystals
Calcium containing	Calcium oxalate, calcium phosphate, and calcium urate	Hyperuricosuria Primary hyperparathyroidism Distal renal tubular acidosis Phosphate-losing nephropathies	Dumbbell or envelope shaped
Non-calcium containing	Struvite (magnesium ammonium phosphate)	Proteus infection High urinary pH	Coffin lid
	Uric acid	Gout Myeloproliferative disorders Inflammatory bowel disease	Rhomboid
	Cystine calculi	Cystinuria	Hexagonal
	Medications	Antiretrovirals Aciclovir Sulpha-containing drugs	

Figure 166.2 Plain-film X-ray showing a right staghorn calculus.

nephrolithotomy, and ureteroscopy or, less commonly, open nephrostomy.

Once the calculus has passed or been removed, all patients should be encouraged to increase their fluid intake to prevent urine supersaturation and crystal formation. Specific treatments where the cause of calculus formation is known are:

- hypercalcaemia
 - potassium citrate
 - thiazide diuretics
- hyperoxaluria:
 - calcium supplements to decrease enteric oxalate absorption
 - *Oxalobacter formigenes* probiotic treatment is under investigation
- hypocitraturia:
 - potassium citrate
- hyperuricaemia:
 - allopurinol
 - potassium citrate
- cystine calculi:
 - potassium citrate
 - captopril
 - penicillamine
 - tiopronin

167 Renal and bladder cancer

Hannah Chapman and Christine Elwell

Bladder cancer

Definition of bladder cancer

Bladder cancer is the fourth most common cancer in men, and the eighth most common cancer in women. There were 10 335 new cases and 5 002 deaths from bladder cancer in the UK in 2008. Bladder cancer arises from the bladder urothelium. In the UK, 90% of bladder cancers are transitional cell carcinomas. Of those, 90% are papillary type. Other types of bladder cancer include:

- squamous cell carcinoma
- adenocarcinoma
- small cell carcinoma
- sarcoma

Aetiology of bladder cancer

Smoking is associated with a fourfold increased risk of bladder cancer. Carcinogens present in tobacco are excreted in the urine (e.g. 4-aminobiphenyl and nitrosamine). Occupational exposure to aromatic amines and aniline dyes (e.g. in the textile industry) has been an important risk factor. With improvements in health and safety, this factor is becoming less significant. Radiotherapy to the pelvis, and cyclophosphamide use, are other risk factors.

Chronic urinary stasis (e.g. due to neuropathic bladder) can lead to squamous metaplasia, a precursor to squamous cell carcinoma. Chronic infection with the parasite *Schistosoma haematobium* is associated with squamous cell carcinoma of the bladder. It is most prevalent in Egypt and sub-Saharan Africa.

Typical symptoms of bladder cancer, and less common symptoms

Symptoms of bladder cancer include:

- painless macroscopic haematuria (80%–90%)
- dysuria, urinary frequency, urinary urgency (20%–30%)
- flank pain and symptoms of uraemia (due to ureteric obstruction)
- bony pain (due to metastases)
- leg oedema (due to compression of iliac vessels by tumour)

Demographics of bladder cancer

The peak incidence of bladder cancer is at 69–71 years. Transitional cell carcinoma is four times more common in men than in women. However, squamous cell carcinoma is twice as common in women as in men. Bladder cancer is more common in Caucasians.

Natural history of bladder cancer, and complications of the disease

Eighty per cent of patients have non-muscle-invasive disease. Although the prognosis is good, in around 70% of cases, the cancer recurs. However, progression to muscle-invasive disease is uncommon.

Twenty per cent of patients have muscle-invasive disease. The natural history is one of local spread to surrounding organs, such as prostate, seminal vesicles, rectum, uterus, and vagina. Metastasis to lymph nodes, lung, liver, and bone is also common.

Carcinoma in situ (CIS) is a precursor to cancer, and 80% of patients will develop muscle-invasive cancer if untreated.

Approach to diagnosis of bladder cancer

The presence of microscopic or macroscopic haematuria should raise the suspicion of bladder cancer. Haematuria can be intermittent, so a negative repeat urinalysis does not exclude cancer. Diagnosis requires

histopathological evidence, ideally corroborated by evidence from imaging, and/or examination under anaesthetic.

Other diagnoses that should be considered aside from bladder cancer

Other diagnoses that should be considered aside from bladder cancer include:

- urinary tract infection (may coexist with cancer; if treatment with antibiotics fails to resolve symptoms and/or haematuria, consider further evaluation)
- nephrolithiasis
- renal cancer
- haemorrhagic cystitis

'Gold-standard' diagnostic test for bladder cancer

Flexible cystoscopy and trans-urethral resection of bladder tumour (TURBT) is the gold-standard investigation for bladder cancer. Muscle should be included in the resection specimen. TURBT provides information on tumour grade and depth of invasion, which will influence management. It can also reveal the presence of coexisting CIS.

Acceptable diagnostic alternatives to the gold-standard test for bladder cancer

Urine cytology is the standard non-invasive test for bladder cancer. It is particularly useful if a patient is not fit enough for cystoscopy. It has an 80% sensitivity, and specificity for Grade 3 tumours. It is less reliable for lower-grade tumours. Bladder washings are sensitive, but the false-positive rate is high. Urinary cytology is affected by instrumentation, such as catheterization.

Other relevant investigations for bladder cancer

Other relevant investigations for bladder cancer include:

- a full blood count and renal function and liver function tests
- an IV urogram (may reveal a filling defect)
- ultrasound renal tract
- CT of the chest, abdomen, and pelvis (to assess local disease, and identify lymph-node and distant metastases)

Prognosis of bladder cancer and how to estimate it

Prognostic factors for bladder cancer include tumour grade, depth of invasion (T stage), multifocality, and the presence of CIS.

The 5-year survival rates for bladder cancer are:

- non-muscle-invasive disease: 80%–100%
- muscle-invasive disease: 40%–50%
- metastatic disease: <5% (median survival 3–6 months)

For squamous cell carcinoma of the bladder, the 5-year survival rate for T3/4 disease is 19%. Small cell carcinoma of the bladder usually presents in the advanced stage, and has a poor prognosis.

Treatment for bladder cancer, and its effectiveness

Treatment of non-muscle-invasive bladder cancer

TURBT is the standard treatment for non-muscle-invasive bladder cancer. If the risk of progression is low, a single dose of adjuvant intravesical mitomycin is given. For high-risk patients, a course of adjuvant BCG halves the recurrence rate. Patients require cystoscopy surveillance, due to the high recurrence rate. Cystectomy can be considered for patients who develop recurrence despite BCG

and for patients with multifocal disease or with multiple high-grade recurrences.

Treatment of muscle-invasive bladder cancer

Radical cystectomy and pelvic nodal clearance is associated with a 3% mortality rate. It requires the formation of either an ileal conduit or an orthotopic neobladder. The 5-year survival rate with cystectomy is 40%–50%. Radical radiotherapy is the alternative, with similar outcomes but bladder preservation. The decision between cystectomy and radiotherapy depends upon a patient's preference, and their fitness for surgery.

Neoadjuvant chemotherapy (prior to either definitive treatment) adds a 5% survival benefit.

Palliative treatment for bladder cancer

If a patient is not fit enough for cystectomy or radical radiotherapy, palliative radiotherapy to the bladder can alleviate pain and haematuria. There is also a role for palliative chemotherapy in metastatic or locally advanced disease.

Renal cancer

Definition of renal cancer

Renal cancer accounts for 3% of cancers in adults in the UK. There are approximately 6000 new cases in England and Wales each year. Renal cell carcinoma is the most common type (80%), and arises from the proximal renal tubule epithelium. A further 5%–10% are transitional cell (urothelial) carcinomas of the renal pelvis. Renal cell carcinomas are subdivided histologically into clear cell (70%), papillary, chromophobic, and collecting duct carcinomas. Benign kidney tumours, such as cysts, are also common.

Etiology of renal cancer

Risk factors for renal cancer include:

- smoking (doubles the risk)
- obesity
- hypertension
- phenacetin analgesics in large quantities
- acquired cystic kidney disease (associated with dialysis)
- asbestos exposure
- von Hippel–Lindau syndrome (an autosomal dominant condition associated with disordered angiogenesis; due to a mutation in the VHL gene on Chromosome 3)
- tuberous sclerosis
- adult polycystic kidney disease

Typical symptoms of renal cancer, and less common symptoms

Renal cancer is frequently asymptomatic and detected incidentally on CT or ultrasound. Symptoms related to the primary tumour may occur, such as:

- painless haematuria (40%)
- flank pain
- flank mass
- left varicocele in males (due to obstruction of the left testicular vein)

Patients might also have pain secondary to bone metastases. Paraneoplastic syndromes are common in renal cell cancer, and 10% present with related symptoms.

Demographics for renal cancer

The mean age at diagnosis for renal cancer is 70 years. Renal cell carcinoma is twice as common in men as in women.

Natural history and complications of renal cancer

Renal cancers spread locally to the adrenal gland, renal vein, inferior vena cava, and perinephric fat. Metastases at presentation are common (30%). The most common sites are lung, bone, liver, and brain. The following complications might also arise due to a paraneoplastic syndrome:

- hypercalcaemia (due to secretion of parathyroid hormone-related peptide, causing confusion, constipation, abdominal pain, and renal impairment)
- polycythaemia (due to secretion of an erythropoietin-like molecule, causing hyperviscosity)
- hypertension (due to secretion of renin)
- hepatic dysfunction (Stauffer syndrome; uncertain mechanism)

Urothelial tumours are often multifocal, and are bilateral in up to 10% of patients.

Approach to diagnosing renal cancer

The main challenge in the diagnosis of renal cancer is distinguishing a benign from a malignant tumour. Renal biopsy is avoided where possible, due to the risk of haemorrhage and tumour seeding.

Other diagnoses that should be considered aside from renal cancer

If a renal mass is discovered on imaging, consider the following differential diagnoses:

- renal cyst
- renal abscess
- renal infarction
- adenoma
- oncocytoma
- metastasis

'Gold-standard' diagnostic test for renal cancer

Contrast-enhanced CT is the diagnostic test of choice for renal cancer. It can differentiate cystic from solid masses. It also permits assessment of lymph node spread and renal vein involvement.

Acceptable diagnostic alternatives to the gold-standard test for renal cancer

Renal ultrasound is useful for diagnosing renal cancer if CT is inconclusive or if a patient cannot be given IV contrast. Cystoscopy with retrograde pyelography can identify filling defects caused by renal pelvis tumours. Ureteroscopy allows direct visualization and biopsy.

Other relevant investigations for renal cancer

Other relevant investigations for renal cancer include a full blood count, a renal function test, a corrected calcium level, an alkaline phosphatase level test, erythrocyte sedimentation rate, and a coagulation profile, as these might identify a paraneoplastic syndrome or suggest metastasis.

If there is doubt about involvement of the inferior vena cava, MRI can be useful. A bone scan is indicated if a patient has bony pain or raised alkaline phosphatase.

Prognosis for renal cancer and how to estimate it

The overall 5-year survival in renal cancer is 44%. Advanced stage and high-grade tumours are associated with a poor prognosis. The 5-year survival for Stage IV disease is only 0%–2%. Other poor prognostic features include:

- poor performance status
- low haemoglobin
- raised lactate dehydrogenase
- raised corrected calcium

In metastatic disease, the prognosis is better when there is a long disease-free interval between nephrectomy and the development of metastases.

Treatment for renal cancer, and its effectiveness

Nephrectomy is the only potentially curative treatment for renal cancer. Radical nephrectomy is associated with a 65% 5-year survival rate. Partial nephrectomy is possible for tumours less than 4 cm in diameter. Compared with open nephrectomy, laparoscopic surgery is less invasive and requires less post-operative analgesic and a shorter recovery time.

In advanced disease, palliative nephrectomy can relieve pain and haematuria. Spontaneous regression of metastases following nephrectomy is a recognized, but rare, phenomenon. Arterial embolization and radiofrequency ablation are alternative palliative treatments for the primary tumour.

Metastastectomy of an isolated metastasis can improve survival in renal cancer. Palliative radiotherapy reduces pain related to bone metastases. Radiotherapy can also be used to treat intractable haematuria.

Renal cell cancers are chemoresistant. However, there now are several promising targeted treatments in use:

- sunitinib (multikinase inhibitor)
- sorafenib (multikinase inhibitor)
- temsirolimus (mTOR inhibitor)

- bevacizumab (recombinant humanized anti-vascular endothelial growth factor monoclonal antibody)

168 Renal replacement therapy

William G. Herrington, Aron Chakera, and Christopher A. O'Callaghan

Definition

Renal replacement therapy (RRT) provides a substitute for the function of normal kidneys. Options for RRT include haemofiltration, haemodialysis, peritoneal dialysis, and renal transplantation. Haemofiltration is only used in the acute setting (see Chapter 162). Endocrine functions of the kidney are replaced with erythropoietin and vitamin D therapy.

Etiology

The most common cause of end-stage renal disease (ESRD) in the developed world is diabetes mellitus. Other common causes include renovascular disease, hypertension, chronic glomerulonephritis, adult polycystic kidney disease, and chronic pyelonephritis (see Chapter 163). In about a quarter of cases, the cause remains unknown.

Symptoms

Classic 'uraemic' symptoms include persistent nausea and vomiting, anorexia, malaise, and itching, and usually only occur when the estimated glomerular filtration rate (eGFR) is <15 ml/min 1.73 m².

Demographics

The prevalence of ESRD in the UK is approximately 0.1%. This number is growing by 6% a year, due to the rising prevalence of obesity, diabetes mellitus, and an increasingly elderly population. In the UK, around 40% of patients on RRT are on haemodialysis, 10% are on peritoneal dialysis, and 50% have a functioning transplant. Haemodialysis costs can be approximately £20 000–23 000 a year. RRT accounts for 2% of the NHS budget.

Natural history, and complications

Patients with chronic kidney disease who commence dialysis usually remain dependent on RRT, and progressively lose any residual renal function. Patients with acute kidney injury may recover renal function (depending on the cause), although recovery can take several months. In addition to the complications associated with chronic kidney disease (see Chapter 163), there are also dialysis- and transplantation-specific problems. These include infections; hypo- and hypertension related to fluid shifts; access difficulties; and dialysis modality failures.

Approach to diagnosing the disease

Indications for RRT include acidosis, hyperkalaemia, volume overload, or symptomatic uraemia. Uraemic encephalopathy and pericarditis are rare phenomena.

Differential diagnosis

Where there is a steady decline in the glomerular filtration rate (GFR), it is often possible to predict the timing of ESRD. Occasionally, acute illnesses can precipitate acute on chronic kidney disease. If there is a sudden decline in GFR, an alternative renal insult should be sought (e.g. dehydration, urinary tract infection, drug toxicity (see Table 168.1).

Table 168.1 Percentage distribution of primary renal diagnosis in patients starting on renal replacement therapy

Diagnosis	UKRR	ANZDATA	USRDS
Uncertain	26.2	5	4

'Gold-standard' investigation

The gold-standard investigation for RRT is serial serum creatinine measurement, which can be converted into eGFR.

Other relevant investigations

The main investigations for a patient heading for RRT are focused on the mode of RRT. For example, this might include imaging of blood vessels in the arm if an arteriovenous fistula is to be created for haemodialysis.

Prognosis and how to estimate it

There is no difference in the mortality for haemodialysis and that for peritoneal dialysis. Transplantation, however, has lower mortality and lifestyle benefits, if the patient is fit for surgery; the 5-year mortality on dialysis is strongly predicted by age (see Table 168.2).

Treatment (effectiveness and complications)

Patients with progressive renal disease should be referred to renal services at least 6 months before the expected requirement for RRT. This allows time for education and discussion about RRT modalities, optimization of medical therapies, and workup for renal transplantation to be completed. If patients choose haemodialysis, an

Table 168.2 Approximate unadjusted 5-year survival in UK incident dialysis patients 1997–2010

Age (years)	Five-year survival (%)
18–34	90
35–44	80
45–54	70
55–64	55
65–74	35
>75	20

Data from www.renalreg.org.

arteriovenous fistula is created where possible as it can take several weeks to mature sufficiently for use. Following insertion of a peritoneal dialysis catheter (e.g. Tenckhoff), there is usually at least a 2-week delay before it is used.

Patients should be given enough information about each dialysis modality to allow an informed choice to be made. Not all patients wish to undergo dialysis. In particular, patients with other terminal conditions or are very elderly may opt for conservative therapy (see Chapter 172).

Haemodialysis

Haemodialysis is the process of blood being exposed to dialysate fluid across a semipermeable membrane. Waste products pass into the dialysis fluid from the blood and are removed. Most dialysis machines can also remove fluid by ultrafiltration. Vascular access is achieved through centrally inserted catheters (see Figure 168.1A),

or more preferably through arteriovenous fistulae or grafts. A large-bore dual lumen venous catheter is used for temporary haemodialysis. Usual access sites are the internal jugular or femoral veins. Tunnelling a line allows a cuff to form and protects from ascending infection (Figure 168.1B). Most patients attend three times per week, with each session lasting 4 hours. Patients on home haemodialysis may choose to dialyse for shorter periods 5–6 times per week.

Arteriovenous fistulae are the preferred form of access, as they provide the best blood flow and lowest infection risk. They are fashioned surgically by anastomosing the radial or brachial artery to the cephalic or basilic veins (see Figure 168.1B). Dialysis access is precious. Forearm and antecubital veins in renal patients should be protected. IV cannulae should only be placed on the dorsum of the hand (wherever possible).

If veins are damaged, a synthetic graft can be used to join an artery to a distant patent vein.

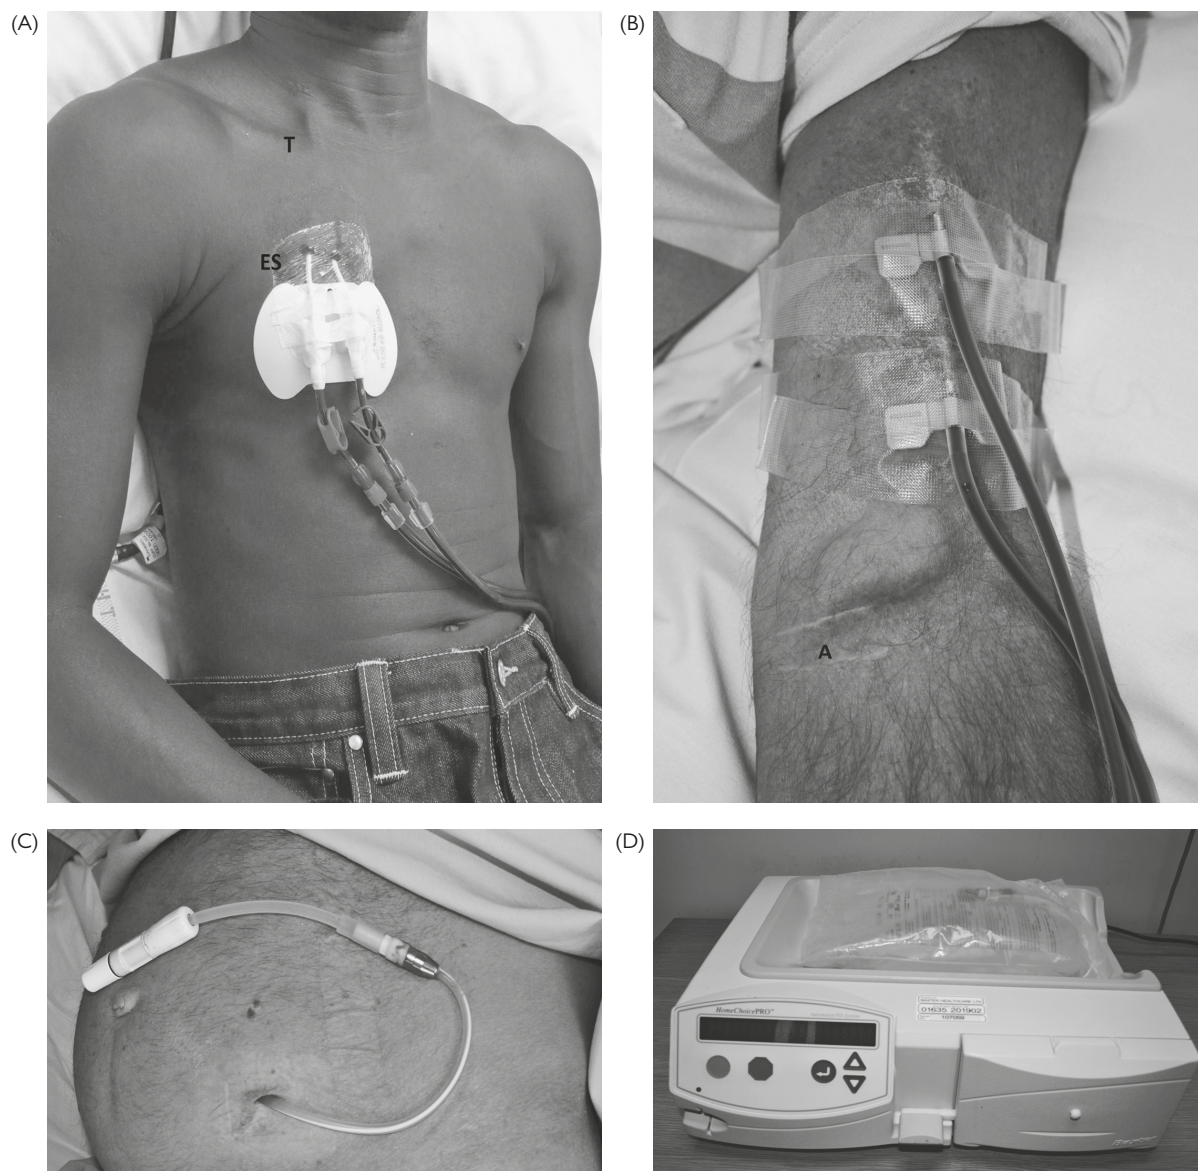

Figure 168.1 (A) A tunneled, dual-lumen dialysis catheter. (B) A left brachiocephalic arteriovenous fistula, showing arterial and venous needles in situ. (C) A Tenckhoff catheter. (D) An automated peritoneal dialysis machine and a dialysate bag; A, area of arteriovenous anastomosis; ES, exit site; T, subcutaneous tunnel from point of insertion in internal jugular vein. Please see colour plate section.

Dialysis catheters and grafts carry a high risk of infection. Transmission of hepatitis B and C between patients is now rare due to screening for blood-borne viruses, and segregation of infected patients. Despite the introduction of high-flux dialysers, removal of beta-2 microglobulin is still poor, and dialysis-related amyloidosis causing joint degeneration can be problematic after several years of dialysis.

Peritoneal dialysis

Peritoneal dialysis uses the peritoneal membrane as a dialysis membrane. Peritoneal dialysis requires a catheter to be inserted into the peritoneal cavity (Tenckhoff catheter; see Figure 168.1C). The catheter tip coils in the pelvis. Dialysate is infused into the abdominal cavity, where it dwells, allowing the blood to equilibrate with the dialysate. Ultrafiltration is primarily achieved through the presence of hypertonic glucose in the dialysate, driving the movement of water into the abdomen. Patients can perform peritoneal dialysis at home or at work, and usually do four exchanges per day. This is called continuous ambulatory peritoneal dialysis. Alternatively, patients can set up dialysis on a machine next to the bed, and do dialysis overnight. This is termed automated peritoneal dialysis (see Figure 168.1D). Survival rates on haemodialysis and peritoneal dialysis are similar.

Contraindications

It may not always be possible to offer a patient peritoneal dialysis, due to concomitant medical or social problems. Peritoneal dialysis requires space at home to store dialysate, and sufficient visual acuity, manual dexterity, and cognitive function to perform exchanges. Abdominal herniae will usually need repair. Dialysate drainage may not be possible in patients with multiple adhesions from previous surgery. However, in general, peritoneal dialysis is a well-tolerated and popular RRT.

Complications

The most common complication of peritoneal dialysis is peritonitis. It is heralded by cloudy bags with or without abdominal pain. It is usually treated with intra-peritoneal antibiotics and does not always necessitate removal of the catheter. The most common cause is contamination during an exchange, so patients undergo a strict education process to reduce infection rates. Peritoneal dialysis peritonitis, however, must be differentiated from an unrelated intra-abdominal cause of peritonitis (e.g. perforation).

Renal transplantation

Renal transplantation involves the implantation of a kidney from either a deceased donor or a living donor. Transplanted kidneys are usually implanted extra-peritoneally into either iliac fossa, with the transplant renal artery and vein attached to the internal or external iliac artery and vein, respectively (see Figure 168.2).

Figure 168.2 An anastomosed transplanted kidney. Please see colour plate section.

Table 168.3 NHS Blood and Transplant annual activity report 2010/2011

Type of transplant	One-year graft survival (%)	Five-year graft survival (%)	One-year patient survival (%)	Five-year patient survival (%)
Living donor	97	92	99	96
Donation after brain death	94	84	96	89
Donation after cardiac death	92	86	95	88

Data from NHS Blood and Transplant annual activity report 2010/2011 www.nhsbt.nhs.uk.

As the immune system recognizes the transplant as foreign tissue, immunosuppressive therapies are required to prevent rejection. Often, this involves monoclonal or polyclonal antibodies as part of induction therapy to block lymphocyte activation or cause lymphocyte depletion, with maintenance therapy including a calcineurin inhibitor (e.g. ciclosporin or tacrolimus), an antimetabolite (e.g. mycophenolate or azathioprine), and, often, a steroid.

Over 2000 renal transplants are performed each year in the UK, with increasing numbers coming from living donors. The short-term outcomes following transplantation are very good (see Table 168.3); however, overall graft survival still only averages approximately 10 years.

The average waiting time for cadaveric transplantation is over 2 years in the UK, but difficulties finding a good match can make the wait much longer for patients from some ethnic groups, those with rarer blood groups, or those who have previously received a transplant (prior sensitization).

Complications of renal transplantation include those related to the operation or, more commonly, are the result of the immunosuppression.

Complications are divided into early onset (within 3 months) and late-onset groups, although, in reality, these exist on a continuum (see Table 168.4).

For eligible patients, transplantation is regarded as the renal replacement modality of choice, as it is usually associated with improved quality of life, and reduced mortality and morbidity when compared with age- and comorbidity-matched controls on dialysis.

Where renal disease is secondary to dysfunction of other organs, for example Factor H deficiency (which causes MPGN/TMA and has a high risk of recurrence in the transplanted kidney) or type 1 diabetes, combined organ transplantations, (e.g. liver–kidney or kidney–pancreas) may be offered at specialized centres.

Advantages and disadvantages of transplantation are given in Table 168.5.

Table 168.4 Complications of transplantation

Early complications of transplantation	Late complications of transplantation
Wound dehiscence	Chronic allograft nephropathy
DVT/pulmonary embolism	Chronic rejection
Delayed graft infection	Calcineurin toxicity
Acute rejection	Graft dysfunction from calcineurin toxicity
Viral infections	Skin cancers
CMV infection in non-exposed recipients of organs from positive donors	Hypertension
Post-transplant lymphoproliferative disorder	Accelerated atherosclerosis
EBV infection/reactivation	Osteoporosis (steroid-containing regimes)
Diabetes	Diabetes (often calcineurin induced)

Table 168.5 Advantages and disadvantages of transplantation

Advantages	Disadvantages
No need for dialysis	Operation
Continuous therapy	Need for immunosuppression
Performs all the functions of a normal kidney	Regular clinic visits initially

169 Inherited renal diseases

William G. Herrington, Aron Chakera, and Christopher A. O'Callaghan

Definition of the disease

There are many hereditary diseases that affect kidney function. By far, the most common of these in clinical practice is autosomal dominant polycystic kidney disease (PKD).

Etiology

The causes of inherited kidney diseases can be divided into cystic, glomerular, tubular, and systemic diseases (see Table 169.1).

Autosomal dominant PKD is the main focus of this chapter. The majority of cases are caused by mutations in the PKD1 gene, which is located on Chromosome 16 and encodes the polycystin-1 protein. A minority of cases are caused by mutations in the PKD2 gene, which is located on Chromosome 4 and encodes the polycystin-2 protein. PKD2 mutations tend to cause a slower decline in renal function than PKD1 mutations. Both polycystin-1 and polycystin-2 co-localize to a calcium channel that regulates cilia function in the renal tubule collecting ducts, but it is unclear exactly how this leads to the development of the cysts. Most cysts are in the renal cortex and can grow to several centimetres in size, occluding normal renal tissue as they expand and so leading to renal impairment.

Nephronophthisis and medullary cystic kidney disease are rare inherited causes of medullary cysts and feature prominent tubulointerstitial fibrosis. The affected genes in these diseases are all also believed to be involved in cilia function. Cysts are not usually big enough to be seen on ultrasound.

Symptoms

PKD can be asymptomatic, but can also cause haematuria, loin pain, urinary stone formation, urinary tract infection, abnormal urinalysis, or renal impairment. Cyst bleeds, infection, or associated stones may present as loin pain or haematuria. Complications are more common late in the disease and when the kidneys are over 15 cm in length. Hypertension is common. Occasionally, the first presentation is an intracranial bleed due to a ruptured berry aneurysm.

Failure to thrive or anaemia is a common presentation in children with autosomal recessive polycystic kidney disease (ARPKD) and nephronophthisis.

Demographics

The prevalence of PKD in Europe is approximately 1 in 800.

Natural history and complications

Polycystic kidney diseases typically progress to end-stage renal disease over many years. Risk factors for progressive renal failure include male sex, hypertension, PKD1 mutations, and large kidneys (>750 ml for each kidney). Complications of cysts include infection, bleeding, and stones (20%). Polycystin proteins also regulate tubular and vascular development in other organs. PKD is associated with liver cysts (80%), pancreatic cysts, other biliary diseases, and intracranial aneurysms (8%). Screening for a berry aneurysm with a magnetic resonance angiogram is indicated if there is a family history or personal history of intracranial haemorrhage or suggestive headaches. PKD is also associated with diverticular disease, inguinal herniae, and mitral valve prolapse.

ARPKD and nephronophthisis cause end-stage renal disease in childhood. ARPKD is associated with liver fibrosis and portal

hypertension. Medullary sponge kidney does not usually impair renal function, but may cause recurrent stone formation and urinary stasis, which predisposes to infections.

Approach to diagnosing the disease

PKD is a major differential diagnosis in any patient with renal impairment. A family history may not be present. Diagnosis is more challenging when it is a first presentation of the disease. Large polycystic kidneys may be ballotable but the diagnosis is usually made first with an ultrasound scan. Screening of young people is usually delayed until after they are 20. However, the absence of cysts does not exclude the disease until at least the late 20s.

Other diagnoses to be considered

Cortical cysts can arise with age, or with chronic kidney disease (acquired cystic disease). These cysts are usually less than 3 cm in diameter and are associated with a reduced kidney size. They have no functional significance.

'Gold-standard' diagnostic test

The gold standard for diagnosis of PKD is ultrasound examination (see Table 169.2).

Without a family history of cysts, criteria have to be correlated to the clinical situation.

Acceptable diagnostic alternatives

Other imaging techniques such as CT or MRI scanning can also be used to diagnose polycystic kidney disease. Genotyping is not routinely performed, due to the large number of mutations and large size of the PKD genes. Nephronophthisis and medullary cystic kidney disease cysts are not seen on ultrasonography, but may be identifiable on fine-cut CT or renal biopsy, and there are genetic tests for some variants.

Prognosis and how to estimate it

A reciprocal creatinine or estimated glomerular filtration rate plot against time can be useful in predicting the rate of decline. Sudden changes in renal function may represent obstruction from a stone or a clot.

Treatment and effectiveness

Genetic screening for children is not routinely advocated, as there are currently no proven disease-modifying treatments.

Management is similar to that for most chronic kidney disease (see Chapter 163); however, patients with PKD often have high haemoglobin levels, and do not develop renal anaemia. This may in part reflect increased erythropoietin secretion by cystic kidneys.

Treatments to prevent cyst growth and renal decline are under investigation. Increasing water intake to >3 l per day to reduce vasopressin levels is advocated by some nephrologists. Alternatively, for selected patients, vasopressin-2 antagonists like tolvaptan slow cyst growth and probably modify the rate of renal progression. Patients on tolvaptan need to drink large volumes of water each day and have their liver function monitored.

Table 169.1 Causes of inherited renal diseases

Cystic diseases		
Disease	Gene product	Clinical features
Adult polycystic kidney disease	Polycystin	Polycystic kidneys Polycystic livers Intracranial aneurysms
Autosomal recessive kidney disease	Fibrocystin	Polycystic kidneys Liver fibrosis
Tuberous sclerosis	Hamartin Tuberin	Renal angiomyolipomas Epilepsy/developmental delay Angiofibromas
Nephronophthisis	Nephrocystin	Progressive renal impairment Cerebellar vermis aplasia (Joubert syndrome) Retinitis pigmentosa (Senior-Løken syndrome)
Medullary cystic kidney disease	Tamm-Horsfall protein?	Progressive renal impairment
Glomerular diseases		
Disease	Gene/gene product	Clinical features
Alport syndrome	Type IV collagen	Sensorineural deafness
Thin basement membrane	Type IV collagen	Haematuria (benign course)
Congenital nephrotic syndromes	Nephrin Podocin Laminin	Steroid resistant
Focal Segmental Glomerulosclerosis	APOL1	Proteinuria and progressive renal impairment
Tubular diseases		
Disease	Gene/gene product	Association
Bartter syndrome	Na-K-Cl co-transporter Luminal potassium channel Basolateral Cl channel	Growth and mental retardation
Gitelman syndrome	Na-Cl co-transporter	Salt craving Cramps
Dent's disease	CLCN5	Nephrocalcinosis Rickets Renal stones
Renal tubular acidosis: • type 1 (distal) • type 2 (proximal)	Multiple	Exclude underlying autoimmune disease Most cases in adults are secondary to myeloma or drugs
Hereditary nephrogenic diabetes insipidus	Vasopressin-2 receptors	Polyuria
Cystinuria	SLC3A1 SLC7A9	Renal stones
Systemic diseases		
Disease	Gene/gene product	Association
Fabry's disease	Alpha-galactosidase	Angiokeratomas Atherosclerosis
Thin basement membrane	Type IV collagen	Benign course
Cystinosis	CTNS	Renal failure Growth retardation Corneal deposits
Hereditary renal amyloidosis	Transthyretin Lysozyme Apolipoprotein A	Renal failure
Nail-patella syndrome	LMX1B	Absent patella Dystrophic toenails and fingernails

Table 169.2 Ultrasound criteria for the diagnosis of adult polycystic kidney disease in patients with a family history

Age (years)	No. of cysts required for diagnosis
<30	≥2 in a single kidney, or bilateral cysts
30–59	≥2 in both kidneys
>60	≥4 in both kidneys

170 The kidney in systemic disease

William G. Herrington, Aron Chakera, and Christopher A. O'Callaghan

Definition of the disease

Many systemic diseases can affect the kidney (see Box 170.1). The main categories are autoimmune conditions, haematological malignancies, and infections. Many details of these conditions are covered in other chapters.

Etiology

Systemic conditions can affect the kidney in a variety of ways:

- (a) Malignancy can cause infiltration of normal renal tissue; immunoglobulin deposition in the renal vessels, glomeruli, or tubules; and paraneoplastic renal dysfunction as occurs in secondary focal segmental glomerulosclerosis.
- (b) Autoimmune conditions can cause inflammation of the glomeruli or tubules, or deposition of inflammatory proteins (AA amyloidosis).
- (c) Infections can cause inflammation in glomeruli in association with immune complex deposition.

- (d) Vascular disease and vasculitis reduce kidney blood supply and cause renal ischaemia.
- (e) Multiple myeloma: Myeloma can cause renal impairment by multiple mechanisms. These include cast nephropathy (30%–60%; see Chapter 160), amyloid light-chain (AL) amyloidosis (20%), light chain deposition disease (10%; see Chapter 161), hyperuricaemia, and hypercalcaemia. Renal disease can occur with a paraprotein, before myeloma bone disease and immunoparesis develop.
- (f) Amyloidosis: Deposition of amyloid protein in the kidney causes renal impairment. AA amyloid fibrils contain serum amyloid A, an acute phase protein that arises with chronic inflammation. AL amyloid fibrils contain immunoglobulin light chains secreted by a plasma cell dyscrasia. With AL amyloidosis, there is a detectable monoclonal paraprotein in 90% of cases; 75% have detectable urinary free light chains; and 15% will meet the diagnostic criteria for multiple myeloma (see Table 170.1). Patients with amyloidosis can present with oedema due to nephrotic syndrome. They may also have coexisting cardiac failure, orthostatic hypotension, or peripheral neuropathy. AL amyloidosis and multiple myeloma carry a poor prognosis, particularly if there is cardiac involvement. Survival at 1 year in dialysis patients has been quoted at 50%, but recent improvements in haematological management may improve this. Kidney involvement in AA amyloidosis is arrested by aggressive treatment of the underlying cause. This may include antibiotics for infections, or intensive immune modulation for autoimmune conditions. The target is a significant reduction in C-reactive protein levels. Treatment of AL amyloidosis with myeloma is with chemotherapy with or without a stem cell transplant.
- (g) Vasculitis is autoimmune inflammation of blood vessels. The size of the vessel affected characterizes kidney involvement. Small vessel vasculitides, including ANCA-positive vasculitis, Henoch–Schönlein purpura, and cryoglobulinaemia, cause a glomerulonephritis. Polyarteritis nodosa is a medium vessel vasculitis which can cause renal impairment secondary to ischaemic damage. Vasculitis is treated with high-dose

	Amyloid light-chain amyloidosis	AA amyloidosis
Sites of amyloid deposition	Gut Liver Spleen Peripheral nerves Autonomic nerves Adrenals Heart Tongue	Gut Liver Spleen Peripheral nerves Autonomic nerves Adrenals
Cause	Plasma cell dyscrasia	Chronic infection (e.g. bronchiectasis) Osteomyelitis Autoimmune disease (e.g. rheumatoid arthritis) Ankylosing spondylitis
Prognosis	20% 5-year survival	Dependent on cause

steroids, and immunosuppression with cyclophosphamide or rituximab.

- (h) SLE can cause several different patterns of glomerulonephritis. Antiphospholipid antibodies can activate the clotting cascade, causing recurrent arterial and venous thrombosis. Antiphospholipid syndrome can be primary or associated with lupus (see Warrell et al., 2010, Table 21.10.3.1). Antiphospholipid syndrome is associated with the lupus anticoagulant, and antibodies against cardiolipin and beta-2 glycoprotein 1. Lupus anticoagulant may cause a raised activated partial thromboplastin time that does not correct on mixing with normal plasma.
- (i) Scleroderma affects the renal vasculature and can cause a hypertensive renal crisis with a microangiopathy. These crises can usually be prevented by early control of hypertension using angiotensin-converting enzyme (ACE) inhibitors. Scleroderma is often associated with serological abnormalities such as anti-ribonucleoprotein and anti-Scl-70 antibodies. Scleroderma is treated with ACE inhibition. Early therapy and control of blood pressure has almost eliminated severe acute renal failure in patients with scleroderma.
- (j) Rheumatoid arthritis is mainly associated with renal dysfunction as an adverse effect of therapy, especially NSAIDs. Rarely, it can be associated with a small vessel vasculitis, or AA amyloidosis. Gold and penicillamine treatment are associated with membranous nephropathy.
- (k) Sarcoidosis can cause a granulomatous tubulointerstitial nephritis and can also cause renal impairment through hypercalcaemia, which can develop into diffuse nephrocalcinosis.
- (l) Thrombotic microangiopathy results from platelet aggregation and thrombosis in small vessels. It is characterized by thrombocytopenia, haemolysis, and tissue ischaemia. The causes include pre-eclampsia, haemolytic-uraemic syndrome (HUS) (usually accompanied by diarrhoea, typically caused by *Escherichia coli* serotype O157 or *Shigella* spp.), and thrombotic thrombocytopenic purpura (TTP) (usually accompanied by central nervous system involvement). Thrombotic microangiopathy often presents with a fever, hypertension, purpura, and acute kidney injury. The clinical context usually suggests the cause. HUS is usually associated with bloody diarrhoea. TTP can cause fits and confusion. Thrombotic microangiopathy is suggested by thrombocytopenia and anaemia, with evidence of haemolysis (a raised bilirubin and lactate dehydrogenase, low haptoglobins, red-cell fragments on blood film, and a negative Coomb's test). Culture of stool and blood is indicated in HUS associated with diarrhoea. In classical HUS, ADAMTS13 activity is normal. Plasma exchange (with fresh frozen plasma) may improve outcomes and the complement inhibitor Eculizumab is now also recommended for selected cases.
- (m) Hepatitis B is associated with membranous nephropathy (see Chapter 161).
- (n) Hepatitis C can cause a mixed essential cryoglobulinaemia which may inflame small and medium sized vessels. Renal disease associated with hepatitis C often responds well to antiviral therapy.
- (o) HIV infection is classically associated with a collapsing variant of focal segmental glomerulosclerosis, HIV-associated nephropathy. HIV infection can also cause a diffuse proliferative glomerulonephritis or a thrombotic microangiopathy. Treatment can have renal side effects. Indinavir is associated with crystaluria, tubular stones, and interstitial nephritis. Cidofovir and adefovir can cause proximal tubular toxicity. HIV-associated nephropathy may respond to antiviral therapy.
- (p) Infective endocarditis is associated with renal impairment, which can be an immune-complex-mediated glomerulonephritis. Aminoglycosides and septicaemia can cause acute tubular necrosis, and penicillin antibiotics may induce a tubulointerstitial nephritis. Valvular vegetations may break off and deposit as septic emboli in the kidney.

Symptoms

A systemic illness may be present if there are symptoms, signs, or abnormal investigations that indicate the involvement of other organ

systems. For this reason, a careful and full history and examination are necessary in all patients with suspected kidney disease, to help determine whether the renal condition is secondary to a systemic illness (which may or may not be known about) or is a primary illness restricted to the kidneys. Renal disease may be the presenting feature for some multisystem diseases but sometimes a systemic disease has already diagnosed. Renal complications can occur with many chronic multisystem diseases, and renal function and urinalysis should be monitored routinely in conditions such as SLE, scleroderma, and sarcoidosis.

Demographics

Diabetic and ischaemic nephropathy are the most common. By contrast, thrombotic microangiopathies, polyarteritis nodosa, and antiphospholipid syndrome are very rare. However, they often affect the young (10–40 years of age). Better rheumatological and antibiotic treatments mean AA amyloidosis is becoming rarer. Amyloidosis and plasma cell dyscrasias are diseases of late middle age (>50 years).

Natural history, and complications

The natural history of renal complications of systemic disease is very variable. If the underlying cause can be treated, prognosis is often good. Delay in treatment may be associated with permanent renal impairment.

Approach to diagnosing the disease

A good clinical history with a thorough systems review will normally give clues to diagnosis. In nephrotic syndrome, suspected glomerulonephritis, or acute kidney injury, the standard immunological and paraprotein screens will often highlight plasma cell dyscrasias and viral infections (see Chapter 157). Finding anaemia, a raised bilirubin, and thrombocytopenia will usually trigger a clinician to perform a haemolysis screen.

Differential diagnosis

When considering a vasculitis, always exclude systemic infection (especially infective endocarditis) or paraneoplastic states.

'Gold-standard' diagnostic test

A renal biopsy is usually the best investigation for diagnosing a disease affecting the kidneys, when other investigations do not indicate the cause. However, it is not always diagnostic, depending on the underlying disease process. Biopsy findings in vasculitis, myeloma, and glomerulonephritides are discussed in Chapters 159 and 161. Biopsies in scleroderma, thrombotic microangiopathy, polyarteritis nodosum, and antiphospholipid syndrome usually demonstrate ischaemic glomerular collapse, as the disease occurs in the vessels leading to the glomeruli.

Other relevant investigations

Other investigations offer important diagnostic clues and may direct treatment (see 'Aetiology' for specific details).

Prognosis and how to estimate it

If the underlying cause can be treated, prognosis is often good. Delay in treatment may be associated with permanent renal impairment.

Treatment and effectiveness

The general supportive measures for nephrotic syndrome, glomerulonephritis, and acute kidney injury are employed as usual. However, additional treatment is also directed to the systemic disorder that has involved the kidneys.

171 Renal vascular disease

William G. Herrington, Aron Chakera, and Christopher A. O'Callaghan

Definition of the disease

Renal vascular disease typically occurs with progressive narrowing of the main renal artery or smaller arterial vessels. Often, both patterns of disease coexist and result in 'ischaemic nephropathy' with damage to renal tissue. Much less commonly, inflammatory vasculitis can affect small or medium vessels.

Aetiology of renal vascular disease

Ninety per cent of renal vascular disease is caused by atherosclerosis. It is associated with the usual cardiovascular risk factors of smoking, diabetes mellitus, hypertension, and dyslipidaemia. Patients with renal vascular disease have an increased risk of cardiovascular death from associated cerebrovascular and coronary heart disease.

Less than 10% of renal vascular disease is caused by fibromuscular dysplasia. The cause is unknown, but smoking is a risk factor. The disease is often bilateral and multifocal. It tends to affect the mid-portion of the renal artery, while atherosclerosis tends to occur at points of stress, especially at the junction of renal arteries with the aorta.

Symptoms

Renal artery stenosis in itself is usually asymptomatic. Renal vascular disease reduces renal perfusion. This activates the renin-angiotensin system, increasing angiotensin II levels. The elevated angiotensin II level causes hypertension through vasoconstriction and increased aldosterone secretion, which promotes sodium and water retention.

Patients with salt and water retention present with peripheral oedema and orthopnoea. Secondary hyperaldosteronism can also cause a hypokalaemic metabolic alkalosis.

Demographics

Atherosclerosis is increasingly prevalent with age. Renal vascular disease has a prevalence of 7% in those over 65 years old. Fibromuscular dysplasia, in contrast, occurs predominately in females under the age of 30 years.

image courtesy of Ian Roberts.

Figure 171.2 Angiogram demonstrating fibromuscular dysplasia ('string of beads').

This article was published in *Grainger & Allison's Diagnostic Radiology 5e*, Adam & Dixon, Copyright Elsevier 2007.

Complications of the disease

Chronic fluid overload can episodically and rapidly decompensate, causing flash pulmonary oedema even when cardiac function is normal. The concept is that reduced renal perfusion, perhaps caused by a dip in blood pressure, results in a sudden activation of the renin-angiotensin system. In practice, however, patients with renal vascular disease often have concomitant coronary artery disease or hypertensive heart disease.

Acute deterioration in renal function can occur due to renal infarction (associated loin pain and raised lactate dehydrogenase) or due to cholesterol emboli. Cholesterol emboli can result from instrumentation or aortic surgery (usually angiography) or thrombolysis/anticoagulation. A shower of cholesterol crystals can occlude small renal vessels (see Figure 171.1). There may be concomitant evidence of digital infarction or livedo reticularis. There is often associated

Table 171.1 Medical treatment of renal vascular disease

	Treatment	Suggested minimum targets
Blood-pressure control	Furosemide Calcium blocker/beta blocker Trial of angiotensin-converting enzyme inhibitor	<130/80 mm Hg
Antiplatelet therapy	Low-dose aspirin	
Lipid-lowering therapy	Statin +/- ezetimibe	As low as possible
Lifestyle advice	Stop smoking Low-salt diet

This article was published in *Granger & Allison's Diagnostic Radiology 5e*, Adam & Dixon, Copyright Elsevier 2007.

inflammation with a raised C-reactive protein level and eosinophil count. Complement levels may be reduced. Therapy is supportive.

Approach to diagnosing the disease

Renal artery disease is suspected in a patient with known vascular disease with hypertension that is difficult to control (hypertensive despite full dose of three antihypertensive agents). Fluid overload and renal dysfunction are common. Supporting examination findings including bruits and absent peripheral pulses. An abdominal bruit is useful but not a specific sign because it may or may not localize to the renal artery. Dipstick is bland or may show low-grade proteinuria. Ultrasonography may show renal asymmetry (>1.5 cm is suspicious) in unilateral disease; however, disease is frequently bilateral.

The only reliable indicator of functional stenosis is a significant (>15%) rise in creatinine on starting an angiotensin-converting enzyme (ACE) inhibitor or angiotensin blocker. If there is sufficient clinical suspicion of the diagnosis, imaging is the key to diagnosis.

A pitfall to avoid is not checking plasma creatinine about a week after initiating or changing an ACE inhibitor or angiotensin II receptor blocker dose.

Differential diagnosis

Any cause of chronic kidney disease can cause renal impairment and hypertension. Alternative diagnoses to consider in resistant hypertension with or without renal impairment include high alcohol or salt intake, obesity, obstructive sleep apnoea, concomitant NSAID use, and primary hyperaldosteronism.

'Gold-standard' diagnostic test

The digital subtraction angiogram is the gold-standard diagnostic test (see Figure 171.2). Magnetic resonance angiography (MRA) is, however, the most common first screening test. It visualizes ostial lesions well, but has the propensity to overestimate a stenosis.

Invasive angiography has the benefit of accurate assessment of stenosis, better visualization of distal arteries and the opportunity for angioplasty and stent placement. The procedure is associated with a 7% complication rate. Complications include bleeding, contrast-induced nephropathy, and cholesterol emboli. Formal angiography

is thus reserved for equivocal cases or when angioplasty is under consideration.

Acceptable alternative investigations

The best screening test is MRA or CT angiography. A duplex ultrasound with Doppler can demonstrate reduced perfusion in experienced hands, but is not a standard screening investigation.

Prognosis and how to estimate it

Renal vascular disease may progress in a stepwise fashion with long intervening periods of stability making it difficult to predict prognosis. Mortality is 8%–16% per year, due to associated vascular disease.

Treatment and its effectiveness

Treatment is medical or interventional. Medical therapy should be universal to prevent progression of vascular disease (Table 171.1). An ACE inhibitor can still be used, providing there is no serious increase in creatinine after starting.

Angioplasty is used for fibromuscular dysplasia, but is seldom indicated for atherosclerotic renal arterial disease. Angioplasty seldom sees benefit compared to medical treatment in terms of recovery of renal function or blood pressure. Anecdotal evidence may still support angioplasty in less common clinical situations, such as rapidly deteriorating renal function (acute occlusion) and flash pulmonary oedema (see Figure 171.3). The lack of benefit from angioplasty may be due to concomitant small vessel atherosclerosis downstream of the proximal lesion (ischaemic nephropathy). Angioplasty can also do harm, and a shower of cholesterol emboli may precipitate the need for dialysis.

172 Management of terminal care in renal disease

William G. Herrington, Aron Chakera, and Christopher A. O’Callaghan

Definition of the disease

The World Health Organization defines palliative care as an approach that improves the quality of life of patients and their families facing the problem(s) associated with life-threatening illness, through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems—physical, psychosocial, and spiritual.

Aetiology of the disease

With the increasing age and burden of comorbidities experienced by patients with significant renal impairment in developed countries, many patients are deciding that they do not want renal replacement therapy or elect to withdraw from dialysis. In some countries, over 30% of deaths in dialysis-dependent patients are reported as being due to withdrawal from treatment. For these patients and patients who opt for conservative (supportive) management, rather than renal replacement therapy, symptom control and maintenance of quality of life are the primary goals.

Several aspects of terminal care are unique in the context of renal impairment. These include the management of symptoms caused by the loss of normal kidney function, such as anaemia, oedema, and hyperphosphataemia, and also altered pharmacokinetics of medications that are renally cleared.

Typical symptoms of the disease, and less common symptoms

The metabolic derangements caused by end-stage renal disease can lead to a variety of distressing symptoms. Table 172.1 lists some of these symptoms and potential treatment options. In addition to the physical manifestations of renal impairment, significant psychological symptoms related to the decision to withdraw from dialysis (or to opt for conservative management) may occur, and these should be addressed.

Demographics of the disease

With the ageing of the population, there are an increasing number of elderly patients, who often have multiple comorbidities, reaching end-stage renal disease. Recent UK renal registry data show that over 50% of dialysis patients have one or more significant comorbid conditions in addition to their renal disease, with the highest incidence occurring in the 65–74-year age group. Although elderly patients dominate the group receiving supportive care, patients of all ages are represented, and the needs and issues may be very different, particularly in younger patients. A proportion of patients will have another terminal disease, which causes their death, and also have end-stage renal disease.

Natural history, and complications of the disease

The terminal course is highly dependent on the degree of renal impairment, which influences the ability to maintain fluid balance and control acidosis. Patients who were previously dialysis

Table 172.1 Common symptoms and treatment options in terminal renal failure

Symptom	Potential treatments
Nausea and vomiting	Haloperidol Metoclopramide Levomopromazine
Pruritus	Optimize magnesium and calcium concentrations UVB Thalidomide Capsaicin cream Mirtazapine
Bone pain	Paracetamol NSAIDs Opioids: reduced dose, as these can accumulate; in some units, methadone and fentanyl are preferred for use, as their metabolites are less likely to accumulate with renal impairment Bisphosphonates
Neuropathic pain	Paracetamol Opioids Amitriptyline Gabapentin
Restless legs	Optimize iron status Pramipexole Clonazepam
Oedema and dyspnoea	Non-pharmacological: reassurance, having the patient sit upright, use of fans Pharmacological: diuretics, oxygen, opioids, benzodiazepines, antisecretory agents (e.g. glycopyrrrolate)
Delirium	Benzodiazepines Levomopromazine

dependent have a mean survival on withdrawal of 8–10 days, but some may live for several weeks. Major complications relate to fluid balance, which can cause distressing dyspnoea and uncertainty regarding the duration of survival. With conservative management of end-stage renal disease becoming an increasingly chosen option for patients (over 10% of patients with end-stage renal disease in some centres), progression to death may be very slow. This creates significant opportunities to improve symptom control and optimize quality of life.

Approach to diagnosing the disease

Advanced care planning should be an integral component of the management of all patients with end-stage renal disease. Patients’ wishes should be documented, and patients should be supported through their decision-making.

Although patients may have elected for conservative management, if there are sudden declines in clinical state, it may be appropriate for reversible factors to be sought and treated, depending on the patient’s wishes and advanced directives. Patients and their families

should be fully informed of their prognosis (as far as possible) and made aware of the treatment options available to them.

The UK's National Service Framework for renal services defined six markers of good practice for terminal care in renal disease:

1. Access to communication skills and knowledge of symptom control
2. Offering prognostic assessment
3. Timely information and joint palliative care plan
4. Ongoing medical care for patients opting not to dialyse
5. Dying with dignity
6. Culturally appropriate bereavement support

Importantly, all members of the renal multidisciplinary team, including pre-dialysis counsellors, nurses, pharmacists, dieticians, social workers, and doctors, can make important contributions to the terminal management of patients with renal diseases and should be involved in their care.

Other relevant investigations

If reversible causes for a sudden deterioration in clinical state are suspected, and the patient wishes treatment, appropriate investigations should be performed, as they would for any other patient group. These may include blood tests, chest X-ray, or other imaging.

Prognosis and how to estimate it

Serial measurements of renal function and electrolytes may help gauge the rate of decline.

Treatment and its effectiveness

A variety of treatments are available for symptom control in patients with end-stage renal disease (see Table 172.1). It is essential to remember that many of the commonly used medications and their metabolites are cleared by the kidneys, and appropriate dose adjustments should be made.

As maintenance of quality of life is important and the time course can be long (particularly in patients with slowly progressive renal diseases), it is important that these patients are not denied therapies that can maintain or improve quality of life, including erythropoietin, for the treatment of anaemia; vitamin D preparation, to prevent bone pain and reduce the risk of fractures; and bicarbonate tablets, to reduce acidosis. Specialist palliative care advice should be sought early or if symptom control is proving difficult.

173 Disorders of plasma potassium

Aron Chakera, William G. Herrington, and Christopher A. O’Callaghan

Definition of the disease

Potassium is the major intracellular cation, and maintenance of potassium homeostasis is critical for normal cellular function. Serum potassium levels usually range from 3.5–4.5 mmol/l (compared with intracellular levels of ~150 mmol/l). Hypokalaemia is defined as a serum potassium level <3.5 mmol/l, and hyperkalaemia as a serum potassium level > 4.5 mmol/l. Serum potassium levels between 3 and 6 mmol/l are usually well tolerated without adverse signs or symptoms; the only exception to this is in those with established severe heart disease (e.g. heart failure with significant left ventricular systolic dysfunction). In these patients, hypokalaemia quite significantly increases the risk of lethal ventricular arrhythmias, in part possibly through QT-interval prolongation. Part of the mechanism of benefit for drugs such as spironolactone and eplerenone is that they help maintain potassium in the normal range and so lessen arrhythmia risk.

Aetiology of the disease

The major cause of hypokalaemia is loss of potassium through either the gut or the kidneys (see Table 173.1); however, it may also be seen transiently with medications that move potassium into cells

Given the high intracellular potassium concentration, hyperkalaemia may be caused by tissue damage, or by impaired renal secretion of potassium. Hyperkalaemia also occurs with acidaemia, as the decrease in pH leads to intracellular buffering of hydrogen ions, which are exchanged with potassium to maintain electrical neutrality (see Table 173.2).

Typical symptoms of the disease, and less common symptoms

Maintenance of the normal intracellular–extracellular potassium gradient determines the resting membrane potential. Both hypo- and hyperkalaemia affect cellular depolarization, leading to neuromuscular symptoms which can rapidly become life-threatening, primarily from cardiac arrhythmias (see Table 173.3).

Category	Causes
Gastrointestinal losses	Vomiting Chronic diarrhoea
Renal losses	Medications <ul style="list-style-type: none"> • Diuretics • Antimicrobials <ul style="list-style-type: none"> • Penicillins • Aminoglycosides • Amphotericin Endocrine disorders <ul style="list-style-type: none"> • Steroid excess • Conn’s syndrome Tubular disorders <ul style="list-style-type: none"> • Renal tubular acidosis • Channelopathies <ul style="list-style-type: none"> • Gitelman syndrome • Bartter syndromes
Redistribution into cells	Glucose administration Bicarbonate administration Beta agonists

Table 173.2 Causes of hyperkalaemia

Category	Causes
Release from cells	Haemolysis Large haematomas Severe tissue damage Acidaemia
Decreased renal potassium losses	Hyperaldosteronism Medications <ul style="list-style-type: none"> • Antibiotics (e.g. trimethoprim) • Potassium-sparing diuretics • NSAIDs • Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers Acute renal failure

Demographics of the disease

Hyperkalaemia occurs in over 5% of hospitalized patients and is most common in older age groups, where it is associated with renal impairment and medication use. Medications that block the renin–angiotensin system, such as angiotensin-converting-enzyme inhibitors (ACE-Is) and angiotensin receptor blockers (ARBs) are often responsible. This is mainly because they lower aldosterone levels, and aldosterone promotes renal potassium excretion.

Hypokalaemia is also common, affecting over 15% of hospitalized patients, and is usually related to diuretic use, gastrointestinal losses, or inadequate potassium in the diet. It is often first noted as an incidental laboratory finding.

Natural history, and complications of the disease

There are no pathognomonic features of hypo- or hyperkalaemia on history or examination, and the presence of clinical signs can depend on the duration of the abnormality. Some patients with significant chronic kidney disease may maintain stable potassium levels of 6.5–7.0 mmol/l, with no symptoms. Where abnormal serum potassium levels are noted, the rate of change is also important. Rapid shifts are associated with worse outcomes. When significant abnormalities in potassium levels are noted before the onset of cardiac or neurological symptoms and treatment is instituted, the prognosis is generally good.

Table 173.3 Symptoms of hypo- and hyperkalaemia

Hypokalaemia	Hyperkalaemia
Weakness (usually severe hypokalaemia)	Fatigue Weakness
Cramps	Paraesthesia
Nausea and vomiting	Paralysis
Palpitations (reflecting supraventricular and ventricular arrhythmias, especially with underlying cardiac disease)	Palpitations Cardiac arrest (due to ventricular arrhythmias and cardiac standstill)
Constipation	
Polyuria (uncommon and typically reflecting chronicity)	
Psychosis (uncommon)	
Depression (uncommon)	

Approach to diagnosing the disease

Most cases of mild–moderate hypo- or hyperkalaemia are identified as incidental findings on routine laboratory tests and do not necessitate extensive investigation. As the presence of clinical signs and symptoms are a late manifestation, a high index of suspicion is often necessary to diagnose the condition. Hyperkalaemia, in particular, should be suspected in any patient with decreased urine output or significant renal impairment, especially if they are on ACE-I/ARB. The priority in any patient with acute kidney injury is to determine whether their potassium level is high, because this can cause imminent cardiac arrest if undiagnosed and untreated. If there is a concern that significant hyper- or hypokalaemia may be present, potassium levels should be assessed urgently on a blood gas machine (using venous or arterial blood taken through a needle that is 22 gauge or larger, to minimize haemolysis), an ECG performed, and a concurrent serum sample sent to the laboratory for formal reporting. A thorough review of the patient's medications and diet should be undertaken, and any causative medications stopped. Examination should focus on cardiovascular status and fluid balance to assess potential causes of renal dysfunction, and any tissue damage or large haematomas noted.

Other diagnoses that should be considered

Hypokalaemia and hypomagnesaemia often coexist, and correction of hypokalaemia can be difficult if there is ongoing hypomagnesaemia. The presence of an abdominal bruit on examination should raise the suspicion of renal artery stenosis, particular if the onset of hyperkalaemia follows the introduction of medications that affect the renin–angiotensin system. Hypokalaemia is an important feature of hyperaldosteronism (e.g. Conn's syndrome) and can also occur with the use of exogenous steroid agents that have mineralocorticoid activity.

If significant unexplained hypokalaemia is noted, the serum bicarbonate level should be measured, as hypokalaemia with acidosis in the presence of normal renal function is suggestive of renal tubular acidosis (which will be hyperchloraemic), whereas hypokalaemia with normal or elevated bicarbonate is consistent with a channelopathy.

'Gold-standard' diagnostic test

The gold-standard test used to detect disorders of plasma potassium is the laboratory serum potassium level.

Acceptable diagnostic alternatives to the gold standard

Accurate potassium levels can be obtained from blood gas machines and, when clinically worrying hypo- or hyperkalaemia is suspected, this test should be performed first, as the results will be available immediately.

Other relevant investigations

As the major cause of mortality from hypo- or hyperkalaemia is cardiac arrhythmia, an ECG should be performed early, whenever these abnormalities are suspected. ECG findings of hyperkalaemia include tall, tented T-waves, increased PR intervals, and broadening of the QRS complex, with loss of P waves and presence of sine wave morphology when severe (see Figure 173.1).

Hypokalaemia is associated with the development of U waves. Assessment of urinary pH, urinary potassium, and other electrolytes may be performed if a primary tubular disorder is suspected. Investigation of hyperaldosteronism includes plasma renin levels, aldosterone levels, and abdominal imaging to differentiate between adrenal adenomas and bilateral adrenal hyperplasia (although small adenomas may be difficult to detect). If needed, direct sampling of blood from each adrenal vein can be performed (see Chapter 188).

Prognosis and how to estimate it

The prognosis depends on the severity of the derangement and how rapidly it has occurred. In some series, the mortality is over 50% when there are significant delays in treatment. The presence of ECG abnormalities due to hypo- or hyperkalaemia is indicative of a poor prognosis, unless urgent treatment is instituted.

Treatment and its effectiveness

The management of hypokalaemia relies on replacement with oral or IV potassium, depending on the patient's status. As most potassium is intracellular, a decrease in serum potassium of 1 mmol/l equates to a total body potassium loss of 100–300 mmol. IV potassium should not usually be given faster than 20 mmol/hour, unless the patient is on a cardiac monitor. Patients on long-term diuretic therapy (e.g. patients with congestive cardiac failure, particularly if not receiving a potassium-sparing diuretic) are at high risk and should have serum potassium levels assessed regularly.

Figure 173.1 ECG showing sine wave morphology in a patient with severe hyperkalaemia; this may progress to ventricular standstill or fibrillation.

Action	Medication	Time to effect	Duration of effect
Stabilize the myocardium	Calcium gluconate, calcium chloride	1–2 minutes	20–30 minutes
Intracellular redistribution of potassium	Glucose + insulin	10 minutes	2–4 hours
	Sodium bicarbonate	10 minutes	2–4 hours
	Beta agonists (e.g. salbutamol)	5–10 minutes	2–4 hours
Removal of potassium	Diuretics (e.g. furosemide)	30–60 minutes	2–3 hours ≥6–12 hours Continues while on machine
	calcium polystyrene sulfonate, sodium polystyrene sulfonate*	4–6 hours orally, 1–2 hours rectally	
	Dialysis	1–2 minutes	

Note: Calcium gluconate/chloride should be used with caution in cases where digitalis toxicity is suspected, as it may potentiate arrhythmias. IV magnesium sulfate can be given as an alternative.

*New oral potassium binders are being developed, including patiromer and sodium zirconium cyclosilicate.

The treatment of hyperkalaemia also depends on the severity of the elevation and the rate of increase (see Table 173.4). In general, a serum potassium in the range of 5.0–6.0 can be considered mild elevation; 6–6.5, moderate elevation; and >6.5 should be considered severe elevation in most cases, particularly if it is unclear whether the levels may still be increasing. Management of severe hyperkalaemia involves:

- stabilization of the myocardium (where there are ECG changes or neuromuscular signs or symptoms)
- temporizing measures to redistribute potassium to the intracellular space
- definitive treatment to remove potassium from the body

174 Disorders of plasma sodium

Aron Chakera, William G. Herrington, and Christopher A. O'Callaghan

Definition of the disease

The normal range for serum sodium levels in most laboratories is 135–145 mmol/l. Hyponatraemia is defined as a serum sodium concentration of < 135 mmol/l (<120 mmol/l is severe), and hypernatraemia as a concentration >145 mmol/l. As sodium is the major extracellular electrolyte, and freely diffuses throughout the extracellular space, it plays a key role in regulating osmolarity. Hyponatraemia is almost always associated with a hyposmolar state, except for the rare circumstances when there are other osmotically active substances present at high levels (e.g. glucose).

Aetiology of the disease

As sodium freely diffuses through the extracellular spaces, abnormalities in serum sodium reflect changes in the total amount of sodium and/or (more commonly) the total amount of fluid present. (In healthy individuals, regulation of serum sodium levels is tightly controlled by osmoreceptors.)

Given the relationship between sodium and water, accurate assessment of fluid balance is an integral part of determining the causes of hypo- or hypernatraemia (see Table 174.1).

An important cause of hyponatraemia in clinical practice is the syndrome of inappropriate diuresis (SIAD). Table 174.2 lists the major etiologies of SIAD.

Hypernatraemia, in contrast, almost always indicates dehydration, due to excessive free water loss (see Table 174.3 for other symptoms). This may be due to gastrointestinal losses, sweating, or renal losses, as occur in diabetes insipidus or with severe hyperglycaemia in diabetes mellitus. Iatrogenic causes of hypernatraemia include excessive infusions of normal saline, sodium bicarbonate, or Gelofusine which contain ~150 mmol/l sodium. As dehydration causes a hyperosmolar state, in normal circumstance this triggers thirst; for hypernatraemia to develop, there must also be inadequate access to water. This is a particular problem with elderly

Table 174.2 Major causes of syndrome of inappropriate diuresis

Causes	Common examples
Tumours	Small cell carcinoma of bronchus, mesothelioma Head and neck cancers Gastrointestinal malignancies Lymphomas
Lung diseases	Pulmonary infections Severe asthma
Neurological conditions	Bleeds (e.g. subarachnoid haemorrhage) Trauma Infections Tumours Other: Guillain-Barré syndrome, multiple sclerosis
Endocrine disorders	Hypothyroidism Addison's disease
Medications	Amiodarone Chlorpropamide NSAIDs Carbamazepine Selective serotonin reuptake inhibitors Tricyclic antidepressants Ecstasy (MDMA)
Miscellaneous	Surgery Pain Stress Severe nausea

and hospitalized patients, who may be unable to regular their own water intake.

Typical symptoms of the disease, and less common symptoms

The typical and less common symptoms of the disease are stated in Table 174.3.

Demographics of the disease

Hypo- or hypernatraemia occurs in 5% of patients in general hospital wards, and at higher levels in high-dependency and intensive care

Table 174.1 Mechanisms and causes of hyponatraemia

Mechanism	Cause
Reduced water excretion (hypervolaemic hyponatraemia)	CCF Cirrhosis Nephrotic syndrome Renal failure SIAD <ul style="list-style-type: none"> • drugs • cancers • CNS and pulmonary diseases • pain
Increased water intake (hypervolaemic hyponatraemia)	Polydipsia Hypotonic IV infusions
Increased sodium loss (euvoalaemic or hypovolaemic hyponatraemia)	Diuretics Salt-wasting tubular diseases
Miscellaneous	Pseudohyponatraemia Spurious (drip arm) Hypothyroidism Adrenal insufficiency

Abbreviations: CCF, congestive cardiac failure; CNS, central nervous system; IV, intravenous; SIAD, syndrome of inappropriate diuresis.

Table 174.3 Symptoms of hypo- and hypernatraemia

Hyponatraemia	Hypernatraemia
Attention deficits	Irritability
Impaired gait	Muscle twitches
Confusion	Confusion
Hyporeflexia	Hyperreflexia
Muscle cramps	Spasticity
Seizures	Seizures
Lethargy → coma	Lethargy → coma
Dysgeusia (uncommon)	

units. Elderly patients and patients with renal disease or head injuries that affect their ability to regulate sodium excretion or fluid intake are particularly at risk.

Natural history, and complications of the disease

Hyponatraemia has been shown to be an independent predictor of mortality in unselected general medical patients (whereas mortality from hypernatraemia generally reflects the presence of multiple comorbidities). Although relatively uncommon, rapid correction of hyponatraemia (especially if chronic) can cause an osmotic demyelination syndrome (central pontine myelinolysis), characterized by altered sensorium, cranial nerve, and long-motor tract dysfunction which can progress to loss of consciousness and death. The risk of this is increased when the initial serum sodium level is <120 mmol/l and if correction to normal is too rapid. As a guide, sodium levels should not be increased by more than 12 mmol/l in the first 24 hours (0.5 mmol/l hr⁻¹) of treatment.

Approach to diagnosing the disease

As the symptoms of hypo- or hypernatraemia are non-specific, these diagnoses will be missed, unless there is a high index of suspicion in hospitalized patients, and regular assessment of serum sodium levels in at risk groups. An awareness of the common medications and diseases associated with abnormalities of sodium homeostasis is important. Given the relationship between sodium and fluid balance, a thorough clinical assessment of volume status is essential. Once a diagnosis is made, ongoing clinical and laboratory assessment is crucial to determine the response to treatment and to tailor further treatment.

The following drugs are associated with hyponatraemia:

- diuretics
- antidepressants (e.g. selective serotonin reuptake inhibitors, monoamine oxidase inhibitors)
- antipsychotics
- anticonvulsants (e.g. chlorpromazine)
- chemotherapy agents (e.g. cyclophosphamide, cisplatin)
- ecstasy (MDMA)
- arginine vasopressin analogues (e.g. desmopressin, oxytocin)
- sulfonylureas (e.g. glipizide, glibenclamide, chlorpropamide)
- NSAIDs

Other diagnoses that should be considered

Hypervolaemic hyponatraemia, with evidence of fluid overload, such as a raised jugular venous pressure, and peripheral or pulmonary oedema, should prompt assessment of cardiac, hepatic, and renal function. Hyponatraemia in hospital may be secondary to SIAD, and assessment for potential CNS or respiratory diseases should be considered.

Most laboratories now analyse sodium with ion-specific electrodes on whole-blood specimens (without dilution) whereas, previously, measurements were made on prediluted serum or plasma. These prediluted samples could result in pseudohyponatraemia in the presence of hyperlipidaemia or hyperproteinaemia, due to an increase in the non-aqueous phase of plasma (which does not contain sodium).

'Gold-standard' diagnostic test

The gold-standard diagnostic test is laboratory assessment of serum sodium levels.

Acceptable diagnostic alternatives to the gold standard

Venous or arterial blood gas measurements, or measurements with portable devices such as the iSTAT® are useful alternatives, particularly when repeated assessment is needed, for example in the treatment of hyponatraemia.

Other relevant investigations

Abnormalities of other electrolytes often occur at the same time and it is important that these are assessed. Measurement of serum and urine osmolality may be useful in determining the cause. For example, an inappropriately high urine osmolality, in the presence of low plasma osmolality with hyponatraemia and fluid overload, suggests SIAD. As thyroid and adrenal insufficiency may be subclinical, biochemical assessment of these endocrine axes, with a serum thyroid-stimulating hormone and short tetracosactide test should be considered, if no other diagnoses are evident.

When diabetes insipidus is suspected as the cause of hypernatraemia, a water-deprivation test has high sensitivity and specificity for distinguishing central and nephrogenic diabetes insipidus, but should only be performed in a supervised inpatient setting. This test involves repeated measurements of simultaneously collected urine and serum electrolytes and osmolality, body weight, and urine output, while all fluid intake is prevented.

Prognosis and how to estimate it

Prognosis is dependent on the degree of hypo- or hypernatraemia, and the presence of comorbid conditions. The increased mortality in hospitalized patients with hypo- or hypernatraemia should be appreciated and prompt regular review.

Treatment and its effectiveness

Where possible, the underlying cause of the hypo- or hypernatraemia should be treated. A euvolaemic state should be aimed for, with appropriate prescription of IV fluids when necessary. In general, hypertonic saline solutions are not necessary for the correction of hyponatraemia and can produce a correction that is too rapid. A new class of medications, the vaptans (non-peptide arginine vasopressin antagonists), which inhibit the action of vasopressin, have been trialled for euvolaemic and hypervolaemic hyponatraemia with good effect, and conivaptan (IV preparation) is now approved for this use in the USA. Demeclocycline 300–600 mg twice per day is now seldom used in the treatment of hyponatraemia, due to its adverse side effect profile, which includes renal impairment.

Hypernatraemia should be treated by careful clinical estimation of fluid deficit, and its correction with appropriate fluids, usually a combination of glucose and saline. Fluid deficit can be estimated using the following equation:

$$\text{Fluid deficit} = \text{TBW} \times (\text{current Na level} - 140) / 140,$$

where TBW is total body water; in males, TBW = 0.6 x lean weight; in females, TBW = 0.5 x lean weight.

175 Disorders of plasma calcium

Aron Chakera, William G. Herrington, and Christopher A. O'Callaghan

Hypercalcaemia

Definition of hypercalcaemia

The extracellular calcium ion concentration is tightly regulated through the actions of parathyroid hormone (PTH) and vitamin D (1,25-dihydroxyvitamin D) on bone, kidney, and intestines. Abnormalities in these homeostatic mechanisms may lead to increased serum calcium concentrations, resulting in hypercalcaemia. Hypercalcaemic disorders may be divided into those associated with a high/high-normal serum PTH level, and those associated with a low serum PTH concentration.

Aetiology of hypercalcaemia

The aetiology of hypercalcaemia is given in Box 175.1

Primary hyperparathyroidism is the most common cause of hypercalcaemia in ambulant patients, with 85% of cases being due to a single adenoma, and the remainder being parathyroid hyperplasia; <1% are parathyroid carcinomas. Hyperparathyroidism is commonly found in patients with multiple endocrine neoplasia (MEN; types I and II). Chronically low vitamin D levels and chronic renal failure with persistently low calcium levels may stimulate the autonomous increased production of PTH, resulting in tertiary hyperparathyroidism, which in turn causes hypercalcaemia. Malignancy-induced hypercalcaemia is the more common cause in hospitalized patients. Familial hypocalcaemic hypercalcaemia (FHH) accounts for 2% of all asymptomatic hypercalcaemia.

Typical symptoms of hypercalcaemia, and less common symptoms

With mild hypercalcaemia (<3.0 mmol/l), many patients are asymptomatic. As calcium levels rise, symptoms develop secondary to increased calcium concentrations and end-organ damage.

Typical symptoms include malaise, depression, confusion, lethargy, polyuria, polydipsia, constipation, abdominal or flank pain, musculoskeletal vague aches, and nausea or vomiting. Patients may have band keratopathy or show signs of proximal myopathy, dehydration, underlying malignancy, or hypertension. Some may present with coma.

Demographics of hypercalcaemia

The average age of diagnosis of primary hyperparathyroidism is 50–60 years, with an approximate incidence of 30–40 per 100 000

in the general population. It is two to three times more common in women than in men. The condition is rare in children. In MEN I, it is found in virtually all gene carriers by the age of 40 years, while it is seen in 10%–30% of families with MEN IIa. Hypercalcaemia secondary to malignancy increases with age and there is no sex preponderance. FHH is caused by mutations in the calcium-sensing receptor and is an autosomal dominant disorder with virtually complete penetrance.

Natural history of hypercalcaemia, and complications of the disease

Patients with primary hyperparathyroidism frequently present without symptoms and are detected after routine laboratory screening reveals hypercalcaemia. Although asymptomatic, these patients commonly develop bone disease, such as osteoporosis. Most sites are affected, but bone loss occurs predominantly in peripheral cortical bone such as the distal radius, with minimal involvement of the lumbar spine, although 15% of patients present with vertebral osteopaenia. With advanced disease, osteolytic lesions may result in bone cysts and, rarely, the condition osteitis fibrosa cystica; the latter is mainly found in tertiary hyperparathyroidism. As calcium levels increase, patients are predisposed to develop renal stones, which are present in 10%–20% of patients. Other renal complications include hypercalcaemia and nephrocalcinosis. Both renal and skeletal complications are progressive. Peptic ulcer disease related to hypercalcaemia-induced gastrin release may be found, especially in patients with MEN I. Pancreatitis is rarely found. More commonly, patients develop neuropsychiatric and cognitive complaints with features of depression and anxiety. Cardiovascular complications may be related to hypertension.

Patients with chronic hypercalcaemia may present with other complications associated with long-standing high calcium levels, such as calcification of the basal ganglia, resulting in extrapyramidal symptoms and seizures, or epidermal changes with dry skin and brittle nails.

Hypercalcaemia of malignancy mainly presents with non-specific symptoms which overlap with the clinical features of the underlying disease and may lack many features associated with hyperparathyroidism.

Approach to diagnosing hypercalcaemia

The following approaches should be used to diagnose hypercalcaemia:

- check for hypercalcaemia-related symptoms, which may be vague and long-standing, and for complications related to end-organ damage
- identify symptoms and signs of hyperthyroidism and malignancy, especially of the breast, thyroid, lung, kidney, and prostate, as well as any squamous cell tumours and haematological malignancies (e.g. myeloma, lymphoma)
- confirm corrected hypercalcaemia
- identify drugs causing hypercalcaemia
- check serum PTH and, if high or normal, perform a fractional urine calcium excretion test, where
- if PTH is high or normal, and urine calcium excretion > 0.01 mmol/l, this indicates primary hyperparathyroidism; if, in addition, the renal function is abnormal, consider tertiary hyperparathyroidism
- if PTH is high or normal, and urine calcium excretion < 0.01 mmol/l, this indicates FHH
- if PTH is low or suppressed, exclude malignancy, hyperthyroidism, Addison's disease, sarcoidosis, and other granulomatous disorders

Box 175.1 The aetiology of hypercalcaemia

Common (>90% of cases)

- hyperparathyroidism (primary, tertiary)
- malignancy (PTH-rP (parathyroid-hormone related peptide) secreting tumours, bony metastases, multiple myeloma)

Uncommon

- vitamin D intoxication
- familial hypocalcaemic hypercalcaemia
- thyrotoxicosis
- sarcoidosis and other granulomatous disorders
- milk-alkali syndrome

Rare

- thiazides, lithium
- Addison's disease
- vitamin A poisoning
- immobilization

Other diagnoses that should be considered aside from hypercalcaemia

Primary hyperparathyroidism may be associated with MEN types I and II.

'Gold-standard' diagnostic test for hypercalcaemia

Confirm hypercalcaemia, and then take a morning blood sample of PTH together with a corrected serum calcium level. Measure urinary calcium excretion if PTH is normal or high.

Acceptable diagnostic alternatives to the gold-standard test for hypercalcaemia

If PTH is high-normal or high, investigate for primary and tertiary hyperparathyroidism and FHH. If PTH is low, investigate for other causes, via the following tests:

- serum phosphate: this is low or normal in primary hyperparathyroidism and malignancy, and high in vitamin D-related disorders
- fasting urine calcium excretion
- serum alkaline phosphatase; this is high in primary hyperparathyroidism and malignancy
- thyroid function tests (to exclude hyperthyroidism)
- renal profile and liver function tests, including albumin
- plasma and urine protein electrophoresis (to exclude myeloma)
- a short tetracosactide test (to exclude adrenal insufficiency)
- skeletal X-rays (of hands, knees, and the lateral thoracolumbar spine)

Other relevant investigations for hypercalcaemia

Other relevant investigations for hypercalcaemia include:

- PTHrP (parathyroid hormone-related peptide); this peptide mediates hypercalcaemia associated with some malignancies
- vitamin D levels (calcitriol); this is useful in diagnosing hypercalcaemia secondary to granulomatous disorders (serum angiotensin-converting enzyme may be elevated in sarcoidosis)
- creatinine clearance; to exclude tertiary hyperparathyroidism and screen for hypercalcaemia-induced kidney disease
- 24-hour urine calcium, with or without biochemical stone analysis
- renal tract ultrasound, X-ray, and CT; to exclude calculi, nephrocalcinosis
- bone mineral density and bone turnover markers; for PTH-induced osteoporosis

In addition, consider chest radiographs and bone scintigraphy, to investigate for malignancy.

Prognosis for hypercalcaemia, and how to estimate it

The prognosis for malignancy-induced hypercalcaemia is poor, with the 1-year survival being 10%–30%. The prognosis for other hypercalcaemia-related disorders is excellent once the disease is treated.

Treatment for hypercalcaemia, and its effectiveness

Treatment of acute hypercalcaemia

If serum calcium >3.0 mmol/l or the patient is symptomatic or dehydrated, prompt IV infusions of large quantities of 0.9% normal saline, around 3–6 l over the first 24 hours. Loop diuretic may be added **only** if there is a risk of salt or fluid overload. Dialysis may be required in severe renal failure.

When the patient is well hydrated, IV bisphosphonates may be used to treat the cause of hypercalcaemia. These drugs are usually effective for conditions with increased PTH and PTHrP inhibiting bone resorption and tubular reabsorption of calcium, and are mainly used in malignancy and primary hyperparathyroidism, but are less effective in the latter. Pamidronate is given as a single IV infusion of between 30 mg and 90 mg, and plasma calcium usually falls by about 72 hours. The drug is usually well tolerated but patients may develop bone pains or a flu-like illness. The dose must be reduced with a glomerular filtration rate <30 ml/min. IV zoledronic acid 4 mg is more effective in achieving normocalcaemia than pamidronate and

provides a longer median time to relapse of approximately 4 weeks vs 2.5 weeks. Zoledronic acid is mainly indicated in malignancy-induced hypercalcaemia. Denosumab can be used if malignancy-induced hypercalcaemia does not respond to zoledronic acid.

Salmon calcitonin may need to be given in patients resistant to bisphosphonates. In addition, some resistant cases respond to corticosteroid therapy such as prednisolone 40 mg/day. High-dose steroids are also used as first-line treatment of hypercalcaemia from vitamin D intoxication and granulomatous disorders (e.g. sarcoidosis).

Treatment of primary hyperparathyroidism

For a discussion of the treatment of primary hyperparathyroidism, see Chapter 187.

Hypocalcaemia

Definition of hypocalcaemia

Hypocalcaemia occurs when there are abnormalities in the physiological regulation of PTH, and vitamin D results in calcium levels are lower than the desired normal range. Failure of release of calcium from bone, and increased binding of calcium in the circulation, are other factors causing hypocalcaemia.

Aetiology of hypocalcaemia

The aetiology of hypocalcaemia is given in Box 175.2

Typical symptoms of hypocalcaemia, and less common symptoms

With mild hypocalcaemia, patients are usually asymptomatic. As calcium levels decrease, individuals may develop fatigue; tingling and numbness of toes, fingers, or lips; tetany; carpopedal spasm; cramps; confusion; bone pain; proximal myopathy; or prolonged QT interval on the ECG. Some patients may complain of dry skin, alopecia, or brittle nails. Less common features are cataracts, dental hypoplasia, papilloedema, psychoneuroses, seizures, and subnormal intelligence. Two important signs for diagnosis are Chvostek's sign (twitching of the corner of the mouth with tapping of facial nerve) and Trousseau's sign (carpopedal spasm by inflation of sphygmomanometer cuff above arterial pressure for 3 minutes).

Demographics of hypocalcaemia

Hypocalcaemia is found in all ages, with the differential diagnosis depending on patient age. It is found in males and females equally.

Box 175.2 The aetiology of hypocalcaemia

- hypoparathyroidism, due to
 - autoimmunity
 - surgery
 - infiltration
 - radiation
 - poor development
 - pseudohypoparathyroidism (a receptor defect resulting in high parathyroid hormone and low calcium)
- vitamin D deficiency
- phosphate administration
- tumour lysis syndrome
- hungry bone syndrome
- renal failure
- rhabdomyolysis
- pancreatitis
- drugs (e.g. phenytoin, cisplatin, calcitonin)
- malabsorption syndromes
- respiratory alkalosis (normal total calcium but low ionized calcium)
- hypomagnesaemia (functional hypocalcaemia due to an inhibition of PTH release)
- apparent hypocalcaemia (may be an artefact of low albumin levels)

The incidence will depend on the cause. It is found in around 20% of hospitalized patients.

Natural history and complications of hypocalcaemia

The hallmark of acute hypocalcaemia is neuromuscular irritability. Patients often complain of paraesthesia of the extremities, along with fatigue and anxiety. As calcium levels decrease, painful muscle cramps develop and may progress to tetany and spasms. In extreme cases, bronchial or laryngeal spasms may occur. Patients may also develop cardiovascular complications, including ECG changes such as prolonged QT or T-wave abnormalities, and reversible cardiomyopathy.

Dental abnormalities may be present if hypocalcaemia started in young age. Subcapsular cataracts may develop with chronic disease, as well as psychotic or neurotic disorders.

Patients with pseudohypoparathyroidism (type 1a) display short stature, obesity, short metacarpals, and a round face. This condition is known as Albright's hereditary osteodystrophy.

Approach to diagnosing hypocalcaemia

Symptoms and signs of hypocalcaemia should be elicited from the patient. Questions should be directed towards establishing the possible cause for low calcium levels, and appropriate laboratory tests performed. Patients with acute hypocalcaemia require immediate resuscitation.

Other diagnoses that should be considered aside from hypocalcaemia

In patients with vitamin D deficiency, besides acquired disorders (renal, liver disease, malabsorption, decreased sunlight), inherited disorders such as vitamin D-dependent rickets types I and II and X-linked hypophosphataemic rickets should be considered. Hypoparathyroidism may be part of DiGeorge syndrome, Kearns-Sayre syndrome, Kenny-Caffey syndrome, HDR (hypoparathyroidism, sensory neural deafness, renal dysplasia) syndrome, and autoimmune polyendocrine syndrome type I.

'Gold-standard' diagnostic test for hypocalcaemia

The gold-standard test for hypocalcaemia is a corrected serum calcium level, taken concurrently with a morning serum PTH.

Acceptable diagnostic alternatives to the gold-standard test for hypocalcaemia

Acceptable diagnostic alternatives to the gold-standard test for hypocalcaemia include tests for:

- vitamin D levels
- magnesium levels (abnormal levels are found with prolonged diarrhoea, diuretics, cisplatin, and alcohol abuse)
- phosphate levels (these are high in PTH deficiency, and low in non-parathyroid disease)

- renal and liver function, including tests for albumin (raised serum alkaline phosphatase suggests osteomalacia; renal failure causes vitamin D deficiency)

In addition, consider a coeliac screen.

Other relevant investigations for hypocalcaemia

Other relevant investigations for hypocalcaemia include:

- ECG
- imaging studies (e.g. chest X-ray if infiltrative disorders are suspected)
- thyroid function test, fasting glucose (random if symptomatic); Synacthen test if autoimmune polyglandular syndrome type 1 is suspected
- thyroid function test and gonadal status in pseudohypoparathyroidism (G-protein abnormalities)

Prognosis of hypocalcaemia, and how to estimate it

Severe, symptomatic hypocalcaemia may result in cardiovascular instability with hypotension, arrhythmias, and syncope, and may rarely progress to death. The disease causing the hypocalcaemia influences prognosis and varies accordingly.

Treatment of hypocalcaemia, and its effectiveness

In chronic hypocalcaemia secondary to parathyroid dysfunction, the aim is to raise calcium levels at or just below the normal limit. This may be done initially with large doses of calcium supplements, and if disease is not controlled vitamin D analogues, such as calcitriol or alfacalcidol, should be added. Plasma calcium levels should be checked frequently after each change in dose, and three monthly while on maintenance. In vitamin D deficiency, patients are usually treated with ergocalciferol or cholecalciferol.

Acute asymptomatic hypocalcaemia (<1.9 mmol/l), or symptomatic hypocalcaemia (with tetany or seizures) requiring control over a short time period, should be treated urgently with an infusion of 10 ml of 10% calcium gluconate diluted in 50–100 ml of 5% glucose infusion over about 10 minutes. This should be repeated until symptoms resolve. A maintenance infusion over 24 hours may be required, with careful monitoring of calcium levels and ECG. Concurrent oral calcium should be given, as well as calcitriol if the patient is PTH deficient.

176 Disorders of plasma phosphate

Aron Chakera, William G. Herrington, and Christopher A. O'Callaghan

Definition of the disease

The normal serum level of phosphate is between 0.8 and 1.4 mmol/l.

Aetiology of the disease

Hyperphosphataemia

The commonest cause of sustained hyperphosphataemia is renal impairment, because the kidney normally excretes phosphate (note that phosphate levels normally rise following meals and that there is significant diurnal variation). A considerable phosphate load may also be provided by some medications, in particular, those used for bowel preparation.

Hypophosphataemia

Hypophosphataemia (see Table 176.1) may arise from reduced intake or absorption, increased renal excretion, or intracellular redistribution, particularly in response to carbohydrate loads with refeeding after starvation. Excessive renal phosphate loss can reflect tubular damage or inherited phosphate-wasting nephropathies.

Typical symptoms of the disease, and less common symptoms

As serum levels of calcium and phosphate are reciprocally related, high serum phosphate levels produce the same symptoms as hypocalcaemia. Hypophosphataemia is usually asymptomatic unless severe (serum phosphate <0.3 mmol/l), when it may cause generalized muscle weakness, rhabdomyolysis, and neurological symptoms, including dysaesthesia, confusion, and, eventually, coma.

Demographics of the disease

Hyperphosphataemia is common amongst patients with chronic kidney disease, with phosphate levels generally rising as the glomerular filtration rate falls below 30. Hypophosphataemia is usually encountered in malnourished patients and patients receiving total parenteral nutrition.

Table 176.1 Causes of hypophosphataemia

Reduced phosphate intake/absorption	Alcoholism Malnutrition Chronic diarrhoea Phosphate-binding medications
Renal phosphate loss	Hyperparathyroidism Diuretics X-linked and autosomal dominant hypophosphataemic syndromes Fanconi syndrome
Intracellular phosphate redistribution	Refeeding syndrome Glucose infusions Malignancies Growth hormone excess Adrenergic agents

Natural history, and complications of the disease

Mild derangements in calcium or phosphate are usually asymptomatic and are not associated with any complications. Increased serum phosphate levels and a high calcium–phosphate product are associated with increased cardiovascular mortality and can promote dystrophic calcification (see Figure 176.1).

Approach to diagnosing the disease

As the laboratory tests for calcium and phosphate have high sensitivity and specificity, false-positive or false-negative results are unusual. Therefore, the key issue is to establish the underlying cause of the disorder.

'Gold-standard' diagnostic test

The gold-standard diagnostic test for disorders of plasma phosphate is the ionized serum phosphate level.

Acceptable diagnostic alternatives to the gold standard

There are no acceptable alternatives to the ionized serum phosphate level for diagnosing disorders of plasma phosphate.

Other relevant investigations

Calcium levels should always be measured, given the reciprocal nature of its relationship with phosphate. Ionized calcium levels are usually between 1.1 and 1.3 mmol/l (NB serum albumin levels must

Figure 176.1 Dystrophic calcification involving the left pre-patellar bursa.

always be checked to allow for correction for albumin binding if ionized calcium levels are not measured). As hypomagnesaemia impairs the release of parathyroid hormone, assessment of serum magnesium levels should also be performed. If a renal cause of a phosphate abnormality is suspected, a 24-hour urine collection for calcium, phosphate, magnesium, and other electrolytes is indicated.

Prognosis and how to estimate it

Prognosis is dependent on the underlying condition.

Treatment and its effectiveness

Hyperphosphataemia is managed by dietary phosphate restriction; avoidance of high phosphate foods such as dairy products,

sardines, chocolate, and nuts; prescription of phosphate-binding medications (to be taken with meals); and/or commencement of renal replacement therapy in patients with severe renal impairment.

177 Disorders of plasma magnesium

Aron Chakera, William G. Herrington, and Christopher A. O'Callaghan

Definition

Normal serum magnesium levels are in the range of 0.7–1.0 mmol/l and, as for calcium, most of the total body magnesium is found in bone and soft tissues. Magnesium is essential for normal cell metabolism (as a cofactor for numerous enzymes) and for neuronal function, and regulates parathyroid hormone release. Alterations in serum magnesium levels are usually asymptomatic unless severe.

Aetiology of hypomagnesaemia and hypermagnesaemia

As there are large tissue reserves of magnesium, hypomagnesaemia usually only develops with chronic gastrointestinal or renal losses, or prolonged dietary insufficiency. Hypermagnesaemia is almost always iatrogenic, due to excessive supplementation. The main causes of hypomagnesaemia are listed in Table 177.1.

Typical symptoms of hypomagnesaemia and hypermagnesaemia, and less common symptoms

As magnesium, like calcium, is a divalent cation, the symptoms of magnesium deficiency are similar to those of calcium deficiency. The deficiency is generally characterized by neuromuscular and cardiac excitability, manifesting as cramps, twitching, and palpitations and, in severe cases, confusion and seizures. Vertigo, ataxia, and psychosis are uncommon presenting complaints.

Demographics of hypomagnesaemia and hypermagnesaemia

Hypomagnesaemia is a common finding in hospitalized patients, particular in acute care setting such as the ICU. Diabetic patients are particularly at risk. Hypomagnesaemia in the community is usually secondary to chronic malnutrition. The commonest cause is alcoholism. Hypermagnesaemia is almost always iatrogenic.

Table 177.1 Causes of hypomagnesaemia

Renal magnesium loss	Inherited diseases <ul style="list-style-type: none">● Bartter's syndrome● Gitelman syndrome Medications <ul style="list-style-type: none">● Diuretics● Platinum-containing chemotherapy agents● Calcineurin inhibitors Osmotic diuresis <ul style="list-style-type: none">● Diabetes● Mannitol
Inadequate intake/ increased gut losses	Malnutrition Chronic diarrhoea Inflammatory bowel disease Prolonged nasogastric suction Fistulae Proton-pump inhibitors

Natural history, and complications of hypomagnesaemia and hypermagnesaemia

Severe hypomagnesaemia can be life-threatening. It can cause tetany, convulsions, and cardiac arrhythmias. The prognosis is usually related to the underlying disease. Deficiency states due to excessive renal losses often respond to cessation of the offending medication or adequate replacement and, in these cases, the prognosis is good.

Approach to diagnosing hypomagnesaemia and hypermagnesaemia

The history and examination findings in hypomagnesaemia are non-specific, but the diagnosis should be considered in patients who complain of muscle cramps, particularly where there are risk factors present (see Table 177.1). Where increased renal losses are suspected, urinary magnesium levels should be measured, and inherited forms of tubular dysfunction considered. These are often associated with a history of salt craving. If a positive family history is elicited, genetic testing for some inherited disorders is now available. These include inherited channelopathies such as Gitelman syndrome, which causes sodium, potassium, and magnesium loss in the distal tubule, and Bartter's syndrome, which causes similar losses from the loop of Henle.

Other diagnoses that should be considered aside from hypomagnesaemia and hypermagnesaemia

Depending on the cause of the abnormal magnesium level, other electrolyte abnormalities may also be present and should be excluded.

'Gold-standard' diagnostic test of hypomagnesaemia and hypermagnesaemia

A serum magnesium level is the gold-standard test for hypomagnesaemia and hypermagnesaemia.

Acceptable diagnostic alternatives to the gold standard

There are no acceptable diagnostic alternatives to the gold-standard test for hypomagnesaemia and hypermagnesaemia.

Other relevant investigations for hypomagnesaemia and hypermagnesaemia

As most tests measure total serum magnesium, free and bound (which accounts for ~20%) levels may be falsely low in hypoalbuminaemic states. Therefore, the serum albumin should be measured.

A fractional excretion of magnesium of greater than 3%, with a low serum magnesium and normal kidney function, is diagnostic of renal magnesium wasting. Twenty-four-hour urine collections to calculate

renal magnesium excretion may also be performed. The fractional excretion of magnesium (FEMg²⁺) may be calculated as follows:

$$\text{FEMg}^{2+} = 100 \times \left(\frac{[\text{Mg}]_{\text{urine}} \times [\text{Cr}]_{\text{plasma}}}{[\text{Mg}]_{\text{plasma}} \times [\text{Cr}]_{\text{urine}}} \right).$$

Intracellular assessment of magnesium in red blood cells, mononuclear cells, or skeletal muscle may provide a better measure of total body magnesium levels, as serum levels do not correlate well with intracellular levels. These tests are only routinely performed in research laboratories.

If a patient with symptoms consistent with hypomagnesaemia has a normal serum magnesium, and other diagnoses have been excluded, a magnesium loading test (IV infusion of magnesium, to see if symptoms resolve) can be performed, but false-positive results are common.

Hypocalcaemia and hypokalaemia frequently coexist with hypomagnesaemia, and serum levels should be measured.

An ECG should be performed if there are palpitations or evidence of cardiac arrhythmias. Findings are usually non-specific, but may include widened QRS complex and a prolonged PR interval. It is associated with ventricular arrhythmias, and evaluation of magnesium levels is, therefore, of particular value in patients with cardiac conditions such as heart failure.

Prognosis of hypomagnesaemia and hypermagnesaemia, and how to estimate it

The prognosis of hypomagnesaemia and hypermagnesaemia is generally good, as many causes are reversible on cessation of the offending agent, or respond well to replacement therapy.

Treatment of hypomagnesaemia and hypermagnesaemia, and its effectiveness

Severe depletion generally requires IV replacement with magnesium sulfate. Mild depletion, or chronic renal losses may be managed with oral magnesium preparations (which usually contain 2–4 mmol of magnesium/tablet), but these are often poorly tolerated due to adverse gastrointestinal side effects.

178 Disorders of acid–base balance

Aron Chakera, William G. Herrington, and Christopher A. O’Callaghan

Definition of the disease

A change in the pH of the blood to outside the normal physiological range (pH 7.35–7.45) defines a disorder of acid–base balance. The disorder can be either acidaemia (pH <7.35) or alkalaemia (pH >7.45).

Aetiology of the disease

Normal metabolism results in a net acid production of approximately 1 mmol/kg day⁻¹. Physiological pH is regulated by excretion of this acid load by the kidneys and the lungs (as carbon dioxide). A series of buffers in the body reduces the effects of metabolic acids on body and urine pH. For acid–base disorders to occur, there must be excessive intake, or loss of acid (or base), or, alternatively, an inability to excrete acid. For these changes to result in a substantially abnormal pH, the various buffer systems must be overwhelmed. The pH scale is logarithmic, so relatively small changes in pH signify large differences in hydrogen ion concentration. Causes of acidaemia and alkalaemia are outlined in Tables 178.1 and 178.2, respectively.

Typical symptoms of the disease, and less common symptoms

Most minor perturbations in acid–base balance are asymptomatic, as small changes in acid or base levels are rapidly controlled through consumption of buffers, or through changes in respiratory rate. Alterations in renal acid excretion take some time to occur. Only when these compensatory mechanisms are overwhelmed do symptoms related to changes in pH develop (Table 178.3). Patients may be symptomatic from the underlying cause of the acid–base disturbance earlier.

Demographics of the disease

Acidaemia and alkalaemia are common in hospitalized patients, and typically reflect the severity of the underlying disease process. Over 50% of patients in critical care areas may have pH levels outside the normal range. Patients with renal or respiratory disease are

Table 178.2 Causes of alkalaemia

Cause	Mechanism	Examples
Acid loss	Gastrointestinal	Vomiting Prolonged nasogastric suctioning Villous adenomas
	Renal	Medications (e.g. diuretics) Channelopathies (e.g. Gitelman syndrome) Hyperaldosteronism Cushing’s syndrome
	Respiratory	Hyperventilation
Alkali gain	Excessive intake	IV bicarbonate solutions Medications (e.g. antacids)

particularly at risk, because of the key roles played by the renal and respiratory systems in excreting excess acid.

Natural history, and complications of the disease

The natural history of acid–base disturbances primarily depends on the underlying cause. When the cause is reversible, for example, acidosis due to acute renal failure from obstruction, the prognosis is good. The presence of underlying chronic renal or respiratory disease is associated with a worse prognosis.

Alkalaemia with a pH >7.55 is associated with a high risk of mortality. As a general rule, alkalaemia is tolerated less well than acidaemia. Alkalaemia causes hypocalcaemia by increasing the affinity of calcium for proteins, and hypokalaemia by driving intracellular potassium redistribution. It also results in vasoconstriction, which in combination with hypoventilation (to retain carbon dioxide) leads to hypoxaemia and promotes tissue ischaemia and organ dysfunction. The consequence is neuromuscular irritability, cardiac arrhythmias, seizures, and, eventually, coma and death.

Acidaemia with pH levels less than 7.2 also increases the risk of cardiac arrhythmias and has negative inotropic effects, impairing cardiac output. Chronic acidaemia results in bone buffering of excess acid, which can lead to significant bone loss and fractures.

Approach to diagnosing the disease

A history should be taken to determine the presence of any pre-existing diseases, particularly renal, respiratory, or gastrointestinal disorders that may explain impaired acid–base balance. The possibility of toxin ingestion should be considered, and a list of all current

Table 178.1 Causes of acidaemia

Cause	Mechanism	Examples

Tetany	Confusion
Palpitations (from cardiac arrhythmias)	Palpitations
Seizures	
Renal stones (chronic)	

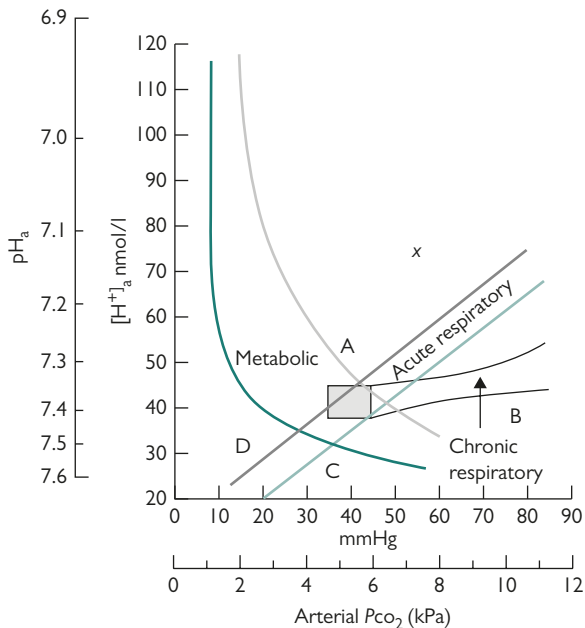

Figure 178.1 A practical acid–base diagram. The band marked ‘acute respiratory’ is the 95% confidence range of values obtained in normal individuals voluntarily hyperventilating or breathing air or carbon dioxide mixtures for short periods. After a few days of carbon dioxide retention, an increase in plasma bicarbonate produces substantial or complete compensation for the respiratory acidosis; the band in chronic respiratory acidosis is, therefore, different from that for the acute response, as the presence of the extra bicarbonate means that the arterial pH (pH_a) decreases to a lesser extent than would be expected for a given rise in the partial pressure of carbon dioxide in arterial blood (Arterial P_{CO_2}).

medications and over-the-counter preparations reviewed. If the patient is clinically stable a family history should be taken to determine whether inherited renal (or other) diseases may be contributing to the impaired homeostasis.

Initial clinical assessment should focus on ‘ABCs’ and the identification of any imminent life threats (e.g. an impaired conscious state, cardiac arrhythmias, or evidence of ischaemic tissue (e.g. raised lactate)) before a complete examination is performed. Hyperventilation with a low carbon dioxide level is the normal response to severe acidaemia; therefore, a normal respiratory rate (or normal carbon dioxide level) suggests imminent respiratory collapse. An arterial blood gas should be performed early on, to identify whether there is a primary respiratory or metabolic disorder (based on the carbon dioxide and bicarbonate levels; see Figure 178.1), to provide an estimate of the base excess or base deficit, and to allow calculation of the anion gap. In the presence of acidosis, a high carbon dioxide level suggests a respiratory acidosis, whereas a low carbon dioxide level suggests a metabolic acidosis with respiratory compensation. Conversely, in the presence of alkalosis, a low carbon dioxide level suggests a respiratory alkalosis, whereas a high carbon dioxide level suggests a metabolic alkalosis with respiratory compensation.

If a chloride level is available, the anion gap can be calculated by using the following equation:

$$\text{anion gap} = (\text{K}^+ + \text{Na}^+) - (\text{Cl}^- + \text{HCO}_3^-).$$

The normal range of the anion gap is 12–20 mmol/l. An elevated anion gap should prompt review of the plasma lactate (lactate is

produced by anaerobic metabolism (e.g. in ischaemic tissue)), assessment for ketones (particularly in diabetics), and increase suspicion of poisoning with alcohols, including methanol and ethylene glycol or salicylates.

Further workup should be guided by results from the blood gases and initial blood tests and will usually include a chest radiograph to assess for respiratory disease. Abdominal imaging should be performed if there is evidence of renal dysfunction, or suspicion of intra-abdominal pathology.

Excess aldosterone can cause a metabolic alkalosis by promoting renal acid excretion. Therefore, plasma renin and aldosterone levels should be measured if derangements in adrenal hormones are suspected with alkalaemia. Adrenal imaging may then be indicated.

Other diagnoses that should be considered

Unexplained metabolic alkalosis, particularly if associated with hypokalaemia and hypomagnesaemia, may reflect diuretic abuse. A urine screen for diuretics can be performed.

‘Gold-standard’ diagnostic test

Arterial blood gas assessment is the gold-standard test for diagnosing abnormalities of acid–base balance.

Acceptable diagnostic alternatives to the gold standard

A venous blood gas can provide useful information if there is likely to be a delay, or difficulty in obtaining an arterial sample.

Other relevant investigations

If a renal cause of acidosis is suspected, a urinary pH is helpful, as a failure to appropriately acidify the urine is the presence of acidaemia suggests renal tubular acidosis.

Ethylene glycol poisoning causes oxalate crystal formation in the urine, which may be visible on microscopy.

Prognosis and how to estimate it

Alkalaemia is a poor prognostic sign, with mortality approaching 100% when pH levels are >7.6 . Acidaemia with a pH <7.2 is also associated with significantly increased mortality, and consideration should be given to escalation of care to a high-dependency or intensive care unit. Regular assessment of pH in response to treatment provides the best marker for estimating prognosis.

Treatment and its effectiveness

The treatment of severe acidosis depends on whether it is primarily respiratory or metabolic in aetiology. Where an underlying cause is identified, specific measures should be employed where available (e.g. fomepizole, for ethylene glycol or methanol poisoning; antibiotics, for sepsis; surgery, for ischaemic bowel). Metabolic acidosis may be also be corrected by IV infusion of base (usually bicarbonate) but, in the presence of multi-organ dysfunction and/or cardiac disease, current evidence suggests it should be used with caution. A significant problem that arises with IV bicarbonate therapy is the sodium and water administration that this entails. The concomitant volume expansion increases the risk of pulmonary oedema. Other concerns include the possibility of worsening intracellular acidosis through the generation of carbon dioxide, and lowering calcium and potassium levels, which could increase cardiac arrhythmias. Haemodialysis or filtration can rapidly correct bicarbonate deficiency.

Treatment of alkalaemia involves correction of chloride deficits if present (renal bicarbonate reabsorption requires adequate chloride levels) and treatment of the underlying cause. Excess mineralocorticoid or renal tubular diseases associated with salt wasting are characterized by hypokalaemia and may respond well to potassium-sparing diuretics. In severe cases, IV infusions of acidic compounds (sodium chloride, hydrogen chloride, or potassium chloride) may be given. Specialist advice should be obtained.

179 Porphyrria

Patrick Deegan

Definition of the disease

This section discusses six diseases caused by inborn errors of metabolism affecting the biosynthesis of haem. Haem is a tetracyclic metal-binding compound involved in oxygen transport (in haemoglobin and myoglobin) and redox reactions (e.g. in the cytochrome P450 system). A few very rare forms are not discussed.

Aetiology of the disease

Each of these conditions is caused by a single gene defect in one of the enzymes involved in the biosynthesis of haem. Inheritance is usually autosomal dominant with incomplete penetrance. The enzyme defect results in disease, not as a result of deficiency of the reaction product, but as a result of accumulation of precursors. Early, soluble precursors, 5-aminolaevulinic acid, and porphobilinogen (not porphyrins as such) are neurotoxic and, when present in great excess, as occurs when flux through the haem synthetic pathway is increased in response to particular medications or hormones, lead to acute neurovisceral crises. Later cyclical precursors (porphyrins) in the pathway are also water soluble and excreted in urine, but are susceptible to activation by electromagnetic radiation in the visible spectrum and are converted to free-radical metabolites that cause pain, inflammation, and tissue damage in the skin. The final haem precursors (also porphyrins) are hydrophobic and excreted in the bile and faeces and are also activated by light to toxic metabolites.

Typical symptoms of the disease, and less common symptoms

There are three main clusters of clinical features:

- neurovisceral crises (acute attacks)
- blistering photosensitive skin rashes with scarring
- photosensitive skin pain

The acute attack presents as severe abdominal pain with constipation; altered mentation and behaviour, including psychosis; autonomic instability with fluctuating heart rate and blood pressure; and peripheral neuropathy, including ascending paralysis and respiratory failure. The urine is typically a dark reddish colour and darkens further on exposure to light. The first attack may be fatal. Acute intermittent porphyria is associated with acute attacks alone. Variegated porphyria and hereditary coproporphyria are associated with both acute attacks and blistering skin rashes. Porphyrria cutanea tarda is associated with blistering on sun-exposed areas, but without acute attacks: this condition is more usually sporadic than inherited and the sporadic form is associated with iron overload and chronic liver injury. Congenital erythropoietic porphyria is inherited in an autosomal recessive manner; the condition gives rise to haemolytic anaemia and severe photosensitivity, resulting in facial disfigurement. Erythropoietic protoporphyria is associated with intense pain, sometimes erythema, on light-exposed skin, but without blistering. In a small proportion of patients with erythropoietic protoporphyria, a syndrome of haemolysis and progressive cholestatic liver disease may occur.

Demographics of the disease

Porphyria acute attacks affect women more than men and often have their onset around puberty. Each condition is rare; the prevalence of heterozygosity for mutations causing acute intermittent

porphyria, the most frequent porphyria, is around 1 in 10 000, but only around one-tenth of these individuals will develop acute attacks. Porphyrria cutanea tarda is more common in middle-aged men. The skin manifestations of congenital erythropoietic porphyria and erythropoietic protoporphyria present in childhood, while the other cutaneous porphyrias may present later. Variegated porphyria is more common in South Africa, as a result of a founder mutation. Acute intermittent porphyria is more common amongst the inhabitants of Northern Sweden.

Natural history, and complications of the disease

As mentioned, only about 10% of individuals heterozygous for acute intermittent porphyria or variegated porphyria develop acute attacks. The remaining 90% are regarded as having 'latent' porphyria and are at risk of development of acute attacks, especially when exposed to certain 'unsafe' medications that upregulate the flux through the haem biosynthetic pathway. Acute attacks may also be precipitated in the few days before the menstrual period. Acute attacks, especially if left untreated, may lead to neuropathy and ascending paralysis with respiratory failure, requiring ventilation and prolonged intensive care support. Death or long-term disability may result from neurologic injury. In the course of an acute attack, the patient may develop a marked hyponatraemia associated with inappropriate antidiuretic hormone secretion: convulsions, cerebral oedema, and death may result. In the case of the cutaneous porphyrias, scarring and extensive photodamage occur on sun-exposed skin. This is particularly evident and disfiguring in congenital erythropoietic porphyria. Patients with erythropoietic protoporphyria complain of sun-induced pain from an early age and avoid light. A small proportion (around 5%) of patients with erythropoietic protoporphyria develop a self-perpetuating syndrome of haemolysis, increasing photosensitivity, and cholestatic liver failure.

Approach to diagnosing the disease

It is critical to make an early diagnosis of an acute porphyric attack. The key to the diagnosis is awareness. A careful family history will often provide the essential clue. Anaesthetists, surgeons, and intensivists should be aware of the association of acute attacks with anaesthetic drugs, particularly barbiturates used in induction. Acute porphyria should be on every physician's list of the medical causes of abdominal pain and on the list of causes of dark or red urine. Blistering porphyrias will be referred to a specialist. Skin pain without signs should not be ignored.

Other diagnoses that should be considered

Other causes of non-surgical abdominal pain include diabetic ketoacidosis, heavy metal poisoning, herpes zoster, sickle cell crises, and familial Mediterranean fever. Neuropathy with ascending paralysis and autonomic instability also suggests Guillain-Barré syndrome. Organic causes of psychosis clearly include the effects of alcohol and drugs.

'Gold-standard' diagnostic test

The definitive diagnosis of porphyria should take place in a specialist laboratory. Samples of urine, blood, and faeces, protected from light and sent to a specialist laboratory, will reveal patterns of excess porphyrins and their precursors and will thus allow the specific defect

to be pinpointed in most cases. Difficulty sometimes arises in cases of suspected latent acute intermittent porphyria, where the pattern of metabolite excretion can be normal. Activity of hydroxymethylbilane synthase, the enzyme defective in acute intermittent porphyria, will be reduced by approximately 50% in heterozygotes, but this difference is often not sufficiently robust for diagnosis. For each porphyria, where facilities allow, sequencing of the relevant gene will allow confirmation of a biochemical diagnosis.

Acceptable diagnostic alternatives to the gold standard

In the acute situation, where the clinical question is whether the current signs and symptoms might be due to an acute attack of porphyria, a widely available urine porphobilinogen screening test is very helpful. Most hospital clinical chemistry departments should be able to offer this test and interpret the results. Some patients with acute intermittent porphyria will have a positive porphobilinogen screening test result between attacks, but no patient with a genuine acute attack should have a negative result.

Other relevant investigations

Serum sodium should be estimated at least daily in patients in an acute attack. Patients with erythropoietic protoporphyria should have 6-monthly blood tests looking for evidence of haemolysis and cholestasis. Serum liver-related blood tests are required in the monitoring of patients with porphyria cutanea tarda and erythropoietic protoporphyria. As porphyria cutanea tarda is associated with hepatitis C and HIV, the physician should inquire into these possibilities. Patients with acute intermittent porphyria, variegate porphyria, and hereditary coproporphyria may have an increased risk of hepatoma, and some experts recommend 6-monthly to annual liver ultrasound examinations. Renal impairment may develop in patients with acute intermittent porphyria.

Prognosis and how to estimate it

In women, acute attacks often remit after the menopause. Neuropathy can recover with careful medical support. It is difficult to predict which patients with erythropoietic protoporphyria will develop liver failure, but attention should be paid to coexisting risk factors for liver disease, including alcohol intake, gallstone disease, and hepatic steatosis. Increasing photosensitivity is an early warning symptom.

Treatment and its effectiveness

For patients at risk of acute attacks, patient and physician awareness of provoking factors is essential. Patient support groups and specialist websites are useful sources of information. Medic-alert bracelets and similar patient-held information can be helpful in the acute setting. Lists of safe and unsafe medication are available on websites and national formularies. Prevention of acute attacks can often be achieved through hormonal manipulation (gonadotropin-releasing hormone analogues to suspend the menstrual cycle), avoidance of fasting, and institution of high carbohydrate intake during periods of intercurrent illness. An acute neurovisceral attack presents several difficulties in management. The patient is often very distressed, agitated, and behaviourally disturbed. Great care is required in all aspects of prescribing, but morphine is a safe analgesic, and prochlorperazine is a safe anti-emetic. Careful fluid balance is required to avoid hyponatraemia; avoid 5% glucose solutions if possible. IV haem arginate is indicated for the acute treatment of moderate, severe, or unremitting acute attacks, and is usually effective in arresting the acute aspects of the attack, although established neuropathy may take months to resolve.

The dermatologic features of porphyria are managed by avoidance of light in the visible spectrum, through the use of clothing and pigmented barrier creams. Porphyria cutanea tarda often responds very well to venesection to control the modest degree of iron overload. The dermatological aspects of erythropoietic protoporphyria are sometimes helped by oral therapy with betacarotene or acetylcysteine. Many patients gain benefit from the use of narrow-band UVB exposure to induce skin pigmentation.

Established liver failure in a number of patients with erythropoietic protoporphyria has been rescued by liver transplantation, but disease can recur in the graft.

Genetic counselling and family-based case finding is recommended, to allow preventative measures to be taken in individuals with latent porphyria.

180 Aminoacidopathies, urea cycle disorders, and organic acidurias

Robin Lachmann and Elaine Murphy

Definition of the diseases

Aminoacidopathies, urea cycle disorders, and organic acidurias, are rare disorders resulting from disturbed protein or intermediary metabolism. Deficiency of an enzyme leads to accumulation of its substrate and deficiency of its product, both of which can contribute to pathogenesis.

Aetiology of the diseases

Aminoacidopathies are caused by deficiencies in enzymes involved in amino acid metabolism and are often characterized by the accumulation of a toxic amino acid. The two diseases most likely to be encountered in adult medicine are phenylketonuria (PKU), which is caused by a deficiency of phenylalanine hydroxylase, and maple syrup urine disease (MSUD), which is due to a branched-chain amino acid decarboxylase deficiency. High levels of phenylalanine progressively damage the developing brain, leading to severe learning difficulties. The high levels of leucine which accumulate in MSUD produce an acute encephalopathy which, if not treated, can be rapidly fatal.

The urea cycle is necessary for the detoxification of ammonia and the elimination of excess nitrogen. Patients in whom the cycle is impaired are at risk of hyperammonaemia, which leads to an acute encephalopathy and cerebral oedema. The commonest urea cycle disorder (UCD), ornithine transcarbamylase (OTC) deficiency, is X-linked and is the only condition discussed here which is not inherited in an autosomal recessive manner.

Organic acidurias are a complex group of disorders involving the metabolism of protein and fat into products which can be used in the general metabolism of the cell. Most present early in life with acute acidosis and encephalopathy, due to the accumulation of toxic metabolites.

For these disorders of protein breakdown, acute decompensations are triggered when the metabolic flux through the affected pathway cannot be supported by the residual enzyme activity. Decompensation can be triggered by a dietary protein load, with the most severe cases presenting in the neonatal period. In older children and adults, a catabolic state (such as intercurrent infection or fasting) with breakdown of endogenous protein for gluconeogenesis, frequently precipitates the acute presentation.

Typical symptoms of the diseases, and less common symptoms

Acute presentations of these disorders generally involve encephalopathy with confusion and an altered level of consciousness. Cerebral oedema then leads to seizures, coma, and death. In adults, hyperammonaemia can present subacutely with personality change, abnormal behaviour, and psychiatric symptoms.

Long-term complications of these disorders may include learning difficulties and behavioural problems. Patients with organic acidurias are particularly prone to basal ganglia damage. Specific features of other diseases include spastic paraparesis (arginase deficiency, a UCD) and certain forms of methylmalonic acidemia (MMA, an organic aciduria), chronic renal failure (MMA), and eczema (PKU).

Demographics of the diseases

Aminoacidopathies are all rare. PKU has a carrier frequency of 1 in 50 and an incidence of about 1 in 10 000 births in Northern Europe: the other conditions are all less common than this.

Although the classical, severe forms of disease will present in the first few months of life, there are more attenuated forms which can present later in life.

Natural history, and complications of the diseases

The natural history of aminoacidopathies depends on the severity of the metabolic defect. In untreated patients with PKU, the degree of brain damage relates directly to the phenylalanine level. Patients with classical MSUD require continuous dietary therapy to prevent frequent decompensation but people with the milder, intermittent form maintain a normal amino acid profile except under conditions of metabolic stress.

Although mild mutations in the OTC gene can present for the first time in adult men, OTC deficiency in most hemizygous males is untreatable and they die in the neonatal period. Heterozygous female relatives can, however, have extremely variable clinical involvement, ranging from presentation in infancy with hyperammonaemia to adults who only have a slight aversion to high-protein foods. This range of presentation in females is thought to relate to skewed X-inactivation.

Late presentations of organic acidurias are not well recognized, possibly because adults presenting with reduced level of consciousness rarely have a full range of metabolic investigations performed.

Metabolic decompensations at any time in life can result in permanent brain damage. An adult with MSUD, a UCD, or organic aciduria may only have had one or two episodes of encephalopathy in early childhood, but can be left with significant learning difficulties and other features such as epilepsy or a movement disorder.

Approach to diagnosing the disease

There can be raised levels of the substrate of the affected enzyme, decreased levels of its product, or the presence of metabolites which cannot normally be detected at all. While, with modern analytical techniques, most metabolites can be detected in plasma, many substances are concentrated in the urine and are more easily detected there. Detection of a single metabolite can be pathognomic, but more often it is the pattern of metabolites which is important.

Hypoglycaemia or metabolic acidosis should raise the possibility of an inherited metabolic disease (IMD) and trigger the search for abnormal metabolites. Urine should be tested for ketones; the presence of non-ketotic hypoglycaemia implies a problem with intermediary metabolism. Measure plasma lactate and ammonia in the acute stage. A large anion gap implies the presence of an undetected acid which is most likely due to poisoning or metabolic mayhem.

Definitive diagnosis is complicated by the fact that abnormal metabolites may only be detectable during an acute decompensation and by the delay which can occur in obtaining the results of specialist tests. Where the patient presents in crisis, the approach must be to

think of metabolic disease, to obtain as much information as possible acutely, and to save plasma and urine for further, directed analysis over the following days and weeks.

Other diagnoses that should be considered

Most physicians will never come across a patient with IMD presenting for the first time. However, improved treatment of these individuals in childhood means that they are now surviving into adulthood and it is increasingly likely that acute metabolic decompensations in patients with known metabolic disease will be seen in the general medical setting. An encephalopathic patient cannot always tell you about a preexisting condition, so it is always important to consider these rare diseases as well as commoner causes such as infection or cerebrovascular events.

'Gold-standard' diagnostic test

Direct demonstration of the enzyme deficiency is not always possible, as the enzymes in question are not always expressed in easily accessible cells such as leukocytes or fibroblasts (e.g. some urea cycle enzymes are only expressed in the liver). It may therefore be sufficient to demonstrate pathological mutations in the relevant gene.

Acceptable diagnostic alternatives to the gold standard

Diagnosis is often based on specialist interpretation of a characteristic pattern of abnormal metabolites in blood and/or urine.

Other relevant investigations

Other relevant investigations are guided by the clinical situation.

Prognosis and how to estimate it

Prognosis is largely determined by whether a patient survives their initial metabolic decompensation. For this to happen, the correct diagnosis has to be made and appropriate treatment initiated in a timely manner. Steps can then be taken to avoid future decompensations and prompt treatment given if they do occur.

Nonetheless, there are still cases where the metabolic block is so severe that current treatment is not effective and children die. For those who survive childhood, the risk of decompensation tends to reduce as they get older and, providing they are compliant with their treatment, their prognosis in adulthood relates to any chronic complications, often more than the risk of acute deterioration.

The danger for those who do have metabolic decompensations in adulthood, either as an initial presentation or where the diagnosis is already made, is that the cause of the acute illness will not be recognized and appropriate treatment not given.

Treatment and its effectiveness

The principles underlying the treatment of these disorders are similar. For detailed protocols see the British Inherited Metabolic Disease Group website (<http://www.bimdg.org.uk>).

In acute decompensation, first stop catabolism by giving large amounts of carbohydrate as a source of calories. Each patient should have a specific emergency regimen. At home, this includes glucose polymer drinks: in hospital, glucose is given as an IV infusion, usually 10% dextrose running at 2 ml/kg hr⁻¹.

Second, stop protein intake, to minimize the need for protein metabolism. If, however, patients do not recover quickly and require inpatient treatment for more than a few days, a lack of dietary protein will itself trigger endogenous protein breakdown. In MSUD, this is overcome by using a synthetic amino acid supplement free of the branched-chain amino acids, which cannot be catabolized, but, in the UCDs, for example, where the block affects general protein catabolism, specialist metabolic dietetic advice should be sought regarding the gradual reintroduction of dietary protein.

Third, remove toxic metabolites. Continuous haemodiafiltration will effectively remove ammonia, leucine, and other small molecules from the circulation, and has a role in UCDs, MSUD, and organic acidurias. Specific treatments may also be available. In MSUD, use of a synthetic amino acid supplement can reduce plasma leucine levels by stimulating its incorporation into newly synthesized proteins. In hyperammonaemia, arginine is given to stimulate protein synthesis, and the alternative pathway ammonia scavengers sodium benzoate and sodium phenylbutyrate can be given. Carnitine may be used in some organic acidurias.

With appropriate and aggressive treatment, it should be possible to terminate an acute decompensation, but patients can still suffer long-term neurological consequences due to cerebral oedema or metabolic stroke.

Long-term treatment relies on the same principles. In PKU and MSUD, a low-protein diet is combined with an amino acid supplement containing all the vitamins and minerals which are missing from the restricted diet. In UCDs, a low-protein diet is combined with essential amino acid supplements and oral ammonia scavenger treatment to optimize nutrition and prevent hyperammonaemia. Treatment for organic acidurias is specific to the condition but may include a low-protein diet, vitamin B₁₂ (in the case of MMA), carnitine, and general vitamin and mineral supplementation.

181 Amyloidosis

Sajjan Mittal

Introduction

Amyloidosis is a systemic disease caused by extracellular deposition of insoluble abnormal fibrils that injure tissues and organs. The fibrils are formed by the aggregation of misfolded, normally soluble proteins.

Systemic amyloid light-chain (AL) amyloidosis (primary) is the commonest type of amyloidosis in the developed world, accounting for 80% of cases. The remainder are due to AA amyloidosis (secondary or reactive), familial amyloidosis, or other rare types of amyloidosis.

Classification of amyloidosis

Amyloidosis is broadly classified in five subgroups which are further described in Table 181.1.

Systemic AL amyloidosis

Aetiology

Systemic AL amyloidosis is associated with a clonal plasma cell dyscrasia, and results from extracellular deposition of monoclonal light chain fragments in an abnormal insoluble fibrillar form. In some cases, this may be associated with myeloma or other B-cell malignancies. However, no definite predisposing factor is known.

Epidemiology

AL amyloidosis occurs in about 1 in 1300 people, and the frequency increases with age. Most patients with AL amyloidosis are aged over 45 years, but it occasionally occurs in young adults. The median age of presentation is 64 years, with a male:female ratio of 2:1.

Clinical features

The most common clinical features at diagnosis are nephrotic syndrome with or without renal impairment, heart failure (typically with predominant right heart failure), sensorimotor and/or autonomic peripheral neuropathy, and hepatosplenomegaly. Carpal tunnel syndrome is seen in approximately one-fifth of patients. Macroglossia is found in 5%–10% of cases but is almost pathognomonic of AL amyloidosis. Purpura, particularly in the periorbital (raccoon eyes) and facial areas, is noted in about one-sixth of patients. Gross bleeding is reported in approximately 3% of cases, as a result of acquired deficiency of Factor X and sometimes also Factor IX or with increased fibrinolysis. Bone pain is a major symptom in only 5% and usually is related to lytic lesions or fractures associated with myeloma. AL

amyloidosis can affect most organs except the CNS. Fatigue and weight loss are very common symptoms.

Natural history, and complications of the disease

AL amyloidosis is a progressive disorder which, without treatment, is usually fatal within 5 years. Most of patients die of heart or renal failure.

Diagnostic investigations

Initial investigation should confirm the diagnosis of amyloidosis on tissue biopsy, and this should be followed by investigations to establish the type of amyloid present and the extent of organ involvement. Amyloid deposits stain with Congo red and produce pathognomonic apple-green birefringence under cross-polarized light microscopy, irrespective of type of amyloidosis (Figure 181.1). This is a gold-standard diagnostic test.

Biopsy of an affected organ is usually diagnostic but less invasive alternatives are possible. Screening biopsy of abdominal fat or rectum is diagnostic in 50%–80% of cases. Immunohistochemical staining of tissue sections with a panel of antibodies is used to differentiate AL amyloidosis from AA amyloidosis. DNA analysis is required to exclude hereditary forms.

Serum amyloid protein P (SAP) scintigraphy is a nuclear medicine imaging technique in which radiolabelled protein is injected intravenously to assess the presence and distribution of amyloid deposits. Patients are referred to National Amyloidosis Centre in London for this investigation.

Other investigations to evaluate organ involvement include measurement of plasma brain natriuretic peptide (to detect cardiac involvement), echocardiography (cardiac amyloidosis typically results in a restrictive cardiomyopathy), measurement of 24-hour urine protein excretion, liver function tests, and nerve conduction studies.

Other relevant investigations

Other relevant investigations include full blood count, urea and electrolytes, creatinine, calcium, immunoglobulin electrophoresis, and quantitative serum free light chain assay. Bone marrow aspirate and trephine biopsy, and skeletal survey, are routinely done in amyloidosis patients to confirm or exclude underlying plasma cell dyscrasia.

A coagulation screen is helpful in excluding associated acquired coagulopathy.

Monitoring

Measurement of serum free light chains and immunoglobulins, SAP scintigraphy, and specific functional tests of involved organs are used to assess the response to treatment.

Prognosis

Without treatment, AL amyloidosis has always a progressive course with rapid development of heart or renal failure. Treatment of heart and renal failure is usually ineffective, with median survival of 18–20 months. Outcomes for symptomatic cardiac AL patients remain relatively poor (median overall survival, 10 months).

Treatment and its effectiveness

Treatment of AL amyloidosis is directed at the underlying bone marrow disorder. In principle, chemotherapy in patients with AL amyloidosis is the same as in those with myeloma. The aim of chemotherapy is to decrease the number of abnormal plasma cells, as this will proportionately reduce the production of amyloid-forming protein (light chain protein). As a result, new amyloid formation will decrease and

Table 181.1 Classification of amyloidosis

Amyloid type	Classification	Amyloidogenic protein involved
Amyloid light-chain amyloidosis	Primary, including myeloma	Kappa or lambda light chains
AA amyloidosis	Secondary	Protein A
Familial amyloidosis	Familial amyloid polyneuropathy Cardiopathic	Mutant transthyretin
Senile systemic amyloidosis	Senile cardiac	Normal transthyretin
Dialysis amyloidosis	Dialysis arthropathy	Beta-2 microglobulin

Figure 181.1 Amyloid deposition (amorphous material; boxed area) in a lymph node in amyloid light-chain amyloidosis. Please see colour plate section.

existing amyloid deposits may gradually regress as well. However, regression of amyloid is slow, and often takes 6–12 months after chemotherapy is completed. A consultant haematologist supervises the treatment of patients with AL amyloidosis. Effective and high-quality care requires a multi-speciality and multidisciplinary team familiar with the range of clinical problems likely to be encountered.

CTD (a combination of cyclophosphamide, thalidomide, and dexamethasone), VCD (bortezomib, cyclophosphamide, and dexamethasone) or VTD (bortezomib, thalidomide, and dexamethasone) are the standard first line treatment options with an estimated 3-year survival of 100% in the responders. However, low-dose treatment, such as a combination of melphalan and prednisolone, is used in elderly patients. Upfront autologous transplant is possible in AL amyloidosis. About two-thirds of patients benefit substantially from this type of treatment. However, given a high rate of treatment-related mortality, autologous transplant is not very popular in the UK. Lenalidomide, pomalidomide, carfilzomib and daratumumab are the newer treatment options.

Localized AL amyloidosis

AL amyloidosis can occur in a localized form that is most often identified in the upper respiratory, urogenital, and gastrointestinal tracts, in the skin, and in the orbits. In such circumstances, the amyloidogenic light chains are produced by a subtle focal infiltrate of clonal plasma cells in proximity to the amyloid deposits. This type of amyloid is frequently nodular in character. Local AL amyloid rarely progresses into a true systemic disease. Systemic chemotherapy is not indicated in localized AL amyloidosis. Local radiotherapy or surgical excision is the treatment of choice.

AA amyloidosis

Reactive systemic AA (secondary) amyloidosis is seen in a small proportion of patients with chronic inflammatory diseases (<5%). AA amyloid fibrils are derived from circulating acute phase reactant (serum amyloid A protein (SAA)). Common associated conditions in the developed world are rheumatoid arthritis and Crohn's disease. Familial Mediterranean fever and chronic infections are the other important causes of AA amyloidosis. Most patients present with nephropathy (proteinuria), although liver and gastrointestinal involvement may occur at a late stage. Clinical cardiac and nerve involvement are extremely rare.

Once the process of AA amyloid deposition has started, excessive amounts of SAA continue to be produced and deposited as amyloid in the organs, as long as the underlying inflammatory disease remains active. The aim of treatment in AA amyloidosis is to control the underlying inflammatory disease and thereby reduce the amount of SAA in the blood. Some underlying inflammatory diseases have very specific and highly effective treatments, for example colchicine in patients with familial Mediterranean fever.

Familial amyloidosis

Hereditary amyloidosis is less common than AL or AA amyloidosis. It is due to the inheritance of an abnormal gene which leads to life-long production of a potentially amyloid-forming protein. Most familial forms of amyloidosis do not cause any symptoms until middle age or later. They are all inherited in an autosomal dominant fashion.

Familial amyloid polyneuropathy (FAP) is the most common type of hereditary amyloidosis in the world. It is characterized by deposition of amyloid in nerves, causing limb weakness, loss of sensation, nerve pain, bowel, bladder, and blood pressure disturbances, and sexual dysfunction. FAP is common in some parts of Portugal, Sweden, and Japan, but occurs throughout the world in very small numbers.

Liver transplantation as a treatment for hereditary amyloidosis has been used most extensively so far in patients with FAP as, in these patients, the abnormal amyloid-forming protein, mutant transthyretin, is made almost exclusively in the liver. Replacement of the liver by a liver that makes normal transthyretin protein is aimed at preventing the formation of further amyloid and can stabilize the disease. Combined liver and heart transplant has been successfully performed in a small number of cases with cardiopathic subtype of familial amyloidosis.

Senile cardiac amyloidosis

This condition occurs as a result of transthyretin deposition in heart in old age, resulting in heart failure. This syndrome is extremely rare before 65 years of age. There is no specific treatment but the patients can survive for many years with reasonable quality of life on diuretics.

Dialysis amyloidosis

Dialysis amyloidosis occurs due to accumulation of beta-2 microglobulin in renal failure, and this condition predominantly affects articular and periarticular structures in patients who have end-stage renal failure and who have been on dialysis for at least 7–10 years. Arthralgia may respond to NSAIDs or corticosteroids. However, there is no definite treatment.

PART 7

Diabetes mellitus and endocrine disorders

182 Normal function of the endocrine system

John Newell-Price, Alia Munir, and Miguel Debono

Definition

Endocrinology is the study of hormones (and their glands of origin), their receptors, the intracellular signalling pathways they invoke, and their associated diseases. The clinical specialty of endocrinology focuses specifically on the endocrine organs, that is, the organs whose primary function is hormone secretion, including the hypothalamus, the pituitary, the thyroid, the parathyroid, the adrenal glands, the pancreas, and reproductive organs. An endocrinologist specializes in the diagnosis and management of hormonal conditions.

Hormones

Introduction

Hormones (from the Greek word *harmon*, meaning 'excite') are chemical messengers that are released from cells into the bloodstream to exert their action on target cells. Blood-borne hormones acting at distant sites are 'endocrine' and hormones acting on adjacent cells are 'paracrine', while hormones which feed back on the cell which releases them are 'autocrine'. An 'intracrine' signal is generated by a chemical acting within the same cell. Hormones are crucial mediators of body homeostasis.

Hormone classes

There are five main classes of hormones. These are categorized into the following groups according to structural and/or functional similarities: amine hormones; peptide hormones; cholesterol derivatives and steroids; thyroid hormones; and eicosanoids.

Amine hormones

Amine hormones are hormones that are derived from the modification of amino acids. There are three main amine hormones, which also act as neurotransmitters: **adrenaline**, **noradrenaline**, and **dopamine**. These are phenylalanine derivatives (via the conversion of phenylalanine to tyrosine) and are all secreted by the adrenal medulla; they are also known as **catecholamines**. The synthesis of catecholamines is rate limited by the conversion of tyrosine to dihydroxyphenylalanine by tyrosine hydroxylase. Subsequently, dopamine, then noradrenaline, and then adrenaline are synthesized. Methylation of adrenaline from noradrenaline is mediated by phenylethanolamine-N-methyltransferase. This reaction is cortisol dependent. Amine hormones are then stored in the adrenal medulla and are secreted in response to either nerve or humoral stimuli. Release is episodic, and catecholamines have a short half-life. They bind to alpha and beta adrenoceptors, while dopamine binds to D1 and D2 receptors to exert their physiological effects. Noradrenaline and adrenaline are broken down via catechol-O-methyl transferase into **normetanephrine** and **metanephrine**, respectively. These products are further degraded to **vanillylmandelic acid**. Catecholamines and nor-/metanephrines may be found both in plasma and in urine.

Melatonin is another amine hormone; unlike the catecholamines, it is derived from tryptophan. It is synthesized in and released from the pineal gland at night. It is involved in the resynchronization of sleep and circadian rhythm disturbances.

Peptide hormones

Peptide hormones are composed of amino acids. The number of amino acids may vary from very few—3 in **thyrotropin-releasing**

hormone (TRH)—up to 180 or more in pituitary gonadotrophins. Peptide hormones may be linear (e.g. **angiotensin II**), or may contain a ring structure (e.g. **oxytocin** and **vasopressin**). The larger protein hormones like **insulin**, **thyroid-stimulating hormone (TSH; also known as thyrotropin)**, **follicle-stimulating hormone (FSH)**, and **luteinizing hormone (LH)** are composed of two peptide chains. Intra-chain disulphide bonds, found in some hormones, including **prolactin** and **growth hormone**, help protect from enzyme breakdown and create a tertiary structure necessary to produce an active site. Insulin is made up from both inter- and intra-chain disulphide bonds. Some of the larger proteins may bind to carbohydrate residues and form glycoproteins.

Peptides are mainly stored in secretory granules and are usually released in pulses, which may either be regular or as a response to a stimulus. These hormones, mainly hydrophilic, do not usually diffuse passively through plasma membranes and mainly exert their action by activating receptors at the surface. They have the potential to cause receptor downregulation. Circulating peptides are then broken down either by circulating enzymes or by tissue-bound enzymes.

Cholesterol derivatives and steroids

Cholesterol-derived hormones include **vitamin D** and its metabolites, as well as adrenocortical and gonadal steroids. The adrenal steroidogenic tissue produces glucocorticoids (**cortisol**, corticosterone, and cortisone), mineralocorticoids (**aldosterone**), and sex steroids (androgens), while the gonad steroidogenic tissue produces the sex steroids: **androgens**, **oestrogens**, and **progestins**.

As steroids are insoluble in water, in circulation they are mainly bound to proteins such as albumin, cortisol-binding globulin (CBG), and sex hormone-binding globulin (SHBG). This gives them longer half-lives. These hormones are lipophilic and may passively diffuse into cells and bind with receptors in the nucleus to induce a response, or bind with receptors in the cytoplasm to form a steroid-receptor complex which is then carried to the nucleus. Some are altered to active metabolites intracellularly. Inactivation and clearance of steroid hormones is not very rapid and occurs mainly in the liver (some in the kidney), although a small amount is secreted unchanged in the kidneys.

Vitamin D is synthesized in the skin and then released into the bloodstream to exert its effects in tissues. Cholecalciferol is synthesized in the skin from cholesterol and 7-dehydrocholesterol (obtained from diet); this is then converted to 25-hydroxycholecalciferol in the liver and is then converted to the active 1,25-hydroxycholecalciferol (calcitriol) in the kidney or the inactive 24,25-hydroxycholecalciferol. The main targets of calcitriol are the kidneys, gut, and bone.

Thyroid hormones

The thyroid gland synthesizes two hormones, **thyroxine (T₄)** and **triiodothyronine (T₃)**, from the precursor tyrosine. Tyrosine is cleaved from thyroglobulin in the colloid. T₄ and T₃ contain iodine, which is extracted from the circulation and incorporated into their structures, as it is required for their biological activity. Initially, T₄ and T₃ are bound to thyroglobulin but, when the thyroid is stimulated by TSH, these are cleaved and pass into the circulation. Most of T₃ in the circulation (80%) comes from peripheral conversion from T₄ through the actions of deiodonase enzymes. Thyroid hormones are not water soluble and are carried by proteins such as albumin, transthyretin, and thyroxine-binding globulin (TBG). There is active uptake in cells. The thyroid hormones, like steroids, exert their actions through

receptors in the nuclei, where they bind directly to DNA. T_3 is the main active hormone in the cell, while T_4 is its prohormone.

Eicosanoids

Eicosanoids are chemical messengers that are derived from arachidonic acid or other polyunsaturated fatty acids. Prostaglandins, including prostacyclins and thromboxanes, comprise one class of eicosanoids and mainly act locally (via paracrine or autocrine signaling), although some, like prostacyclins, do have an endocrine effect. Leukotrienes comprise another family of eicosanoids.

Eicosanoids have important roles in uterine contraction, ovulatory cyclicity, inflammation, platelet aggregation, pain sensation, and bronchospasm.

Hormone receptors

Hormone receptors may be found at different sites on cells and play an important role in the effects of hormones on target tissue.

Cell surface receptors

Hormones that do not diffuse across plasma membranes, such as peptide hormones, have receptors at the cell surface. The receptors are commonly coupled with intracellular signalling molecules, and the majority are G-protein-linked receptors. When hormones bind to the receptor, this stimulates either the opening of ion channels in the membrane or the activation of a membrane-bound enzyme that stimulates the production of a secondary messenger. These secondary messengers, such as cyclic AMP, diacylglycerol, and inositol triphosphate, activate protein kinases, which then regulate transcription.

Another common type of cell surface receptor is a transmembrane receptor with either inherent protein tyrosine kinase activity on the intracellular site, or associated molecules with tyrosine kinase activity. Binding of a hormone such as insulin, growth hormone, prolactin, or one of the cytokines to the receptor results in dimerization with another receptor, initiating phosphorylation followed by transcription regulation.

Intracellular receptors

Receptors for steroid and thyroid hormones, which, being lipophilic, readily diffuse across cell membranes, are typically intracellular. All steroid receptors are transcription factors. They bind to DNA and, in conjunction with other transcription factors, initiate, or suppress, RNA synthesis. The receptors predominantly found in the cytoplasm are type 1 receptors and include glucocorticoid, mineralocorticoid, androgen, and progesterone receptors. They are bound to heat-shock proteins. As the steroid binds the receptor, the heat-shock protein is released and the receptor dimerizes with another identical receptor. The hormone–receptor complex then translocates to the nucleus and binds to DNA. The thyroid hormone receptor is a type 2 receptor, which, in contrast, is typically located in the nucleus. The receptors recognize and bind to a base sequence, which known as a hormone response element, on the DNA in order to alter transcription. Steroid hormones may also bind to and activate or repress other transcription factors (e.g. NF- κ B), either in the nucleus or in the cytoplasm ('non-genomic effect'). Steroid and thyroid hormones may stimulate rapid responses in cells by interacting with poorly characterized receptors at the cell surface.

Hormone receptor regulation

Receptor regulation occurs by up- or downregulation of the number of receptors or by desensitization of the receptors. Interactions between hormones and their receptors depend on the number of receptors, the concentration of circulating hormone, and the affinity of the hormone for the receptor. For example, when receptor numbers are reduced, a higher concentration of hormone is needed to occupy a similar number of receptors and achieve an equal target cell response.

Hormonal regulation

In order to induce a specific action at a required time, hormone action needs to be controlled. Hormones are regulated in a number

of ways. They may be secreted constantly or in a pulsatile fashion. Many rhythms for hormone secretion, such as the cortisol circadian rhythm, are regulated by the circadian pacemaker in the suprachiasmatic nucleus, which is mainly influenced by the light–dark cycle through information delivered through retinohypothalamic tracts. Hormones may be released as a response to a nerve stimulus or a hormone (e.g. a releasing hormone). Stimuli may either provoke release from secretory vesicles to produce a rapid effect (in the case of peptide hormones and catecholamines), or enhance hormone synthesis, producing a delayed effect.

Inhibition of hormone release may occur via release-inhibiting factors (e.g. dopamine inhibits prolactin release, and somatostatin inhibits growth hormone release) or by negative feedback inhibition. Feedback loops may involve the hypothalamic–pituitary–adrenal (HPA) axis, which detects changes in the concentration of hormones secreted by peripheral glands (see Figure 182.1A); alternatively, an organ may respond to changes in a variable in the internal environment (see Figure 182.1B).

An important interaction exists between immune and endocrine systems, demonstrating bidirectional communication. Cytokine regulation of the HPA axis during the stress response occurs by stimulation of hypothalamic corticotrophin-releasing hormone (CRH), with resultant release of adrenocorticotrophic hormone (ACTH) from the pituitary, and cortisol from the adrenal.

Hormonal physiology

Thyroid

The thyroid gland secretes all T_4 and 20% of T_3 . The concentration of T_4 is about 50 times greater than that of T_3 . In blood these hormones are almost entirely (>99%) bound to plasma proteins: 70% to TBG, 15% to transthyretin, and 15% to albumin. Only the free hormone is available to the tissues and biologically active; this fraction correlates closely with the metabolic state of the individual but the concentration does not vary directly with the total hormones.

T_3 binds weakly to TBG, compared to T_4 , and so has a faster onset of action and is four times more active than T_4 . T_4 has a half-life of 6.7 days, while T_3 has a half-life in serum of only 1 day. T_4 is converted peripherally in extra-glandular tissue, especially in liver and muscle, to the active T_3 or the inactive form of T_3 , reverse T_3 , according to the tissue requirements for cell growth and metabolism. T_4 and T_3 are metabolized in the liver. Free T_3 shows a circadian rhythm with a periodicity that lags behind TSH, suggesting that the periodic rhythm of free T_3 is due to the proportion of T_3 derived from the thyroid.

The levels of thyroid hormones in the blood are regulated by feedback mechanisms from the HPA axis. TRH from the hypothalamus stimulates release of TSH from the pituitary. TSH secretion is pulsatile, with increased amplitude at night. TSH then enhances uptake of iodide, and both synthesis and release of T_3 and T_4 . T_4 and T_3 subsequently exert negative feedback on TSH synthesis and secretion.

The functions of thyroid hormones are mainly to increase basal metabolic rate, regulate protein, fat, and carbohydrate metabolism, regulate long-bone growth and neuronal maturation, and increase body sensitivity to catecholamines.

Adrenal cortex

The major hormones synthesized in the adrenal cortex are cortisol, aldosterone, and the adrenal androgens. The pathways for the synthesis of these hormones are shown in Figure 182.2.

Cortisol

Cortisol is produced in the zona fasciculata of the adrenal cortex from stored cholesterol. It is derived from the hydroxylation of cortisone; 80% of plasma cortisol is bound to CBG, and 10% is bound to albumin; the remaining 10% is free cortisol (unbound fraction), which provides biological activity. The half-life of cortisol is around 90 minutes.

Cortisol has one of the most distinct and interesting circadian rhythms in the body. The circadian clock (pacemaker) in the suprachiasmatic nucleus drives the paraventricular nucleus in the

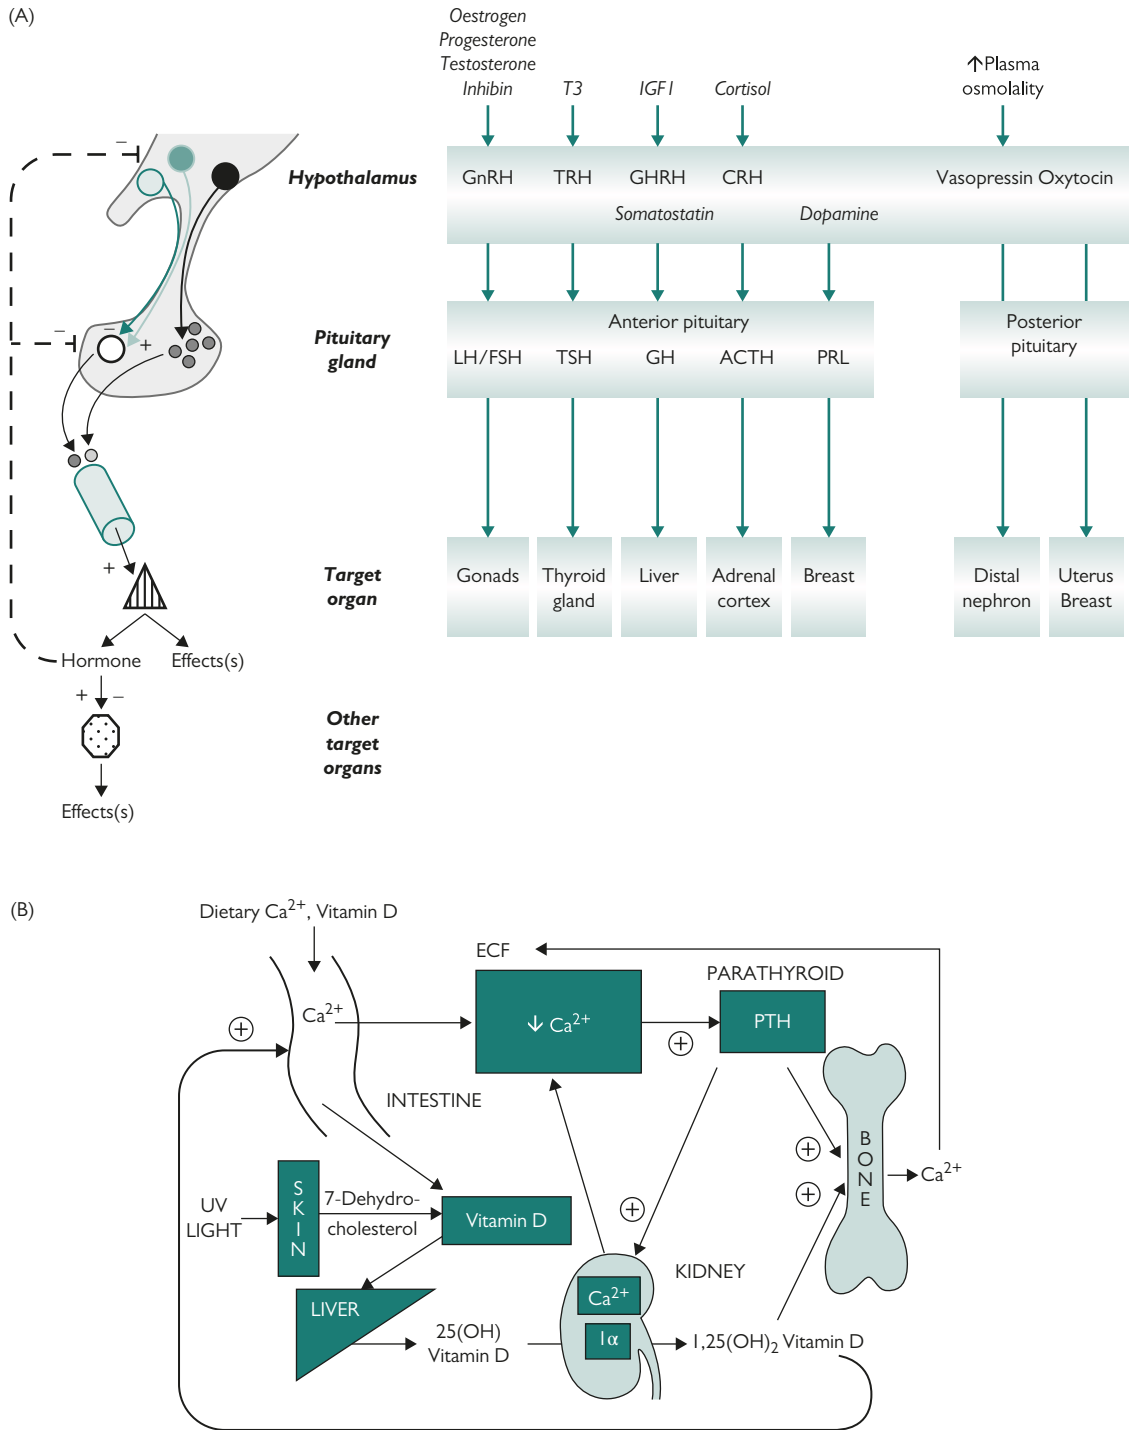

Figure 182.1 (A) Control of hormone production: regulatory pathways integrating the hypothalamus, the pituitary, and various end organs. Hormones shown in italics exert inhibitory effects. Negative feedback regulation occurs at both the hypothalamic and the pituitary level; ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone-releasing hormone; GnRH, gonadotropin-releasing hormone; IGF1, insulin-like growth factor-1; LH, luteinizing hormone; PRL, prolactin; T3, triiodothyronine; TRH, thyroid-releasing hormone; TSH, thyroid-stimulating hormone. (B) Regulation of extracellular fluid (ECF) calcium (Ca²⁺) by parathyroid hormone (PTH) action on kidney, bone, and intestine. A decrease in ECF Ca²⁺ is sensed by the calcium-sensing receptor (CaSR), leading to an increase in the secretion of PTH, which predominantly acts directly on the kidneys and bones, as these possess the PTH receptor (PTHrR). PTH acts to increase (+) osteoclastic bone reabsorption but, as osteoclasts do not have PTHrRs, this action is mediated via the osteoblasts, which do have PTHrRs and, in response to PTH, release cytokines and factors that activate osteoclasts. In the kidney, PTH stimulates (+) 1- α hydroxylase (1 α) to increase the conversion of 25-hydroxyvitamin D (25(OH)D) to the active metabolite 1,25-dihydroxyvitamin D (1,25(OH)₂D). In addition, PTH increases (+) the reabsorption of Ca²⁺ from the renal distal tubule and inhibits the reabsorption of phosphate from the proximal tubule, thereby leading to hypercalcaemia and hypophosphataemia. PTH also inhibits Na⁺-H⁺ antiporter activity and bicarbonate reabsorption, thereby causing a mild hyperchloraemic acidosis. The elevated 1,25(OH)₂D acts on the intestine to increase (+) absorption of dietary calcium and phosphate, and it is important to note that PTH does not appear to have a direct action on the gut. Thus, in response to hypocalcaemia and the increase in PTH secretion, all of these direct and indirect actions of PTH on the kidney, bone, and intestine will help to increase ECF Ca²⁺, which, in turn will act via the CaSR to decrease PTH secretion.

hypothalamus to produce CRH. This stimulates the pituitary to produce pulsatile ACTH in a circadian rhythm rising at 3 am. This drives the adrenal gland to produce cortisol also in a circadian rhythm; hence, cortisol levels are low at the time of sleep onset, rise between 2 a.m. and 4 a.m., peak just after waking, and then fall during the day. Cortisol then exerts a negative feedback on both the hypothalamus and the pituitary.

Around 13–15 cortisol secretory episodes occur during the 24 hours of the day, with a quiescent phase of minimal secretory activity starting prior to sleep and lasting up to after sleep onset. Advances in the measurement of the total amount of cortisol produced in a day shows that this is around 5.7–7.4 mg/m² per day, or 9.5 to 9.9 mg per day. These findings support regimes with lower oral daily hydrocortisone doses of 15–20 mg, allowing for first-pass hepatic metabolism and bioavailability.

In body tissues, interconversion occurs between the active and inactive metabolites, cortisol, and cortisone. Two isoenzymes, 11-beta hydroxysteroid dehydrogenase types 1 and 2, are responsible for this process. The first, expressed mainly in visceral adipose tissue, liver, and gonads, converts exogenous or endogenous cortisone to cortisol. The second converts cortisol to cortisone.

Cortisol stimulates glycogenolysis and gluconeogenesis; causes protein and selective fat breakdown, which is important for skeletal and cardiac muscle function; inhibits bone formation; maintains blood pressure; stimulates free water excretion; and has immunosuppressive and anti-inflammatory functions.

Aldosterone

Aldosterone is produced by the zona glomerulosa of the adrenal cortex and is part of the renin–angiotensin system, which is its main regulator. Aldosterone has a diurnal rhythm which peaks at around 6–7 am and has a nadir at around midnight. Aldosterone secretion is stimulated by plasma angiotensin II, high potassium, acidosis, stretch receptors in the atria, and ACTH. Low renal blood pressure, low sodium, and the sympathetic system will stimulate renin release, which will enhance aldosterone secretion. Aldosterone stimulates potassium and H⁺ secretion into urine, and sodium ions and water into the circulation. It increases blood pressure.

Adrenal androgens

Dehydroepiandrosterone (DHEA) and its metabolite androstenedione are produced in the zona reticularis. These can undergo further conversion to testosterone. In the blood, most DHEA is found as its sulphate, DHEAS. The synthetic pathway is under the control of ACTH. DHEA naturally peaks in the early morning, while serum DHEAS concentrations do not vary throughout the day. The half-life of DHEA is around an hour, and DHEA is secreted episodically.

Gonads

Oestradiol and progesterone

Puberty

The average age of onset of puberty in girls is 10–12 years. Pulsatile secretion of luteinizing hormone-releasing hormone from the hypothalamus at night is the first step in puberty initiation. This results in the pulsatile secretion of LH and FSH from the pituitary. As puberty progresses and sexual characteristics develop, menarche commences.

Menstrual cycle

Through the influence of a rise in FSH during the first days of the cycle, a few ovarian follicles are stimulated and, as they mature, they secrete increasing amounts of oestradiol. The oestrogens initiate the formation of a new layer in the endometrium. One of the follicles becomes dominant and, unlike the other follicles, grows to maturity (this is the 'follicular' or 'proliferative' phase).

As oestrogen levels increase at around day 12, through positive feedback, they trigger release of LH. This LH matures the egg and weakens the wall of the follicle so that ovulation occurs.

The solid body left in the ovary after egg release, the corpus luteum, then produces progesterone and oestrogen. Progesterone makes the endometrium receptive to implantation. The hormones produced by the corpus luteum then suppress LH and FSH, which are essential for the viability of the corpus luteum. After a few days, the corpus luteum atrophies and progesterone levels fall, triggering menstruation and the beginning of the next cycle. This phase usually lasts two weeks and the period is usually consistent (this is the 'luteal' or 'secretory' phase). Menstruation usually lasts for 3–5 days.

Menopause

Menopause is a retrospective diagnosis of 12 months of amenorrhoea. The average age is usually 50 years. Cycles become increasingly anovulatory, even up to 4 years before the menopause, and patients complain of hot flushes, urine symptoms, mood changes, and vaginal dryness. FSH levels start to fluctuate until they remain persistently high. This is followed by low oestradiol levels which correlate with the amenorrhoea.

Oestradiol

Oestradiol is produced from ovarian follicles, by conversion from testosterone, and also by the liver, the adrenals, and the breasts. In males, some oestradiol is produced in the testis but most oestrogens are formed from aromatization of androgens in adipose tissue. Oestradiol is largely bound to SHBG and albumin. Its main function is to promote secondary sexual characteristics in females, increase vaginal lubrication, increase bone formation, decelerate height growth, accelerate metabolism, increase production of binding proteins, increase clotting factors, increase HDL, and decrease LDL.

Progesterone

Progesterone is mainly formed in the ovaries and the brain. It mainly functions to prepare the uterus for implantation, decrease contractility of uterine muscle, and inhibit lactation. Other effects include anti-inflammatory actions, reduction of bronchial spasm, normalization of clotting, and prevention of endometrial cancer.

Testosterone

Leydig cells in the testis produce testosterone. Sertoli cells support spermatogenesis in the seminiferous tubules, in the presence of high testosterone concentration. Gonadotropin-releasing hormone, in a pulsatile manner, stimulates secretion of LH and FSH. LH stimulates synthesis and secretion of testosterone, while FSH stimulates production of seminiferous tubule fluid and substances essential for spermatogenesis. Testosterone exerts negative feedback on both LH and FSH.

The secretion of testosterone has a circadian rhythm, with maximal secretion at around 8 a.m. Spermatogenesis takes approximately 74 days. Testosterone is bound to SHBG and albumin. Around 4% is free and is the active fraction. In target tissues, testosterone is converted to the more potent dihydrotestosterone by 5- α reductase. Testosterone is inactivated in liver and excreted in urine. Testosterone functions include promoting increased muscle mass and strength, increased bone density, stimulation of bone growth, maturation of sex organs, and development of secondary sexual characteristics, libido, and erections; it also maintains cardiovascular health.

Adrenal medulla

Catecholamines are produced mainly by the chromaffin cells of the adrenal medulla, as well as by the postganglionic fibres of the sympathetic nervous system. Adrenaline is under the control of the CNS. The most abundant catecholamines are adrenaline, noradrenaline, and dopamine. Adrenaline and noradrenaline are broken down into metanephrines and normetanephrines, respectively. Dopamine acts as a neurotransmitter in the CNS. Noradrenaline is a neuromodulator of the peripheral sympathetic nervous system. During times of stress, adrenaline is released from the medulla; 20% of noradrenaline is released from the medulla, while the rest spills out from the sympathetic nerves supplying blood vessels.

Effects of catecholamines include increased heart rate and inotropy (beta-1 receptor); vasoconstriction in most vessels (alpha-1 and alpha-2 receptors); vasodilatation in skeletal muscle and liver at low concentrations (beta-2 receptor; adrenaline only) and vasoconstriction at high concentrations (alpha-1 receptor); glycogenolysis; and lipolysis. Other agonist effects on alpha receptors result in increased sweating, pupil dilatation, and alertness.

Anterior pituitary

The main hormones produced by the anterior pituitary are growth hormone, LH, FSH, TSH, ACTH, and prolactin. Growth hormone and prolactin will be discussed here.

Growth hormone

Growth hormone is synthesized, stored, and secreted by somatotroph cells in the anterior pituitary. Growth hormone is secreted more commonly at night (five to six 90-minute pulses/24 hours) and in the circulation is bound to growth hormone-binding protein. Growth hormone-releasing hormone released by neurosecretory nuclei in the hypothalamus into the portal circulation surrounding the pituitary stimulates the release of growth hormone. Other stimulating factors are sleep, hypoglycaemia, and exercise. The effects of growth hormone include increasing height in children and adolescents, increasing muscle mass and protein synthesis, promoting lipolysis and gluconeogenesis, and stimulating the immune system. In addition, in the liver, growth hormone stimulates the production of insulin-like growth factor 1 (IGF1), which itself has growth-stimulating effects on a wide variety of tissues. Growth hormone secretion is inhibited by negative feedback from growth hormone itself and from IGF1, as well as by somatostatin and high glucose.

Prolactin

Prolactin is synthesized and secreted by the lactotroph cells in the anterior pituitary; the secretion is pulsatile, with around 14 pulses/24 hours. A nocturnal peak occurs during sleep, and a lesser peak in the evening. Dopamine secreted from neuroendocrine neurons in the hypothalamus causes tonic inhibition of prolactin. Therefore, any mass effect of compression/disconnection of the pituitary stalk will result in an elevated prolactin measurement, as will the use of any dopamine-antagonist medication.

High prolactin levels suppress LH and FSH. Prolactin also stimulates the mammary glands to produce milk, and increased levels of prolactin are found during pregnancy. Levels of prolactin may also rise with stress, meals, nipple stimulation, and minor surgery. In addition, TRH has a stimulating effect on prolactin levels.

Posterior pituitary

The main hormones released by the posterior pituitary are oxytocin and vasopressin (also known as antidiuretic hormone). They both have a short half-life. Both hormones are synthesized in the supra-chiasmatic and paraventricular hypothalamic neurons. Oxytocin causes contractions in the pregnant uterus, and breast milk ejection during breast feeding. Vasopressin mainly acts to reduce free water excretion. Its release is stimulated by high osmolality and a low blood volume and it acts in the kidney at the collecting duct and the thick ascending loop of Henle to affect water permeability.

Parathyroid glands

The parathyroid glands secrete parathyroid hormone, which acts to increase the concentration of calcium in the blood. Decreased calcium concentrations, through activation of the calcium sensory receptors on the parathyroid cells, stimulate parathyroid hormone secretion. The release of parathyroid hormone then enhances the release of calcium from the bones through indirect stimulation of osteoclasts, which cause bone resorption. In the kidneys, it enhances the reabsorption of calcium from the distal tubules as well as promoting phosphate excretion. It also increases the intestinal absorption of calcium by stimulating the production of active vitamin D (1,25-hydroxycholecalciferol). Vitamin D also promotes reabsorption of calcium from the kidneys, promotes bone growth and remodelling, and has immunomodulatory effects.

A severe decrease in serum magnesium, or a high calcium concentration, may inhibit parathyroid hormone. In addition, the effects of parathyroid hormone are opposed by calcitonin, which acts to decrease calcium concentrations.

183 Diagnosis and investigation in endocrine disorders

John Newell-Price, Alia Munir, and Miguel Debono

The aim of this chapter is to introduce the reader to some of the common investigations used in the diagnosis and management of endocrine disorders. Tests used to identify specific disorders will be discussed in Chapters 184–192.

Thyroid disorders

Primary hypothyroidism

Primary hypothyroidism is diagnosed on the basis of an elevated basal level of thyroid-stimulating hormone (TSH), and low free thyroxine (FT4). Anti-thyroid peroxidase (TPO) antibodies are found in patients with autoimmune thyroid disease. In a patient started on thyroxine replacement, TSH should be rechecked 6–10 weeks later. Ideal treatment yields a TSH between the lower limit of the reference range and 2 mU/l. Values between 2 mU/l and the upper limit of the reference range probably imply mild under-treatment, especially if the patient remains symptomatic. There is no place for measuring FT4 in patients who are on replacement thyroxine, as this only proves that the patient took levothyroxine on the morning in question. Patients with persistently elevated TSH levels, despite being on levothyroxine doses of 200 micrograms or more, are frequently non-compliant, and tests often show normal FT4 and elevated TSH. Alternative diagnoses, such as thyroxine malabsorption due to, for example, coeliac disease, should also be considered. There is no place for measuring triiodothyronine levels in suspected hypothyroidism.

Secondary hypothyroidism

Secondary hypothyroidism is diagnosed by a low FT4 and inappropriately normal or low TSH. It is monitored via FT4 levels. TSH values are usually in the normal range or low and are not useful for monitoring.

Hyperthyroidism

The diagnosis of hyperthyroidism is confirmed by a suppressed TSH (i.e. below 0.03 mU/l) with an elevated FT4 or an elevated free triiodothyronine level (FT3). Normally, obtain the FT4 first and, if normal, then measure the FT3 to confirm the diagnosis of triiodothyronine toxicosis. Positive antithyroid antibodies (TPO/thyroglobulin antibodies) or anti-TSH-receptor antibodies favour a diagnosis of Graves' disease. TSH/FT4 levels should be monitored when the patient is treated with antithyroid medication. Detectable TSH and elevated FT4/FT3 are found in TSH-secreting pituitary tumours or in thyroid-hormone resistance. Exclude the presence of heterophile antibodies causing a falsely high TSH level.

Thyroid nodules

All patients with a **dominant nodule** (i.e. larger or different in consistency, compared to other nodules) in a multinodular goitre should be suspected of having a malignancy, as should all patients who have a solitary nodule in their thyroid. The only investigations needed for thyroid nodules are a TSH test and thyroid antibodies, coupled with fine-needle aspiration cytology (FNAC). Ultrasound or radioisotope scans are not routinely indicated. Repeat FNAC at the first return visit if the first sample is clinically suspicious or was non-diagnostic. Other tests include:

Scintiscanning: This is **rarely required** to define areas of increased or decreased function, to detect the presence of a retrosternal

goitre or ectopic thyroid tissue, and to detect functioning metastases of thyroid carcinoma; homogenous uptake is increased in Graves' disease and reduced in thyroiditis.

Ultrasound scan: This is used to differentiate between cystic and solid nodules and to follow change in size of a nodule; calcification may suggest malignancy.

Non-contrast CT scan: This is used for evaluation of retrosternal and retrotracheal extension of goitre.

Flow-volume loop: This is rarely indicated: tracheal diameter may be assessed on non-contrast CT.

Pituitary disease

Suspected pituitary tumour

Clinical assessment for a suspected pituitary tumour should include assessment of visual fields; if they are determined to be abnormal with a red pin, formal testing should be considered. Measurements for pituitary function include tests for basal levels of:

- prolactin
- FT4
- TSH
- testosterone or oestradiol
- sex hormone-binding globulin
- luteinizing hormone (LH)
- follicle-stimulating hormone (FSH)
- insulin-like growth factor 1

Cortisol can be measured as a 9 a.m. sample and, if the basal level is >500 nmol/l, no further dynamic tests need to be made. If it is <500 nmol/l, one should consider doing an insulin tolerance test (the gold standard), a glucagon test, or a short tetracosactide test including a basal 9 a.m. adrenocorticotropic hormone (ACTH) test. For all three tests, any oestrogen should be stopped 6 weeks beforehand to allow cortisol-binding globulin levels to return to normal (if a large pituitary tumour is present, the need for urgent clinical management may override the need for assessment, and the patient should be given glucocorticoid cover). Where there is clinical suspicion of a functioning tumour, the appropriate tests should be performed (see Chapters 189 and 192).

Radiological investigations in pituitary disease

The following radiological investigations can be used in pituitary disease:

- MRI: provides optimal imaging; IV gadolinium is used for contrast enhancement (a normal pituitary appears very bright)
- CT scans: this is used for certain tumours (e.g. craniopharyngioma)

Dynamic tests for pituitary disease

Insulin tolerance test

An insulin tolerance test is used to diagnose secondary adrenal failure, or growth hormone (GH) deficiency. In the test, IV insulin is given to induce hypoglycaemia (blood glucose <2.2 mmol/l) and stimulate ACTH and GH secretion. Cortisol levels should rise to >550 nmol/l. A peak GH response of <3 µg/l is associated with severe GH deficiency. This test is contraindicated in ischaemic heart disease, epilepsy, severe long-standing hypoadrenalism, and glycogen

storage diseases, or when the patient's age is <2 years, or the cortisol level is <100 nmol/l. In addition, the ECG must be normal.

Glucagon test

A glucagon test is used to diagnose secondary adrenal failure and GH deficiency in patients in whom the insulin tolerance test is contraindicated. This is a routine first-line test for GH deficiency, but is a poor stimulus for ACTH. Glucagon stimulates a glucose rise followed by a drop in sugar, due to insulin secretion. The maximal glucose level is achieved after 90 minutes. Cortisol levels should rise to >550 nmol/l. A peak GH response of <3 µg/l is associated with severe GH deficiency. The test is contraindicated in patients who have not eaten for 48 hours or who have a glycogen storage disease or severe cortisol deficiency (i.e. situations where glycogen stores are low). This test is unreliable in diabetes patients.

Short tetracosactide test

The short tetracosactide test is used for the assessment of primary and secondary adrenal insufficiency (following pituitary surgery, the test should only be utilized after a period of 6 weeks, to avoid false-negative results). In this test, 250 µg tetracosactide is administered intramuscularly, and then cortisol levels are assessed after 30 minutes. In a normal response, cortisol levels rise to >550 nmol/l if the response is normal.

Growth hormone-releasing hormone–arginine test

The growth hormone-releasing hormone (GHRH)–arginine test is used to assess for GH deficiency. The following cut-off levels have been validated for this test: for those with a BMI <25 kg/m², the peak GH is <11 µg/l; for a BMI of 25–30 kg/m², the peak GH is <8 µg/l; and, for a BMI >30 kg/m², the peak GH is <4 µg/l.

Gonadotropin-releasing hormone test

The gonadotropin-releasing hormone test is used to assess LH/FSH reserves. It is rarely used.

Thyrotropin-releasing hormone test

The thyrotropin-releasing hormone (TRH) test is rarely used but may be indicated to distinguish between a TSH-secreting tumour (no change) and thyroid-hormone resistance (increase) or to distinguish between pituitary TSH and hypothalamic TRH deficiency.

Water-deprivation test

The water-deprivation test is extremely difficult to perform properly and is best left to dedicated endocrine units. It is indicated for the diagnosis of diabetes insipidus, and differential diagnosis of thirst, polyuria, and nocturia. Care should be taken in patients with severe clinical diabetes insipidus. Thyroid and adrenal reserve must be normal or adequately replaced, and diabetes mellitus and hypercalcaemia excluded.

For the test, patients are initially allowed fluids overnight. They are then deprived of fluids for 8 hours or until 3% of the body weight is lost. Plasma osmolality and urine volume/osmolality are then measured. A rise in serum osmolality to >305 mOsm/kg confirms diabetes insipidus. If a urine osmolality ≤300 Osm/kg improves with desmopressin, this is suggestive of cranial diabetes insipidus (CDI); no improvement would be suggestive of nephrogenic diabetes insipidus. If urine concentrates with no desmopressin to >800 Osm/kg in a patient with increased thirst and polyuria, and diabetes and hypercalcaemia have been excluded, psychogenic polydipsia may be the cause.

CDI is usually caused by hypothalamic lesions such as craniopharyngiomas; head trauma; cranial surgery; infiltrative disorders; or infections. Alternatively, it may be idiopathic. CDI is virtually never seen as the presenting feature of an anterior pituitary tumour. Familial CDI is rare.

Nephrogenic diabetes insipidus can be caused by chronic renal insufficiency, lithium toxicity, tubulointerstitial disease, hypokalaemia, or hypercalcaemia. Very rarely, it may be familial.

Adrenal gland and sex hormone disorders

Primary hyperaldosteronism

Aldosterone–renin ratio

A random plasma aldosterone–renin ratio is currently the preferred screening test for primary hyperaldosteronism (also known

as Conn's syndrome), as it is easy to do and is less affected by drug therapy, day and diurnal variation, and patient position than tests for either aldosterone or renin alone; in primary hyperaldosteronism, the plasma aldosterone–renin ratio is high. During the test, hypokalaemia should be avoided, and patients should be well hydrated and have an adequate intake of sodium. Spironolactone, other aldosterone antagonists, and oestrogens **must** be discontinued 6 weeks before the test. Angiotensin-converting enzyme inhibitors, beta blockers, dihydropyridine calcium-channel blockers, NSAIDs, and diuretics should be stopped 2 weeks before the test, although alpha blockers may be used. Sometimes one may adopt the approach of not stopping any of the drugs; if the test is abnormal, the drugs are then stopped for subsequent confirmatory suppression tests.

Confirmatory suppression tests

The **fludrocortisone suppression test** is considered by some to be the definitive diagnostic procedure for hyperaldosteronism. In this test, plasma aldosterone should initially be measured mid-morning; the subject should be upright for at least 30 minutes prior to venepuncture. Then, for the next 4 days, fludrocortisone 0.1 mg is administered 6 hourly, and slow Na 3 × 10 mmol tabs are administered 8 hourly. In addition, slow K tabs are administered in sufficient quantity to maintain plasma potassium concentration within the reference range. On Day 4, plasma aldosterone is again measured mid-morning. In primary hyperaldosteronism, aldosterone levels will not be suppressed by fludrocortisone (normal response <140 pmol/l). However, if hypokalaemia develops, aldosterone will be suppressed even if primary hyperaldosteronism is present (false-negative result).

The **furosemide posture test**, acute 4-hour IV saline loading, and a postural stimulation test are other confirmatory tests which may be considered.

States of excess mineralocorticoids

In the presence of hypertension and hypokalaemic alkalosis with low renin and normal or low aldosterone, consider (i) apparent mineralocorticoid excess from a deficiency (congenital, or caused by liquorice) in 11-beta hydroxysteroid dehydrogenase type 2; (ii) congenital adrenal hyperplasia, or adrenal tumours with increased secretion of deoxycorticosterone or corticosterone; or (iii) ectopic ACTH. Alternatively, consider Liddle's syndrome (a renal tubular abnormality; autosomal dominant).

In the presence of hypokalaemic alkalosis without hypertension but with increased renin and aldosterone levels, consider:

- Bartter syndrome (presents at a young age, with seizures, tetany, and hypercalciuria; autosomal recessive)
- Gitelman syndrome (hypomagnesaemia, hypocalciuria)

Cushing's syndrome

Circadian rhythm study

To diagnose Cushing's syndrome, a circadian rhythm study may be performed in which a patient is admitted to hospital and, when unstressed on Day 2, has serum cortisol and ACTH levels taken at 9 a.m., 6 p.m., and midnight. The midnight sample should preferably be taken when patient is asleep, within 5 to 10 minutes from waking. Salivary cortisol samples may also be taken, allowing the test to be done on an outpatient basis.

Dexamethasone suppression tests

For initial screening for Cushing's syndrome an overnight dexamethasone suppression test is recommended. In this test, the patient is instructed to take 1 mg dexamethasone tablets at between 11 p.m. and midnight and to return for a blood test at 9 a.m. on the following morning. In normal subjects, the cortisol will fall to <50 nmol/l.

If there is a high index of suspicion of Cushing's syndrome or if the overnight test contradicts other investigations, a low-dose dexamethasone test should be used. The test is started at 9 a.m.; dexamethasone 0.5 mg orally strictly 6 hourly for 48 hours is given. Cortisol and ACTH levels are taken at 9 a.m., before the first dose of dexamethasone, and then again 48 hours later (also at 9 a.m.). In

normal subjects, cortisol levels will be <50 nmol/l at 48 hours after the start of the test.

The high-dose dexamethasone test is used in the differential diagnosis of ACTH-dependent Cushing's syndrome, or Cushing's syndrome of unknown aetiology. Like the low-dose test, this test is also started at 9 a.m.; however, dexamethasone 2 mg orally strictly 6 hourly for 48 hours is given. Cortisol and ACTH levels are taken at 9 a.m., before first dose of dexamethasone, and then again 48 hours later (also at 9 a.m.). Suppression of serum cortisol by 50% at the end of the test is consistent with Cushing's disease (ACTH dependent).

For dexamethasone suppression tests, all patients need to be off oestrogens for 6 weeks, and caution is recommended in patients with diabetes and gastric ulceration.

Twenty-four-hour urinary free cortisol test

A 24-hour urinary free cortisol test indicates the level of free cortisol in tissues. However, it has a high false-negative rate and should not be used alone.

Adrenal insufficiency

The tetracosactide test is used in the diagnosis of adrenocortical insufficiency—primary or secondary. The test is started at 9 a.m. Cortisol levels are taken at baseline and at 30 minutes after intramuscular or IV injection of 250 µg tetracosactide. If looking for the cause of the insufficiency, whether primary or secondary, basal ACTH is also taken. With a normal adrenal reserve, the cortisol levels should rise to a peak level of >550 nmol/l. This test is not sensitive for early secondary adrenal insufficiency (<6 weeks post pituitary surgery). In addition, it should be avoided in pregnancy.

Hyperandrogenism

Five-day dexamethasone suppression test of adrenal androgens

The 5-day dexamethasone suppression test of adrenal androgens is used in hyperandrogenism to assess the degree of ACTH regulation. In the test, oral dexamethasone 1.5 mg is given twice per day for 5 days. A baseline sample and a Day 6 sample are taken for cortisol, testosterone, sex hormone-binding globulin, androstenedione,

dehydroepiandrosterone sulphate (DHEAS), and 17-hydroxyprogesterone. Androgens are unlikely to suppress in adrenal or ovary adenomas. There may be moderate suppression in polycystic ovary syndrome. In congenital adrenal hyperplasia, good suppression will occur.

Short tetracosactide test for congenital adrenal hyperplasia

The short tetracosactide test is used to diagnose late-onset congenital adrenal hyperplasia. Preferably, the test should be done during the follicular phase of the menstrual cycle. During the test, cortisol and 17-hydroxyprogesterone levels are taken at baseline and at 60 minutes after the administration of 250 µg tetracosactide. A basal 17-hydroxyprogesterone level <6 nmol/l and a peak 17-hydroxyprogesterone level <30 nmol/l are normal.

Adrenal incidentalomas

Approximately 5% of all abdominal CT scans disclose clinically non-suspected adrenal tumours known as incidentalomas. The majority are non-functioning but some may be hormone producing. If adrenal incidentalomas are found, it is necessary to exclude metastases or adrenal cancer, and all patients should be referred to an endocrinologist for investigation. The workup should include renal function tests, fasting glucose, a lipid profile, liver function tests, a full blood count, and the erythrocyte sedimentation rate. In addition, the following tests should be done:

- blood pressure check
- basal DHEAS
- an aldosterone–renin ratio, if the patient is hypertensive
- a 1 mg overnight dexamethasone suppression test
- 2 × 24-hour urine collections for urinary metanephrines

Repeat the CT scan after 6 months to assess for growth if tumours not definitely benign on non-contrast CT scans.

184 Diabetes mellitus

Kevin Shotliff

Definition

Diabetes mellitus, often referred to simply as diabetes, is a syndrome of disordered metabolism (insulin deficiency and/or insulin resistance) resulting in abnormally high blood glucose levels (hyperglycaemia). The term 'diabetes' relates to passing large volumes of urine (polyuria); 'mellitus' refers to the fact that the urine is sweet (glycosuria). Currently, 2%–6% of the UK population have diabetes but only one-half to one-third are thought to be diagnosed. Worldwide, 189 million people were known to have diabetes in 2003 and this may reach 324 million by 2025.

Symptoms

The symptoms of diabetes are split into acute and chronic problems. Acute symptoms are metabolic abnormalities related to high blood glucose levels, although treatment can also cause acute problems with low blood glucose levels or lactic acidosis. Chronic complications are split into macrovascular (cerebrovascular, cardiovascular, and peripheral vascular disease) and microvascular disease (neuropathy, retinopathy, and nephropathy). As type 2 diabetes is often undiagnosed for some time, chronic complications, such as a myocardial infarct or a foot ulcer, can be the presenting problem.

It is hyperglycaemia which largely causes the acute signs and symptoms of diabetes. About 25% of people with type 1 diabetes have some degree of ketoacidosis at diagnosis. This can be associated with abdominal pain and breathlessness (Kussmaul respiration) in those with significant acidosis.

Polyuria (large amounts of urine) and **polydipsia** (thirst) are caused by renal osmotic diuresis due to hyperglycaemia. The kidneys are typically able to conserve glucose up to a certain level (often blood levels up to 10 mmol/l but less in certain situations, such as pregnancy), and excess glucose is then lost in the urine. This glucose takes water with it, so increasing the volume of urine passed. Symptoms of **nocturia, incontinence, and frequency**, due to the dramatic increase in urine production, may be reported.

Blurred vision is caused by osmotic changes in the lens of the eye; these are associated with fluctuations in blood glucose levels. Glucose and water enter the lens of the eye, and the associated swelling of the lens alters its focal length.

People with poorly controlled diabetes often **lose weight** as they are unable to utilize carbohydrates efficiently. Glucose lost in the urine represents unused calories, so other energy stores such as fat or protein must be used instead. Lethargy is also commonly reported.

At very high levels of serum glucose, **confusion** may develop, and may progress further to **coma**. **Mood changes** may also be noted, often by a partner or relative, although both are more common with low blood glucose levels associated with treatments for diabetes.

Recurrent infections (often skin) should alert the physician to screen for diabetes, as hyperglycaemia provides not only high blood levels but also high extracellular tissue fluid levels of glucose.

Diagnosis

Diabetes mellitus is a biochemical diagnosis, indicated when blood glucose levels are over a certain level, as shown in Table 184.1. Investigation and a subsequent diagnosis of type 1 diabetes, and many cases of type 2, is usually prompted by recent-onset symptoms of polyuria and polydipsia, often accompanied by weight loss. These symptoms typically worsen over days to weeks. With type 1 diabetes, diabetic ketoacidosis may be present. Diagnosing other cases of

type 2 diabetes is often incidental on routine health screening, during other medical investigations, or when investigating symptoms such as vision changes, recurrent skin infections, or unexplained fatigue. Diabetes is often detected when a person is admitted to hospital for an illness often associated with diabetes (e.g. heart attack, stroke, neuropathy, cellulitis, poor wound healing, foot ulcers, new visual impairment, fungal infections), or after delivering a baby with macrosomia or hypoglycaemia.

Other causes of increased urine production (polyuria) and thirst which should be considered include:

- increased solute load (e.g. with glycosuria or diuretic use)
- water diuresis (e.g. with cranial or nephrogenic diabetes insipidus; hypercalcaemia; or sickle cell disease)
- other causes, such as paroxysmal tachycardias or migraine

Diagnosis in suspected diabetes mellitus

A diagnosis of diabetes is based on blood glucose levels—fasting, postprandial, or both. In a symptomatic person, a random blood glucose >11.1 mmol/l (200 mg/dl) is diagnostic. Asymptomatic patients or those with intercurrent illness require a further abnormal result when well before a diagnosis of diabetes can be made. The timing of a blood glucose test is important, with fasting and 2-hour post-oral glucose-load measurements being the accepted standards.

Impaired fasting glucose and impaired glucose tolerance are sometimes called prediabetes. The latter in particular is a major risk factor for progression to full-blown diabetes mellitus as well as cardiovascular disease.

Type 1 diabetes

Type 1 diabetes often presents with the patient acutely unwell with breathlessness (air hunger or Kussmaul respiration, with deep regular rapid breaths, suggesting acidosis), abdominal pain, muscle cramps, weight loss, polyuria, and polydipsia. Subsequent nausea and vomiting can worsen both the dehydration and electrolyte losses which often precede the onset of coma (occurring in about 10% of cases of ketoacidosis). The duration of symptoms is typically short, over days to weeks. It is more usually diagnosed in people <40 years old, but can occur later; the peak age of onset is 12 years old. Twenty-five per cent of hospital admissions with diabetic ketoacidosis are a first presentation of type 1 diabetes. Diabetic ketoacidosis is precipitated in 30%–50% cases by infection, 25% of cases relate to poor compliance with therapy, and 10%–13% with inappropriate dose adjustments.

Table 184.1 Blood glucose levels for the diagnosis of diabetes mellitus

Condition	Glucose test	Venous plasma glucose (mmol/l)
Normal	Fasting	<6.0
	Two-hour postprandial	<7.8
Diabetes	Fasting	>7.0
	Two-hour postprandial	>11.1
Impaired glucose tolerance	Fasting	<7.0
	Two-hour postprandial	7.8–11.1
Impaired fasting glycaemia	Fasting	6.0–6.9

The presence of ketones in the urine (++) or more on dip testing) and blood (normal <1.0 mmol/l, ketonaemia >3 mmol/l), with or without metabolic acidosis (arterial pH <7.28, or venous pH <7.3) aids the diagnosis. In obese patients and in those of Afro-Caribbean origin, in particular those from sub-Saharan Africa, type 2 diabetes may present with ketoacidosis. The family history and phenotype of the patient are therefore also useful for making an accurate diagnosis. In patients where the diagnosis is equivocal, measurement of anti-glutamic-acid-decarboxylase and anti-islet-cell antibodies can help to clarify this (e.g. antibody-negative, overweight patients may not need insulin once they recover).

Type 2 diabetes

Type 2 diabetes is a common condition affecting 1 in 10 people over 65 years of age in the UK, with many having evidence of end-organ damage at the time of diagnosis. It is a combination of insulin resistance and an insulin secretory defect or pancreatic 'pump' failure.

Other types of diabetes

While type 1 and type 2 diabetes account for the majority of cases seen, other forms to consider include:

- genetic defects of beta-cell function:
 - maturity-onset diabetes of the young (MODY)
 - mutations in: HNF4B (Chromosome 20; MODY 1), GCK (Chromosome 7; MODY 2), HNF1A (Chromosome 12; MODY 3), IPF1 (Chromosome 13; MODY 4)
 - the mitochondrial DNA 3242 mutation
 - mutations associated with neonatal diabetes (KIR6.2, SUR)
- other defects:
 - genetic defects of insulin action
 - type A insulin resistance
 - leprechaunism (type 2 diabetes, intrauterine growth retardation + dysmorphic features)
 - Rabson–Mendenhall syndrome (diabetes mellitus + pineal hyperplasia + acanthosis nigricans)
 - lipotrophic diabetes
 - diseases of the exocrine pancreas
 - pancreatitis
 - trauma/surgery (pancreatectomy)
 - neoplasia
 - pancreatic destruction (e.g. cystic fibrosis, haemochromatosis)

- endocrinopathies (e.g. Cushing's syndrome, acromegaly, pheochromocytoma, glucagonoma, hyperthyroidism, somatostatinoma)
- drug- or chemical-induced diabetes mellitus
- infections (e.g. congenital rubella or CMV)
- uncommon forms of immune-mediated diabetes (e.g. anti-insulin-receptor antibodies, stiff man syndrome (type 1 diabetes, rigidity of muscles, painful spasms))
- Wolfram syndrome (or DIDMOAD: diabetes insipidus, diabetes mellitus, optic atrophy + deafness (sensorineural))
- other genetic syndromes associated with diabetes: these include Down's syndrome, Klinefelter syndrome, Laurence–Moon–Biedl syndrome, myotonic dystrophy, Prader–Willi syndrome and Turner's syndrome
- gestational diabetes

Aetiology

Table 184.2 outlines the different types of diabetes and their frequency, potential mechanisms, and symptoms.

Demographics

The incidence of diabetes mellitus is increasing rapidly. Type 2 diabetes is more common in developed countries, although both types occur throughout the world. One in three Americans born after 2000 will potentially develop diabetes in their lifetime. Asian and African populations are likely to have the greatest increases in prevalence. An increasing incidence of diabetes in developing countries follows the trend of urbanization and lifestyle changes particularly associated with a 'Western' diet and lifestyle. There is a higher prevalence and increasing incidence of diabetes in indigenous populations in first-world countries than in their corresponding non-indigenous populations. In Australia the age-standardized prevalence of self-reported diabetes in Indigenous Australians is almost four times that of non-indigenous Australians. The Centers for Disease Control and Prevention have termed the change an epidemic. The National Diabetes Information Clearinghouse estimates that diabetes costs \$132 billion/year in the United States.

Diabetes mellitus prevalence increases with age, and the numbers of older persons with diabetes are expected to grow as the elderly population increases in number. Insulin production decreases because of age-related impairment of pancreatic beta cells. Additionally, insulin resistance increases because of the loss of lean tissue and the accumulation of fat, particularly intra-abdominal fat, and the decreased tissue sensitivity to insulin.

Table 184.2 The aetiology of diabetes

	Type 1 diabetes (previously known as insulin-dependent diabetes mellitus)	Type 2 diabetes (previously known as non-insulin-dependent diabetes mellitus)	Maturity-onset diabetes of the young	Latent autoimmune diabetes in adults	Gestational diabetes (diabetes occurring during or first diagnosed in pregnancy)
Frequency	5%–25% of cases	75%–95%	1%–5%	10% of cases of type 2 diabetes	2%–5% of pregnancies
Potential mechanism	Destruction of insulin-producing beta cells in the pancreas by antibodies, alcohol, cystic fibrosis, surgery, neoplasia, pancreatitis, etc.	Combination of genetic and environmental factors; there are also secondary causes, such as acromegaly and Cushing's syndrome	Autosomal or mitochondrial gene mutations presenting as type 2 diabetes by <30 years of age	GAD antibodies to beta cells	A combination of relatively inadequate insulin secretion and responsiveness during pregnancy
Antibodies	ICA, IA2, GAD65, IAA	None	None	Mostly GAD65	None
Potential effect/problem	Absence or deficiency of insulin	Combined resistance to and relative deficiency of insulin	Defects in beta-cell function	Insulin deficiency	Combined resistance to and relative deficiency of insulin
Symptoms	Rapid onset of symptoms (weeks–months)	Insidious onset over years; may be asymptomatic	May have an insidious onset over years; may be asymptomatic	Onset of symptoms may be rapid (weeks–months)	May be asymptomatic; macrosomia and hypoglycaemia soon after birth in the baby

Abbreviations: GAD65, glutamic acid decarboxylase autoantibody; IA2, islet antigen 2 autoantibody; IAA, insulin autoantibody; ICA, islet cell autoantibody.

Complications

Acute complications (hypoglycaemia, ketoacidosis, or non-ketotic hyperosmolar coma) may occur if the disease is not adequately controlled. Patient education, understanding, and participation is vital since the complications of diabetes are far less common and less severe in people who have well-controlled blood glucose levels. Serious long-term complications include cardiovascular disease (doubled risk), chronic renal failure (commonest reason for dialysis in the UK and the US), retinal damage (which is believed to be the commonest cause of blindness in the working population of the Western world) and nerve damage. Poor healing of wounds, particularly of the feet, can lead to gangrene, and possibly to amputation (diabetes is the leading cause for non-traumatic lower limb amputation in adults). Adequate treatment of diabetes, as well as increased emphasis on lipid and blood pressure control and lifestyle factors (such as not smoking and maintaining a healthy body weight), may improve the risk profile of most chronic complications. Lifestyle modification may also help prevent people predisposed to type 2 diabetes and those at prediabetic stages from developing type 2 diabetes. Although few people actually go into total 'remission' as a result of lifestyle modification, exercise, and weight loss, some with type 2 diabetes may find they need less oral hypoglycaemic agent or insulin therapy since the body tends to have lower insulin requirements during and shortly following exercise.

Other relevant investigations

While not used for diagnosis, an elevated level of glucose irreversibly bound to haemoglobin (termed 'glycosylated haemoglobin', or 'Hb A1c') of 6.0% (42 mmol/mol) or higher (the 2003 revised US standard) is considered abnormal by most labs, and is starting to be considered as a diagnostic tool. The units for Hb A1c are changing from percentage to millimoles of Hb A1c per mole of haemoglobin. Hb A1c is primarily used as a treatment-tracking test reflecting average blood glucose levels over the preceding 90 days (approximately). However, some physicians may order this test at the time of diagnosis to track changes over time. The current recommended goal for Hb A1c in patients with diabetes is 6.5%–7.5% (48–58 mmol/mol) but physicians often aim for <7.0% (53 mmol/mol), which is considered good glycaemic control, although some guidelines are stricter (<6.5% or 48 mmol/mol). People with diabetes with Hb A1c levels within this range have a significantly lower incidence of complications such as retinopathy and nephropathy.

Treatments

After diagnosis, all patients with diabetes need to see a dietician and a diabetes nurse specialist and have a full medical assessment. The first priority is to decide whether the patient has type 1 or type 2 diabetes, as patients with type 1 diabetes need insulin immediately. Patients with type 2 diabetes need initial dietary advice with or without medication. Typically, metformin was added in after 3 months of diet and exercise alone but is now recommended to be added in at diagnosis. The advice given should always take into account the patient's circumstances and culture and be individually tailored in order to be achievable.

The education of all newly diagnosed patients is intended to provide an incentive for good compliance. A full education package should include:

- an explanation as to what diabetes is and what it means to the patient
- aims of treatment, (e.g. rationale of reducing complications and exact values of blood glucose, Hb A1c, lipids, and blood pressure to aim for)
- types of treatment—not just drugs but also dietary advice and lifestyle modification such as increased physical activity, stopping smoking, and, if needed, reducing alcohol intake
- self-monitoring (e.g. the method(s) of doing this, the reasons for doing it, the target fasting and postprandial levels for that individual (e.g. 4.5–7.0 mmol/l fasting and 4.5–9.0 mmol/l postprandial) and what to do with the results (e.g. whether to alter therapy or not))
- an idea of some chronic complications of diabetes and what to look out for (e.g. a podiatrist's input and review is advised,

especially for those with type 2 diabetes) and reinforcing the need for regular checks (e.g. annual eye screening)

- advice regarding DVLA, insurance companies, and Diabetes UK

While insulin therapy is mandatory from diagnosis in all people with type 1 diabetes, patients with type 2 diabetes should be entered into an educational package with an initial trial of diet, exercise, and weight reduction (if obese, which most will be) with consideration of **metformin** in most patients, especially the overweight, and possibly **sulfonylureas** in the lean, if there are no contraindications. After this initial assessment, all patients should be put into a formal review system, whether by their GP or in a hospital diabetic clinic, for further education, maintenance of good control, and complication screening.

General management and treatment

Dietary advice

In the overweight patient (e.g. BMI >25) a reduction in total calorie intake to aid weight reduction is also required. A standard diabetic diet should aim to have:

- <10% of its energy in the form of saturated fat (<8% if the patient is hyperlipidaemic)
- <30% from all fats
- 50%–60% as carbohydrate, mostly consisting of complex high fibre carbohydrates
- sugar limited to about 25 g/day
- sodium content <6 g/day in most people, or <3 g/day if the patient is hypertensive

Alcohol is a significant source of calories, and reducing alcohol consumption by the overweight or hypertriglyceridaemic patient is advisable. The current 'standard' diet for a person with diabetes is a weight-reducing, low-fat, low-glycaemic-index diet with a reduction in sodium content, as most patients will have type 2 diabetes and are slightly overweight; this needs to be modified according to the individual patient, however.

Oral hypoglycaemic agents

Biguanides

Metformin is the first-line therapy in the obese or in overweight people with type 2 diabetes and is also used in some insulin-treated, insulin-resistant, overweight subjects to reduce insulin requirements. The UK Prospective Diabetes Study (UKPDS) showed significantly better results from metformin for complications and mortality compared to other therapies in the overweight patient with type 2 diabetes. Although a 1–2 kg weight loss is seen initially after the start of metformin usage, UKPDS data suggests metformin does not significantly alter weight over a 10-year period.

Metformin's mode of action

Metformin works by decreasing hepatic gluconeogenesis and increasing muscle glucose uptake/metabolism, so increasing insulin sensitivity. With long-term use a 0.8%–2.0% reduction in Hb A1c occurs.

Side effects/contraindications of metformin

Metformin is contraindicated in patients with renal (suggested as a creatinine >140 nmol/l, although an estimated glomerular filtration rate <30 has also been suggested), hepatic, or cardiac impairment, or who consume significant amounts of alcohol. Gastrointestinal side effects include nausea, epigastric discomfort, and diarrhoea and occur in up to half of patients in the first 1–2 weeks of treatment, but are usually transient. If the starting dose is low (e.g. 500 mg once daily) and it is taken with food, this can be reduced and many people develop a tolerance to these symptoms and are able to take higher doses; <5% are totally intolerant. Rarely, skin rashes and lactic acidosis occur. The latter, when seen, is usually in patients with significant sepsis, hepatic, renal, or cardiac impairment. Using radiological contrast media with metformin is associated with an increased risk of lactic acidosis and therapy should be stopped at the time of or prior to such investigations and restarted 2 days after the test unless renal function has been affected by the procedure, in which case, delay until this has resolved. Lactic acidosis occurs very infrequently (e.g. 0.024–0.15 cases/1000 patient years in a Swedish study). Although

it is known to reduce folic acid and vitamin B₁₂ absorption, this is not usually a significant problem clinically with metformin.

Sulfonylureas

Sulfonylureas are used as a first-line treatment in non-obese patients with type 2 diabetes. The first-generation agents chlorpropamide, tolbutamide, and tolazamide are rarely used today. Instead, second-generation agents such as glibenclamide, gliclazide, and glipizide are now more commonly used. Third-generation agents, such as glimepiride, are also available.

Mode of action of Sulfonylureas

Sulfonylureas act by stimulating a receptor on the surface of beta cells, closing a potassium channel and opening a calcium channel, with subsequent insulin release. A doubling of glucose-stimulated insulin secretion can be expected, with both first- and second-phase insulin secretion affected. This results in a 1%–2% reduction in Hb A1c long term.

Side effects of Sulfonylureas

The side effects of Sulfonylureas are hypoglycaemia and weight gain. In the UKPDS, the mean weight gain seen after 10 years of sulfonylurea therapy was 2.3 kg, while the incidence of major hypoglycaemic events was 0.4%–0.6%/year. The elderly are particularly at risk of hypoglycaemia with longer-acting agents such as glibenclamide and these should be avoided in that age group. Occasional skin reactions, alterations in liver function tests, and minor gastrointestinal symptoms may occur. Also avoid sulfonylureas in porphyria.

Prandial glucose regulators

Prandial glucose regulators can be used in type 2 patients who have inadequate control on diet or metformin, predominantly targeting postprandial hyperglycaemia due to their short duration of action.

Repaglinide, a carbamoylmethyl benzoic acid derivative, is a non-sulfonylurea oral hypoglycaemic agent which stimulates the secretion of insulin from pancreatic beta cells. It works on separate parts of the beta-cell sulfonylurea receptor from the sulfonylureas. Its use results in an approximate 0.6%–2% reduction in Hb A1c levels. Its very short duration of action reduces the risk of hypoglycaemia, compared to some sulfonylureas. It has an insulinotropic effect within 30 minutes of oral administration and causes a return to normal insulin levels within 4–6 hours (the elimination half-life is around 1 hour). It should not, however, be used in patients with renal or hepatic impairment and may result in hepatic dysfunction, so periodic liver function test monitoring is required.

Nateglinide is a D-phenylalanine derivative with an insulinotropic effect within 15 minutes of oral administration and causes a return to normal insulin levels by 2 hours (the elimination half-life is 1.5 hours), so reducing the risk of subsequent hypoglycaemia. Its efficacy is similar to that of repaglinide.

Alpha-glucosidase inhibitors

Alpha-glucosidase inhibitors are used in type 2 patients who have inadequate control on diet or other oral agent alone. When taken with food, acarbose reduces postprandial glucose peaks by inhibiting the digestive enzyme alpha-glucosidase, which normally breaks carbohydrates into their monosaccharide components, thus retarding glucose uptake from the intestine and reducing postprandial glucose peaks. Some improvement in lipids has also been reported.

These undigested carbohydrates then pass into the large intestine, where bacteria metabolize them, which may explain the common side effects of postprandial fullness/bloating, abdominal pain, flatulence, and diarrhoea. Starting at 50 mg once daily and gradually increasing the dose at 2–3 weekly intervals to a maximum of 200 mg three times per day improves tolerance to this therapy. Less commonly, jaundice and elevated hepatic transaminase levels can also be seen. In the UKPDS, adding acarbose to other therapies resulted in a further 0.5% drop in Hb A1c.

Thiazolidinediones

Thiazolidinediones act as insulin-sensitizing agents by activating the peroxisome proliferator-activated receptor, which stimulates gene transcription for glucose transporter molecules such as GLUT1 and

GLUT4. The first of this class was troglitazone, which was withdrawn soon after its UK launch because of reports of hepatotoxicity but was still used in other countries until newer agents were available. Rosiglitazone was withdrawn due to cardiovascular concerns. Pioglitazone gives a 0.6%–2.0% drop in Hb A1c. It does not seem to have the same problem with hepatotoxicity, and there is often an improvement in liver function, especially with non-alcoholic steatohepatitis. Although the risk of hepatic dysfunction is not high with this drug, initial checks of liver function and monitoring of liver function tests are still currently advised. In view of the more common problem with fluid retention, avoidance in heart failure is also strongly suggested. The indication for using these agents varies around the world and in the UK they are used in combination with other oral agents but not with insulin, although the combination with insulin is licensed in the US. Recent studies suggest a possible link with osteoporosis, and side effects also include fluid retention, weight gain, and hepatotoxicity.

The incretin system (glucagon-like polypeptide-1 mimetics and dipeptidyl peptidase-4 inhibitors)

Glucagon-like polypeptide-1 (GLP-1) and gastrointestinal polypeptide are hormones made in the L-cells of the jejunum and ileum in response to a food load entering the gastrointestinal tract. These incretin hormones stimulate glucose-dependent insulin secretion, suppress glucagon secretion, and slow gastric emptying, with an improvement in insulin sensitivity.

Exenatide (Byetta) is a GLP-1 mimetic taken as a twice-daily injection of 5 µg or 10 µg doses or as a once-weekly 2 mg modified-release depot injection with a 0.6%–0.8% reduction in Hb A1c after 30 weeks use and a 1.6–2.8 kg weight loss over the same period. Liraglutide 1.2 mg is a once-daily version.

Dipeptidyl peptidase-4 (DPP-4) breaks down gastric inhibitory polypeptide and GLP-1 and this enzyme can be inhibited by oral drugs such as sitagliptin, vildagliptin, saxagliptin and linagliptin (i.e. DPP-4 inhibitors) with a resultant 0.4%–0.7% reduction in Hb A1c over a 12-month period and are weight neutral, if not helping to reduce weight. Liver monitoring with vildagliptin is currently recommended, and linagliptin needs no dose adjustment in renal impairment.

Side effects of incretin-system drugs

Side effects of incretin-system drugs are as follows:

- sitagliptin: gastrointestinal disturbance, upper respiratory tract infection, nasopharyngitis, and peripheral oedema
- vildagliptin: as for sitagliptin, plus abnormal liver function tests
- exenatide: gastrointestinal upset with nausea, vomiting, abdominal distension, diarrhoea, headache, dizziness, increased sweating, and injection site reactions

Gliflozins (sodium glucose transport protein 2, or SGLT-2 inhibitors)

The SGLT-2 inhibitors block reabsorption of glucose in the kidney, by inhibiting a pathway in the kidney, which normally exchanges sodium for glucose, this can cause people to lose up to 70g of glucose in the urine daily, is independent of insulin action, and whilst reducing circulating glucose, also helps reduce weight in view of the calories lost by this glycosuria. Potential electrolyte loss and an increased risk of lower urinary tract infections need to be monitored.

Insulin

Insulin is required in all patients with type 1 diabetes, and some with type 2, for the preservation of life; in other patients with type 2 diabetes, it is needed to achieve better glycaemic/metabolic control or for the relief of hyperglycaemic symptoms. Most insulin is now in a biosynthetic human form (from yeast or bacteria) but there is also a sizable minority of patients still taking bovine or porcine insulin. Bovine insulin is extracted from cattle pancreas and is more antigenic than both human and porcine alternatives and so gives more lipohypertrophy and lipoatrophy.

Insulin can be given by IV or subcutaneous routes; more recently, short-acting insulin was also given as an inhaled formulation, but this

was recently withdrawn. Standard insulins come as 10 ml vials for use with a 0.5 ml or 1.0 ml syringe or as 3.0 ml cartridges for use in pen devices. The insulin itself is unmodified/neutral or mixed with agents such as protamine or zinc to alter its onset of action, peak effect, and duration of action. Human insulin analogues that give more rapid onset or greater duration of action are also widely available and used. There are >30 types of insulin preparation available, which should allow full 24-hour cover for a wide variety of lifestyles.

The main problems with all insulin regimens are weight gain and hypoglycaemia. The latter occurring overnight can be troublesome, especially as the patient may not know it has occurred and may just react to the morning hyperglycaemia by increasing their evening insulin dose. Occasional checks of 3 am blood glucose levels may help sort this out. Care with alcohol and adjustments of insulin and pre-bed snacks if nocturnal physical activity such as sex is on the cards will also reduce nocturnal 'hypos'.

Types of insulin

Short-acting (soluble/neutral) insulins

Unmodified or neutral insulins are short-acting but are not identical. Humulin® S has an onset 30 min after injection, with a peak onset at 2–3 hours and a duration of up to 6–8 hours. In contrast, Hypurin® Porcine Neutral has an onset 60 minutes after injection, with a peak at 2–5 hours, and a duration of 6–8 hours. All the soluble human formulations require a 20–30-minute interval between injecting and eating to be maximally effective.

Insulin analogues

Insulin lispro, insulin aspart, and insulin glulisine have been modified to allow injecting and eating to occur simultaneously, as they have a more rapid onset of action and earlier peak effect, with peak blood insulin levels approximately 1.5–2.5 times that from the same dose of standard neutral human insulin. The duration of action is also shorter at 5 hours and this may cause problems if there are long gaps between meals.

Long-acting analogues such as insulin glargine and insulin detemir are also available, which give a flatter profile with a duration of action of 22–24 hours. These can be used as part of a basal bolus regimen with short-acting analogues or standard soluble insulins. They appear to be associated with less hypoglycaemia than other background insulins and may reduce the risk of nocturnal hypoglycaemia. Their use as a once-daily insulin alone or in combination with oral agents such as glimepiride or the prandial glucose regulators is also proving popular in the elderly type 2 patient.

While insulin glargine has a slightly longer duration of action, making it a popular once-daily preparation, insulin detemir, because of its albumin-binding properties, is reported to give less between-dose variability in the same individual and, with a duration of action of 20–22 hours, may be used in similar situations, although a significant proportion of people need to use it twice daily.

Intermediate-acting (isophane) insulins

Insulin action can be extended by the addition of protamine to give isophane insulin, with an onset of action 1–2 hours after injection, a peak at 4–6 hours, and a duration of action of 8–14 hours. Different preparations have slightly different profiles when looking at peak effect and maximal insulin concentrations, as with soluble preparations.

Biphasic/mixed insulins

Combinations of soluble/neutral insulins or short-acting insulin analogues with isophane insulins are extremely popular. The amount of soluble insulin present varies from 10%–50%, with 30% being the most popular. Depending on its monocomponents, onset is normally at 30 minutes, the peak effect is at 2–6 hours, and the duration is at 8–12 hours. Insulin analogue biphasic preparations have an onset, peak, and duration all slightly shorter than these.

Insulin regimens

Twice-daily free mixing

Twice-daily free mixing was historically very popular, although now it is used much more rarely. The usual starting regimen was two-thirds isophane insulin and one-third soluble insulin, with two-thirds

of the total daily dose given before breakfast, and one-third before the evening meal. The main problems are (1) mixing the two types of insulin, and (2) pre-lunch hypos. If on the same doses twice daily, watch out for pre-evening-meal hyperglycaemia and increase the morning isophane dose to compensate for this, with a reduction in the morning soluble insulin dose often needed to reduce pre-lunch hypoglycaemia.

Twice-daily fixed mixture

Most commonly, a twice-daily fixed mixture consists of 30% soluble insulin and 70% isophane insulin; although this is not ideal for pre-lunch control or alterations in diet and exercise that are not pre-planned, it is indicated in type 2 patients with poor control, those with significant osmotic symptoms, and those in whom there is no room to increase oral agents. A suitable starting regimen is a 30:70 mixture, with two-thirds taken before breakfast, and one-third before the evening meal. The exact doses tend to vary widely depending on insulin sensitivity but a reasonable starting regimen may be 10–15 units before breakfast, and 5–10 units before the evening meal.

Basal bolus regimen

In a basal bolus regimen, soluble insulin or an insulin analogue is given three times per day in pre-meal doses, with a pre-bed dose of isophane insulin or a long-acting insulin analogue; this regimen potentially has more flexibility with meal times, portions, and exercise than the previous regimens. The larger number of injections and the more frequent capillary blood glucose measurements needed makes it less popular with some patients.

If starting with a basal bolus regimen as the first type of insulin regimen, give three equal pre-meal doses and alter as required (e.g. 4–6 units is a reasonable starting dose, with 6–8 units of isophane insulin before bed). If converting to a basal bolus regimen from a twice-daily biphasic regimen, you need to reduce the total daily insulin dose by up to 10%. Initially, give 30%–50% of the total daily insulin needed as a pre-bedtime dose of isophane insulin or a long-acting insulin analogue and split the remaining insulin evenly between the meals as soluble or short-acting insulin analogue. Once the patient is on this regimen, the evening isophane insulin or insulin analogue often needs to be increased to maintain adequate fasting sugars.

In patients using short-acting insulin analogues and, less often, those on standard soluble insulins, a twice-daily dose of isophane insulin or a long-acting insulin analogue is occasionally needed, especially if there is a long gap between lunch and the evening meal.

Continuous subcutaneous insulin infusion

Continuous subcutaneous insulin infusion is used in the US but not as commonly in the UK, possibly because of cost issues as well as potential problems with pump failure, ketoacidosis, and cannula site infections, although, with improvements in technology, these are less common problems now. Soluble insulin or a short-acting insulin analogue is given continuously via a subcutaneous cannula into the anterior abdomen. National Institute of Clinical Excellence guidance on the use of insulin pumps is available and worth reading.

Insulin and oral agent mixtures

In type 2 patients, several combinations are occasionally used. The two most popular are bedtime insulin plus daytime tablets, or more frequent insulin plus metformin. In the first, oral agents continue during the day with a pre-bed dose of isophane insulin or a long-acting insulin analogue used to give acceptable fasting sugars before breakfast. Although often starting at 10 units/night, doses five to six times that are not infrequently needed. This regimen is suitable if someone else such as a district nurse or relative gives the insulin. The second regimen adds up to 2 g/day of metformin to any standard insulin regimen to reduce insulin requirements and improve control without the problem of further weight gain often seen if the insulin is continually increased.

185 Hypoglycaemia

Kevin Shotliff

Introduction

Hypoglycaemia, which is a common complication of the treatment of diabetes, should be excluded in any unconscious or fitting patient, even if diabetes is not known. If prolonged, it can result in death. Most insulin-treated patients can expect to experience hypoglycaemic episodes at some time, with up to one in seven having a more severe episode each year, and 3% suffering recurrent episodes. In addition, 25% of people on long-term insulin lose their hypoglycaemic awareness, and these are of particular concern. Nocturnal hypoglycaemic episodes with a hyperglycaemic response the next morning (due to increased counter-regulatory hormones—the Somogyi phenomenon) tend to occur in younger insulin-treated patients; such episodes should not be forgotten, although it may only present with morning headaches or a 'drunken' feeling.

Definition/diagnosis

Hypoglycaemia is a biochemical diagnosis made when the blood glucose is <2.5 mmol/l and the patient shows symptoms of neuroglycopenia. However, it is often first picked up by the patient, their family, or their doctor from the symptoms listed in 'Clinical features'. In any patient not known to have diabetes, a detailed screen should be undertaken to determine the cause.

Pathogenesis

Hypoglycaemia occurs when there are imbalances between the glucose supply, glucose utilization, and the insulin level so that there is more insulin than is needed at that time. A reduced glucose supply can occur when a meal or snack is missed, or as a late effect of alcohol, which reduces hepatic gluconeogenesis. It can also be due to delayed gastric emptying with autonomic neuropathy, be associated with malabsorptive states such as coeliac disease, Addison's disease, or an acute illness, such as gastroenteritis. Increased utilization of glucose occurs with exercise, and high insulin levels (exogenous or endogenous) occur mostly with sulfonylurea or exogenous insulin therapy and rarely with insulinomas (incidence of 1–2 per million per year). The net result of such imbalances is hypoglycaemia.

Therapies for people with diabetes and hypoglycaemia

Human insulin therapies have a slightly faster onset of action and a shorter duration of action than their animal predecessors, and many patients report alterations in hypoglycaemic awareness when they switch from one to the other. Even so, no definite evidence of specific hypoglycaemic alterations due to human insulin itself has been reported. The shorter-acting insulin analogues may have a similar effect in some patients, compared to standard human insulin therapies, as well.

Sulfonylurea therapy can cause hypoglycaemia due to beta cell stimulation. This is most commonly seen from **glibenclamide (~50% greater risk of hypoglycaemia with this agent than with other secretagogues)**, especially in the elderly and those with reduced renal excreting ability, but can occur in anyone who takes this therapy and fasts.

Other secretagogues can have a similar effect to sulphonylureas, such as the meglitinides (e.g. nateglinide and repaglinide) as can insulin-sensitizing agents such as angiotensin-converting-enzyme inhibitors

and thiazolidinediones (e.g. **pioglitazone**). But the biguanide **metformin** and the alpha-glucosidase inhibitor **acarbose** are unlikely to precipitate hypoglycaemia.

Hypoglycaemia in those without known diabetes

In patients without known diabetes who are not taking drugs known to cause hypoglycaemia, other causes need to be sought. These are typically split into either fasting hypoglycaemia (occurring >5 hours after food) or reactive/postprandial hypoglycaemia (typically occurring 2–5 hours after food). The main conditions to consider/exclude in these patients are:

- drug-induced hypoglycaemia resulting from:
 - exogenous insulin or sulfonylurea therapy (either deliberate or accidental)
 - alcohol (impairs gluconeogenesis and alters glycogen stores)
 - salicylates (alters hepatic glucose efflux)
 - quinine (causes hyperinsulinaemia)
- infections:
 - septicæmia (e.g. Gram-negative or meningococcus septicæmia) has high metabolic requirements and causes a reduced energy intake
- tumours:
 - insulinomas (85% benign, 15% malignant)
 - non-islet cell tumours (e.g. large mesenchymal tumours such as fibrosarcomas)
- hormone deficiency:
 - Addison's disease
 - hypopituitarism
 - growth hormone deficiency
- organ failure:
 - acute liver failure
 - chronic renal failure
- starvation:
 - anorexia nervosa
 - kwashiorkor
- autoimmune disorders:
 - the presence of anti-insulin antibodies causing hypoglycaemia; this is a rare condition which is commonest in Japanese patients (insulin autoimmune syndrome, or Hirata's disease; strongly associated with HLA-DR4)
 - the presence of insulin-receptor activating antibodies (again rare but commonest in middle-aged women)
- inborn errors of metabolism
 - glycogen storage disease
 - hereditary fructose intolerance
 - maple syrup disease
- post-surgery hypoglycaemia:
 - post-gastrectomy hyperglycaemia (e.g. 'dumping'): rapid gastric emptying produces a greater-than-normal insulin response, causing an hypoglycaemic episode 2–3 hours postprandially

Clinical features

Hypoglycaemia should be considered in any patient with an unexplained collapse, loss of consciousness, or 'funny turn'. The features of hypoglycaemia can be divided into two main groups: autonomic symptoms and neuroglycopenic symptoms. The autonomic symptoms usually occur first (when the blood glucose is <3.6 mmol/l), but some drugs, such as alcohol and non-selective beta blockers, may mask these with neuroglycopenia (at a blood glucose <2.6 mmol/l) so that confusion then occurs with no warning. Some

patients lose these predominantly autonomic warning symptoms and are therefore at higher risk of injury. Typically, there is a deterioration in neuropsychological performance as the blood glucose falls to 3.0–3.5 mmol/l and there is a subjective perception of hypoglycaemia at 2.7–2.9 mmol/l. EEG changes are evident when the blood glucose falls to 2.0 mmol/l.

Signs and symptoms of hypoglycaemia

Autonomic

The autonomic symptoms of hypoglycaemia are:

- sweating
- pallor
- anxiety
- nausea
- tremor
- shivering
- palpitations
- tachycardia

Neuroglycopenic

The neuroglycopenic symptoms of hypoglycaemia are:

- confusion
- tiredness
- lack of concentration
- headache
- dizziness
- altered speech
- incoordination
- drowsiness
- aggression
- coma

Investigation

Capillary blood glucose testing strips are widely used but are unreliable for low glucose levels, and any symptomatic patient with a capillary testing strip reading <4.0 mmol/l should at least have a laboratory glucose measured. In view of the potential causes for this, any patient with hypoglycaemia and no obvious therapy for this should be investigated fully. Even diabetics who are taking oral or injectable therapies known to cause hypoglycaemia warrant further review. Renal dysfunction and hepatic dysfunction are both well-known causes and so initial tests should include:

- laboratory blood glucose
- urea and electrolytes
- liver function tests

In patients not known to have diabetes with hypoglycaemia, further investigation may be needed and can include:

- laboratory blood glucose
- insulin and C-peptide (if high insulin and no C-peptide consider exogenous insulin)
- beta-hydroxybutyrate (elevated in most cases but suppressed with insulinoma, sulphonylureas, and exogenous insulin)
- sulphonylurea screen
- cortisol \pm a short tetracosactide test
- consider insulin-like growth factors 1 (reduced) and 2 (high) if non-islet cell tumour hypoglycaemia suspected
- consider an autoimmune screen for anti-insulin and anti-insulin-receptor antibodies
- chest X-ray for fibrosarcoma, mesothelioma
- consider an overnight or 72-hour fast, to look at glucose/insulin levels

Management

In the conscious patient, oral carbohydrate (high glycaemic index and usually 20 g) is often sufficient to resolve the problem. This 20 g is equivalent to (can be given as):

- seven Dextrosol tablets
- four jelly babies
- 15–20 jelly beans
- 115 ml Lucozade (310 ml Lucozade Sport)
- 180 ml Coca-Cola
- 144 ml of a carton of Ribena
- 200 ml of milk

Having raised the sugar rapidly with a high-glycaemic-index food, then give the patient something to maintain a normal blood glucose level when this quick-acting carbohydrate wears out (e.g. a lower-glycaemic-index food such as a sandwich or two digestive biscuits). In the confused patient, buccal gels (e.g. a 30% glucose gel) are an alternative, although this should not be used in the unconscious patient as there is a risk of aspiration.

In the unconscious patient, once a blood sample has been taken for glucose estimation, treat with 25–50 ml of 50% IV glucose or 1 mg of intramuscular or deep subcutaneous glucagon. However, glucagon mobilizes glycogen from the liver and will not work if given repeatedly or in starved patients with no glycogen stores. In this situation or if prolonged treatment is needed, IV glucose is better (50% initially then 10%). The worry with 50% glucose is tissue necrosis if extravasation occurs; because of this, some units use 20% glucose initially and convert to 5% or 10% glucose for continuation therapy. The potential for larger fluid loads being needed to give the same amount of glucose with the lower concentration does not seem to be a problem in this situation but will need to be tailored to the individual patient.

Subsequent management

Having corrected the acute event, determine why it happened, especially if the patient is not known to have diabetes or to take therapy known to be associated with hypoglycaemic episodes. If possible, then alter treatment or lifestyle to keep the hyperglycaemia from recurring. Extreme exercise may require an alteration in insulin doses for 24 hours afterwards, and alcohol causes not only initial hyperglycaemia but also a degree of hypoglycaemia 3–6 hours after ingestion, and may alter insulin requirements the next morning. Education to avoid precipitating hypoglycaemic episodes in these situations is advisable. A severe hypoglycaemic episode may be associated with a deterioration in the patient's ability to respond, as well as a subsequent hypoglycaemic episode in the next few days, and education regarding care to adjust therapy and lifestyle to avoid this risk is important. During an acute hypoglycaemic event, patients who are on a long-acting sulphonylurea will need careful monitoring, as the drug may last longer than the glucose or glycogen given to correct it, and repeated hypoglycaemic episodes may occur. A continuous IV glucose infusion is therefore often needed for 24 hours, particularly in overdose with these agents. Repeated hypoglycaemic exposure or severe individual episodes can be associated with significant long-term cognitive impairment, although this is a rare end result.

186 Thyroid disease

John Newell-Price, Alia Munir, and Miguel Debono

Hypothyroidism

Definition of hypothyroidism

Hypothyroidism occurs when there is insufficient secretion of thyroid hormones, commonly caused by autoimmune disease. In primary hypothyroidism, the level of thyroid-stimulating hormone (TSH) is elevated, and that of free thyroxine (FT4) is reduced. However, when the origin of the hypothyroidism is pituitary or hypothalamic, FT4 is low and TSH is inappropriately normal or low. Subclinical hypothyroidism is when TSH levels are elevated in the context of an FT4 level in the normal range. Myxoedema is severe hypothyroidism with accumulation of mucopolysaccharides in the dermis and other tissues.

Aetiology of hypothyroidism

In the vast majority of cases, hypothyroidism is caused by autoimmune destruction of the thyroid. The different types of hypothyroidism and their causes are highlighted in Table 186.1

Typical symptoms of hypothyroidism, and less common symptoms

Non-specific onset symptoms include fatigue; lethargy; constipation; cold intolerance; muscle stiffness; cramps; carpal tunnel syndrome; menorrhagia; slowing of movements, deep tendon reflexes, and intellect; decreasing appetite and weight gain; dry skin and hair loss; hoarsening of voice; decreasing visual acuity and hearing; and obstructive sleep apnoea.

In severe hypothyroidism (myxoedema), there may be a dull, expressionless face; sparse hair; periorbital puffiness; macroglossia; and pale, cool skin that feels rough and doughy; but severe hypothyroidism is rare nowadays. Other features of hypothyroidism include an enlarged heart (dilated/pericardial effusion), megacolon/intestinal obstruction, cerebellar ataxia, psychiatric symptoms, peripheral neuropathy, and encephalopathy.

Demographics of hypothyroidism

Hypothyroidism affects 1% of the female population (it is much less common in men). Incidence increases with advancing age. Low dietary iodine and relative iodine deficiency appear to protect against hypothyroidism.

Natural history of hypothyroidism, and complications of the disease

Hypothyroidism is associated with atherosclerosis, hyponatraemia, hypercholesterolaemia, myopathy with raised creatine phosphokinase, and hypochromic microcytic anaemia. Homocysteine and lipoprotein levels may also be raised. Severe complications affect the elderly, and those with myxoedema coma tend to be elderly.

This group is also more likely to have undiagnosed hypothyroidism and thus is at a greater risk of developing perioperative complications.

Patients with subclinical hypothyroidism and positive autoantibodies should be treated, as there is a 5% per year rate of overt hypothyroidism.

Approach to diagnosing hypothyroidism

To diagnose hypothyroidism, measure the TSH level. If this is elevated, check the FT4 level and screen for autoantibodies.

Other diagnoses that should be considered aside from hypothyroidism

If a thyroiditis is suspected, do a full blood count (FBC) and check the erythrocyte sedimentation rate (ESR) and the level of C-reactive protein (CRP).

'Gold-standard' diagnostic test for hypothyroidism

The gold-standard diagnostic tests for hypothyroidism are the tests for TSH and FT4.

Acceptable diagnostic alternatives to the gold-standard tests for hypothyroidism

There are no acceptable diagnostic alternatives to the gold-standard tests for hypothyroidism.

Other relevant investigations for hypothyroidism

Always check the lipid profile and perform an FBC and a test for urea and electrolytes (U&E). In addition, consider investigations to exclude other autoimmune diseases such as type 1 diabetes mellitus, Addison's disease, premature ovarian failure, hypoparathyroidism, myasthenia gravis, and coeliac disease. Vitiligo and alopecia may also exist. Polyglandular autoimmune syndrome type I consists of hypothyroidism, Addison's disease, and mucocutaneous candidiasis.

Prognosis for hypothyroidism, and how to estimate it

Patients who have primary hypothyroidism but are on adequate thyroxine (T4) replacement therapy have a normal life expectancy. The mortality associated with myxoedema coma is very high (>80%).

Treatment of hypothyroidism, and its effectiveness

T4 replacement therapy should be started gradually, to avoid precipitation of arrhythmias. Start with 25–50 µg in the elderly, and 50–100

Table 186.1 The different types of hypothyroidism

Non-goitrous	Goitrous	Pituitary	Hypothalamic	Self-limiting
Post ablative	Chronic thyroiditis	Panhypopituitarism	Neoplasm	Following withdrawal of antithyroid therapy
Congenital defect	Iodine deficiency	Isolated thyroid-stimulating-hormone deficiency	Infiltrative	Subacute thyroiditis and chronic thyroiditis with transient hypothyroidism
Atrophic thyroiditis	Drug elicited		Congenital defect	Post-partum thyroiditis
Post radiation	Heritable biosynthetic defects		Infection	

µg in young patients. Optimize the dosage using TSH measurements approximately 8–10 weeks after any changes. For patients with central or secondary hypothyroidism, FT4 is measured.

Treatment of myxoedema coma

To treat myxoedema coma, treat the precipitating illness. Manage hypothermia by external warming, in the intensive care unit if the patient is comatose. Monitor for cardiac arrhythmias and use central venous pressure for cautious volume expansion.

Check cortisol prior to commencing treatment and replace if low, using hydrocortisone 100 mg IV four times per day. Thyroid replacement can be administered IV or via a nasogastric tube (NGT). Liaise with the pharmacy for preparations. Administer T4 300–500 µg IV or via an NGT; then, 50–100 µg per day until oral medication can be taken. If there is no improvement, give T3 10 µg IV three times per day.

Thyrotoxicosis

Definition of thyrotoxicosis

Thyrotoxicosis results from exposure to excessive thyroid hormone. The term 'hyperthyroidism' denotes only those conditions in which thyroid hyperfunction results in thyrotoxicosis. The most common cause of hyperthyroidism is Graves' disease.

Aetiology of thyrotoxicosis

The aetiology of thyrotoxicosis is outlined in Table 186.2.

Typical symptoms of thyrotoxicosis, and less common symptoms

Patients with thyrotoxicosis may present with hyperactivity; irritability; altered mood; insomnia; heat intolerance; increased sweating; palpitations; fatigue; weakness; dyspnoea; weight loss with increased appetite (weight gain in 10%); pruritus; increased stool frequency; and oligomenorrhoea, amenorrhoea, or loss of libido. Signs include sinus tachycardia; atrial fibrillation; fine tremor; hyperreflexia; warm, moist skin; palmar erythema; hair loss; and muscle weakness. Rarely, patients may develop onycholysis, chorea, high-output heart failure, and periodic paralysis.

Manifestations and conditions associated with Graves' disease

The following manifestations and conditions are associated with Graves' disease:

- diffuse goitre by palpation
- anti-thyroid peroxidase (anti-TPO) or anti-thyroglobulin antibodies (anti-TSH-receptor antibodies are not routinely measured but this test may be of use if the patient is pregnant)

Table 186.2 Aetiology of thyrotoxicosis

Associated with hyperthyroidism	
Excessive thyroid stimulation	<p>Graves' disease 80%, Hashitoxicosis</p> <p>Pituitary thyrotroph adenoma</p> <p>Pituitary thyroid hormone resistance syndrome (excess thyroid-stimulating hormone) (rare)</p> <p>Trophoblastic tumours producing Human chorionic gonadotropin with thyrotrophic activity (rare)</p>
Thyroid nodules with autonomous function	<p>Toxic solitary nodule, toxic multinodular goitre 20%</p> <p>Very rarely, thyroid cancer</p>
Not associated with hyperthyroidism	
Thyroid inflammation	Silent and post-partum thyroiditis, subacute (de Quervain's) thyroiditis
Exogenous thyroid hormones	Overtreatment with thyroid hormone Thyrotoxicosis factitia (thyroxine use in non-thyroidal disease)
Ectopic thyroid tissue	Metastatic thyroid carcinoma Struma ovarii (a teratoma containing functional thyroid tissue)

- ophthalmopathy, such as:
 - grittiness and discomfort of the eye
 - retrobulbar pressure/pain
 - eyelid lag or retraction
 - periorbital oedema
 - chemosis
 - scleral injection
 - exophthalmos
 - extraocular muscle dysfunction
 - exposure keratitis
 - optic neuritis
- localized dermatopathy
- lymphoid hyperplasia
- thyroid acropachy
- associated autoimmune disease in patient or family, such as:
 - type 1 diabetes
 - Addison's disease
 - vitiligo
 - pernicious anaemia
 - alopecia areata
 - myasthenia gravis
 - celiac disease
 - other autoimmune conditions associated with the HLA-DR3 haplotype

Demographics of thyrotoxicosis

Thyrotoxicosis is ten times more common in women than men in the UK. The prevalence in the female population is 2%, with an annual incidence of 3 per 1000 women. Graves' disease accounts for 70% of iodine-sufficient causes.

Natural history and complications of thyrotoxicosis

Graves' disease is caused by an autoimmune reaction to the thyroid, leading to the production of autoantibodies to the TSH receptor; these autoantibodies then mimic the action of TSH. Thirty to forty per cent of patients with Graves' disease have ophthalmopathy.

Toxic multinodular goitre and toxic adenoma, which cause 10% of all cases of thyrotoxicosis, are also common causes of thyrotoxicosis, particularly in iodine-deficient regions. Adenomas are benign, isolated thyroid tumours that independently secrete thyroid hormone. Extracapsular tissue may atrophy as the level of endogenous TSH becomes suppressed. Prevalence is thought to be 2.7%, occurring in the older female age group. There is slow growth over many years; eventually, this is enough to produce overt thyrotoxicosis. Twenty to eighty per cent of cases are thought to be due to a somatic mutation in TSH receptor gene. In other cases, the G_s alpha subunit of the TSH-receptor-coupled adenylate cyclase is mutated. Toxic multinodular goitre has a similar natural history; the slow growth and advanced age of patients frequently mean not many symptoms are reported.

Complications of thyrotoxicosis can occur in every system of the body, as follows:

- cardiovascular system: palpitations, atrial fibrillation, heart failure, angina
- respiratory system: decreased lung compliance, respiratory muscle weakness, exercise intolerance
- renal system: mild polyuria, oedema; occasionally, renal tubular acidosis liver and gastrointestinal tract: increased liver enzymes, hepatomegaly, autoimmune hepatitis, weight loss, hunger, diarrhoea
- muscles: weakness and fatigue, myasthenia gravis, hypokalaemic periodic paralysis
- bones: bone loss, osteoporosis, increased risk of fracture, thyroid acropachy
- reproductive system: disturbed menstrual cycle in females; increased libido and testosterone in males
- eyes (if Graves' ophthalmopathy): double vision, blindness

Approach to diagnosing thyrotoxicosis

The following groups should be screened for thyroid disease:

- patients with atrial fibrillation or hyperlipidaemia
- patients on amiodarone or lithium (6-monthly assessments)

- diabetics (annual review)
- women with type 1 diabetes, in the first trimester of pregnancy and in the post-partum period
- women with a history of post-partum thyroiditis
- patients with Down's syndrome, Addison's disease, or Turner's syndrome, in view of the high prevalence of hypothyroidism in these groups (annual review)

In thyrotoxicosis due to Graves' disease, thyroid function tests reveal a raised FT4 and suppressed TSH (alternatively, raised FT3 in T3 toxicosis). The following antithyroid antibodies are typically present: anti-TPO (70%–80% of cases), anti-thyroglobulin (30%–50% of cases), and anti-TSH receptor antibody (70%–100% of cases). A radioiodine scan may be considered if the diagnosis is uncertain; if the result is positive, the scan will show a diffuse high uptake of radioiodine.

Other diagnoses that should be considered aside from thyrotoxicosis

Other diagnoses that should be considered aside from thyrotoxicosis include T3 toxicosis (suppressed TSH with elevated FT3); euthyroid sick syndrome, which occurs in the context of severe illness, and starvation (biochemistry typically reveals a low T4 and T3 with an inappropriately normal/suppressed TSH); phaeochromocytoma; myeloproliferative disease; and diabetes mellitus.

'Gold-standard' diagnostic test for thyrotoxicosis

The gold-standard diagnostic tests for thyrotoxicosis are blood tests to check for:

- TSH suppression (<0.03 mU/l)
- elevation of FT4 and/or FT3 (usually, if TSH is suppressed, the FT4 test is performed automatically by the laboratory; if the FT4 test is normal, the FT3 level should be checked)
- autoantibodies

Acceptable diagnostic alternatives to the gold-standard tests for thyrotoxicosis

There are no acceptable diagnostic alternatives to the gold-standard tests for thyrotoxicosis.

Other relevant investigations for thyrotoxicosis

Other relevant investigations for thyrotoxicosis include:

- FBC
- U&E
- liver function tests
- ECG
- DEXA, if osteoporosis likely
- uptake scan, if the cause of the thyrotoxicosis is uncertain

Prognosis of thyrotoxicosis, and how to estimate it

If thyrotoxicosis is treated medically, there is a 40% remission rate at 5 years. If, at presentation, the FT3 is very high and there is a large goitre, relapse is likely within the first year, and definitive treatment should be considered.

If thyrotoxicosis is treated with radioiodine, 50%–70% of patients have restored thyroid function and goitre shrinkage at 8 weeks post treatment. If hyperthyroidism persists, it may be treated with a maximum of two further treatments. The incidence of hypothyroidism is 50% at 1 year.

If thyrotoxicosis is treated surgically with subtotal thyroidectomy, hypothyroidism occurs in 10%–20% of those treated, after 10 years.

Treatment of thyrotoxicosis, and its effectiveness

Medical treatment of thyrotoxicosis

Manage thyrotoxicosis initially with thionamides (carbimazole (CBZ) or propylthiouracil (PTU)). There are two regimens that can be used: block and replace (not in pregnancy), or dose titration.

There is a 50% chance of remission with medical treatment of thyrotoxicosis.

Block and replace

The procedure for block and replace is as follows:

- start CBZ 20 mg twice or three times per day, but warn of agranulocytosis (0.1%–5% of patients): if patients develop a sore throat or ulcers, they need to stop therapy and go for an FBC (a written warning sheet should be given)
- 3 weeks after starting block and replace, check the FT4 level:
 - if it is within the normal range, reduce CBZ to 40 mg daily and start T4 100 µg once daily
 - if it is 20–25 pmol/l, continue CBZ for a further week, and then add in the T4
 - if it is 25–35 pmol/l, continue the CBZ for a further 2 weeks and then add in the T4
 - if it is >35 pmol/l, review compliance or any other problems
- 4 weeks after starting block and replace, check the FT4 level again and alter T4 to maintain the FT4 level in the middle of the normal range
- review at 4 months
- stop treatment at 6–12 months
- review at 6 weeks after stopping to check for relapse
- if agranulocytosis develops, thionamides are contraindicated

Dose titration

Titrated therapy can be used in the long term; in pregnancy, PTU is used to avoid aplasia cutis. The procedure for the titration method is as follows:

- if the FT3 level is >6 pmol/l, start CBZ at 40 mg/day (or PTU 150 mg twice daily)
- check the FT4 level at 4–6 weeks and reduce the dose of CBZ to keep the TSH level within the normal range
- continue for 18 months

Note that relapses are more likely if the level of FT3 is high and the goitre is large.

Radioiodine therapy for thyrotoxicosis

Radioiodine therapy is the definitive treatment for multinodular goitre, adenoma, and relapsed Graves' disease. The following guidelines should be observed when performing radioiodine therapy:

- the patient should be clinically euthyroid, to avoid post-radioiodine thyroiditis
- the therapy must be performed by a specialist unit; in addition, it must be patient consented and discussed with both a consultant and an ARSAC holder
- technetium scanning may be required
- precautions are required, and written advice should be given
- radioiodine therapy is contraindicated in children, in pregnant or lactating women, and when the safety of others is in question
- care must be taken if the patient has Graves' ophthalmopathy, as radioiodine therapy may worsen eye signs, particularly in smokers; steroid cover may be indicated

Surgery for thyrotoxicosis

Indications for the use of surgery in the treatment of thyrotoxicosis include:

- a suspicious lesion
- pregnancy, when medical treatment has failed
- patients with poor compliance, relapsed Graves' disease, Graves' ophthalmopathy, or radioiodine failures/fears, or when radioiodine is contraindicated

Thyroiditis

Definition of thyroiditis

Thyroiditis is inflammation of the thyroid gland. It often leads to transient thyrotoxicosis followed by hypothyroidism.

Table 186.3 Cause and characteristic features of thyroiditis

Cause	Characteristic features
Autoimmune thyroiditis (Hashimoto's)	Grossly lymphocytic, and fibrotic thyrotoxicosis or hypothyroidism
Subacute de Quervain's	Viral
Pyogenic	Presence of <i>Staphylococcus aureus</i> , streptococci, <i>Escherichia coli</i> , TB, fungal pathogens
Post-partum thyroiditis	Chronic lymphocytic thyroiditis, transient thyrotoxicosis, or hypothyroidism
Riedel's thyroiditis (very rare)	Extensive fibrosis of the thyroid
Radiation thyroiditis	Transient thyrotoxicosis
Drug induced	Amiodarone use

Aetiology of thyroiditis

The causes and characteristic features of thyroiditis are outlined in Table 186.3.

Typical symptoms of thyroiditis, and less common symptoms

In autoimmune (Hashimoto's with a goitre) or atrophic (without a goitre) thyroiditis, there is usually hypothyroidism. Acute suppurative thyroiditis usually presents with a painful, tender thyroid, and thyroid function is usually normal. In subacute (de Quervain's) thyroiditis, there is malaise, arthralgia, and a recent upper respiratory tract infection with a painful neck; in addition, there is early thyrotoxicosis and late hypothyroidism.

Demographics of thyroiditis

Post-partum thyroiditis has a prevalence of 5%–7% and occurs in 30%–52% of women who are positive for anti-TPO antibodies.

Natural history of thyroiditis, and complications of the disease

In Hashimoto's the goitre is usually non-tender. In de Quervain's thyroiditis, there is an exquisitely tender and nodular thyroid. Symptoms are of malaise and pain. In mild cases, NSAIDs may help; in severe cases, steroids may be of use. Antithyroid drugs are not indicated, but T4 replacement may be required if the patient is rendered hypothyroid.

Post-partum thyroiditis occurs within the first 6 months after delivery; and in most cases, there is complete remission, but progression to hypothyroidism can occur. It is twice as common in patients with type 1 diabetes mellitus.

Riedel's thyroiditis is rare and is characterized by intense fibrosis of the gland and the surrounding region. There may be associated fibrosis of the mediastinum, the retroperitoneum, and the salivary, lacrimal, and parathyroid glands. Sclerosing cholangitis may also occur. Tamoxifen is the first-line treatment in this case, but surgery may be required.

Pyogenic thyroiditis is also rare, and occurs when there is sepsis elsewhere. There is redness and swelling of the thyroid, with systemic upset. Antibiotics, together with incision and drainage, are required.

Approach to diagnosing thyroiditis

After history and examination, the following tests should be used to establish the presence or absence of thyroiditis:

- thyroid function tests (TFTs)
- a screen for antithyroid antibodies
- ESR
- CRP
- FBC

Other diagnoses that should be considered aside from thyroiditis

If there is a dominant nodule, consider fine-needle aspiration biopsy (FNA). There is an association between Hashimoto's thyroiditis and thyroid lymphoma.

'Gold-standard' diagnostic test for thyroiditis

The gold-standard test for thyroiditis is a TSH test.

Acceptable diagnostic alternatives to the gold-standard test for thyroiditis

There are no acceptable diagnostic alternatives to the gold-standard test for thyroiditis.

Other relevant investigations for thyroiditis

Another relevant investigation for thyroiditis is a radionuclide (technetium) uptake scan; in subacute thyroiditis, the uptake is suppressed.

Prognosis of thyroiditis, and how to estimate it

The prognosis for Hashimoto's thyroiditis is good, as it can be optimally treated with T4 replacement. However, Reidel's thyroiditis can prove very difficult to treat, as not all cases respond to tamoxifen, and surgery is challenging due to the intense fibrotic reaction.

Treatment of thyroiditis, and its effectiveness

T4 replacement is very effective in the treatment of thyroiditis. If there is a rapidly increasing goitre in Hashimoto's (very unusual), steroids can sometimes help with pain.

Amiodarone-induced thyroid disease

Definition of amiodarone-induced thyroid disease

Amiodarone is a drug commonly used to treat arrhythmias. Amiodarone-induced thyrotoxicosis type I occurs as a result of iodine excess (due to the amount of iodine in amiodarone; see 'Aetiology of amiodarone-induced thyroid disease') in patients who have latent thyroid disease (usually multinodular goitre). Amiodarone-induced thyrotoxicosis type II is a destructive form of thyroiditis caused directly by amiodarone as a side effect of the drug. Differentiating between amiodarone-induced thyrotoxicosis types I and II is often difficult. Abnormalities of the thyroid occur in up to half of those on amiodarone therapy. Amiodarone-induced hypothyroidism may also occur on long-term amiodarone therapy.

Aetiology of amiodarone-induced thyroid disease

Amiodarone is 30% iodine: while the daily recommended iodine intake is 200 µg, the daily dose of amiodarone contains up to 21 mg of iodine. In addition, amiodarone closely resembles T4. In the euthyroid patient, acutely, there is a protective effect of the iodide concentrations (Wolff–Chaikoff effect), but the thyroid soon escapes this, and T4 production is restored to normal or even elevated. There is inhibition of the 5'-deiodination of T4 to T3 in the peripheral tissues, especially the liver. On treatment the TFTs are usually abnormal, but do not indicate thyrotoxicosis: TSH levels rise early on and then fall to low normal, while FT4 is usually at the upper end of normal or elevated, and FT3 is normal. Conversely, TSH levels may rise but, unless they are >10 mU/l and the FT3 is low, this is not usually indicative of hypothyroidism.

Typical symptoms of amiodarone-induced thyroid disease, and less common symptoms

Patients with amiodarone-induced thyrotoxicosis may present with very few symptoms, due to the inherent beta-blocking action of amiodarone. Amiodarone-induced hypothyroidism is commonly associated with lethargy or worsening heart failure.

Demographics of amiodarone-induced thyroid disease

About 2% of those on amiodarone develop amiodarone-induced thyrotoxicosis, and 6%–13% develop amiodarone-induced hypothyroidism. Those residing in iodine-deficient areas develop amiodarone-induced thyrotoxicosis, and those in high-intake areas develop amiodarone-induced hypothyroidism. Goitre may be associated with amiodarone-induced thyrotoxicosis type I. As the half-life of

amiodarone is up to 52 days, amiodarone-induced thyrotoxicosis can occur several months after discontinuing amiodarone. Amiodarone-induced hypothyroidism is more common in women, and those positive for autoantibodies.

Natural history of amiodarone-induced thyroid disease, and complications

Amiodarone-induced hypothyroidism

A significant proportion of amiodarone-induced hypothyroidism cases settle spontaneously. The risk of amiodarone-induced hypothyroidism is higher in elderly and female patients. When such patients are positive for autoantibodies, the relative risk increases to 13.5. The likely explanation is the inhibitory effects of iodine on T₄ release and synthesis. A goitre is found in about 20% of cases and usually predates use of the amiodarone. Many patients will eventually become euthyroid on stopping the amiodarone, particularly if there was no preexisting thyroid disease; however, stopping the drug may not be possible, due to the underlying cardiac disease. In amiodarone-induced hypothyroidism, amiodarone may be continued, T₄ added, and TSH monitored. In some patients, liothyronine may be needed, due to the inhibitory effects of amiodarone on the conversion of T₄ to T₃. All patients should be referred to a specialist.

Amiodarone-induced thyrotoxicosis

Amiodarone-induced thyrotoxicosis is less common and more complex than amiodarone-induced hypothyroidism and can be difficult to treat in some cases. Clinically, new arrhythmias may give rise to suspicion, as there may be few clinical signs due to the anti-adrenergic effects of amiodarone. Amiodarone-induced thyrotoxicosis occurs more frequently in men and is often acute in onset, but may spontaneously remit. There are two forms: amiodarone-induced thyrotoxicosis type I and amiodarone-induced thyrotoxicosis type II. Amiodarone-induced thyrotoxicosis type I is associated with latent Graves' disease or a multinodular goitre. Here, the iodine load accelerates the thyroid hormone synthesis. Amiodarone-induced thyrotoxicosis type II occurs in a normal thyroid, and the toxic effect of amiodarone causes a subacute thyroiditis. Distinguishing between amiodarone-induced thyrotoxicosis type I and amiodarone-induced thyrotoxicosis type II can be challenging, but Doppler flow ultrasound may show increased flow in amiodarone-induced thyrotoxicosis type I (see Table 186.4). However, in general, there may be a mixture of the two forms.

If amiodarone is withdrawn, the cardiac status may deteriorate, as the beta-blocking effects are lost. In addition, most patients with amiodarone-induced thyrotoxicosis type I still have hyperthyroidism 6–9 months after stopping amiodarone. Long-term follow-up is required, with 6-monthly tests even after remission, as there is a risk of relapse.

Table 186.4 Characteristics of amiodarone-induced thyrotoxicosis types I and II

	Type I	Type II
Underlying thyroid abnormality	Yes	No
Pathogenetic mechanism	Excessive hormone synthesis due to iodine excess	Excessive release of preformed hormones due to thyroid destruction
Goitre	Multinodular or diffuse goitre usually present	Occasionally small, diffuse, firm, sometimes tender
Thyroidal radioiodine uptake	Normal/raised	Low/absent
Serum IL-6	Normal/slightly raised	Profoundly raised
Thyroid USS/Doppler	Nodular, hyperechoic, increased volume	Decreased

Abbreviations: IL-6, interleukin 6; USS, ultrasound.
Reproduced from Newman et al *Heart* 1998;79:121–7.

Approach to diagnosing amiodarone-induced thyroid disease

Check TFTs every 6 months in patients on amiodarone. Look for signs of clinical thyroid disease and/or a goitre. If antithyroid antibodies are present, the radionuclide scan is normal, thyroglobulin and interleukin 6 (IL-6) levels are normal, and there is increased vascularity on vascular Doppler, then amiodarone-induced thyrotoxicosis type I (from iodine toxicity) is indicated. In amiodarone-induced thyrotoxicosis type II, there is a destructive thyroiditis, IL-6 and thyroglobulin levels are increased, and there is decreased uptake on radionuclide scan.

Other diagnoses that should be considered aside from amiodarone-induced thyroid disease

Other diagnoses that should be considered aside from amiodarone-induced thyroid disease include other side effects and complications of amiodarone.

'Gold-standard' diagnostic test for amiodarone-induced thyroid disease

The gold-standard tests for amiodarone-induced thyroid disease are baseline TSH and a screen for antithyroid antibodies. In addition, sex hormone-binding globulin is raised in thyrotoxicosis and is a useful marker where TFTs are equivocal and signs few.

Acceptable diagnostic alternatives to the gold-standard test for amiodarone-induced thyroid disease

There are no acceptable diagnostic alternatives to the gold-standard tests for amiodarone-induced thyroid disease.

Other relevant investigations for amiodarone-induced thyroid disease

Other relevant investigations for amiodarone-induced thyroid disease include a radionuclide scan, and a Doppler ultrasound scan of the thyroid. However, although these may be helpful, they are not often used in routine practice.

Prognosis of amiodarone-induced thyroid disease, and how to estimate it

Prolonged monitoring of TFTs is necessary on and after treatment with amiodarone in amiodarone-induced thyrotoxicosis as patients may become hypothyroid, and relapses occur in amiodarone-induced thyrotoxicosis type II. Complications can include thyroid storm; hypothyroidism; aplastic anaemia secondary to perchlorate use; agranulocytosis; and hepatitis from thioamides. The prognosis for amiodarone-induced hypothyroidism is usually good but for amiodarone-induced thyrotoxicosis it may be poor, as there is likely to be an underlying serious cardiac disorder.

Treatment of amiodarone-induced thyroid disease and its effectiveness

The first-line treatment for amiodarone-induced thyrotoxicosis type I is antithyroid medication (CBZ 30–60 mg/day; rarely, in combination with potassium perchlorate (1 g/day)). If possible, withdraw amiodarone, but this should be done on a case-by-case basis. Radioiodine is not usually effective in amiodarone-induced thyrotoxicosis type II, but surgery is successful, and used particularly if medical treatment is unsuccessful and amiodarone cannot be stopped. In amiodarone-induced thyrotoxicosis type II, steroids, such as prednisolone 40 mg once daily, may be required for 8–12 weeks. Practically, many patients are given both prednisolone and CBZ (if they are euthyroid within 2–3 weeks, the diagnosis is amiodarone-induced thyrotoxicosis type II, so CBZ can be discontinued, and prednisolone tapered).

All antithyroid drugs have a marrow suppressant effect, and patients should be warned and given an information leaflet wherever possible.

Thyroid storm

Definition of thyroid storm

Thyroid storm (crisis) occurs as a result of exacerbation of thyrotoxicosis. It is a rare but life-threatening condition.

Aetiology of thyroid storm

Thyroid storm occurs in patients who have hyperthyroidism or a family history of thyroid disease. It may develop in patients with hyperthyroidism during an acute infection or trauma; when they are undergoing surgery or radioiodine treatment; in the post-partum situation; after radiological contrast; or when antithyroid treatment has been withdrawn. Strokes and seizures have also been documented to precipitate thyroid storm.

Typical symptoms of thyroid storm, and less common symptoms

The symptoms of thyroid storm are similar to those found in acute sepsis and are as follows:

- change in cognitive state
- pyrexia >38.5
- tachycardia or tachyarrhythmia
- severe signs of hyperthyroidism
- vomiting, jaundice, and diarrhoea
- multisystem decompensation: cardiac failure, respiratory distress, prerenal failure

Demographics of thyroid storm

Thyroid storm occurs in up to 1%–2% of patients admitted to hospital with thyrotoxicosis. It is becoming significantly less common, due to earlier diagnosis and treatment of thyrotoxicosis.

Natural history of thyroid storm, and complications of the disease

The exact pathogenesis of thyroid storm is unclear. Frequently, TFT levels are those of uncomplicated thyrotoxicosis. It may be caused by high catecholamine levels or high FT4 levels; alternatively, it may be the acute discharge of thyroid hormones in a particular clinical background that causes the storm. Vigorous palpation of thyroid goitres has also been reported to cause thyroid storm. The high mortality associated with the condition is greater the longer the patient remains untreated. If the patient survives the episode, after appropriate treatment, surgery maybe the treatment option of choice.

Approach to diagnosing thyroid storm

Even if the diagnosis of thyroid storm seems unlikely, initiation of treatment for thyroid storm is prudent management, as therapy may always be discontinued when the patient is stable.

Other diagnoses that should be considered aside from thyroid storm

Another diagnosis that should be considered aside from thyroid storm is underlying precipitating illness.

'Gold-standard' diagnostic test for thyroid storm

The gold-standard diagnostic tests for thyroid storm are as follows:

- clinical diagnosis; in particular, the presence of a goitre with a thrill and a bruit, and ophthalmopathy
- TFTs: abnormal but within the range of uncomplicated thyrotoxicosis
- FT3: may even be low/or normal, due to underlying systemic illness
- FT4: an urgent FT4 test should be available as an emergency procedure in most hospitals
- 2-hour radioiodine uptake

Acceptable diagnostic alternatives to the gold-standard tests for thyroid storm

There are no acceptable diagnostic alternatives to the gold-standard tests for thyroid storm.

Other relevant investigations for thyroid storm

Other relevant investigations for thyroid storm are tests to exclude:

- modest hyperglycaemia
- moderate leucocytosis
- increased serum calcium

- hepatic dysfunction
- altered cortisol levels

In addition, search for any underlying precipitating illness.

Prognosis of thyroid storm, and how to estimate it

Thyroid storm has a poor prognosis, but early diagnosis and institution of treatment may reduce its severity. Mortality rates in hospital, even with early diagnosis, are high, ranging from 10% to 75%.

Treatment of thyroid storm, and its effectiveness

The aim of treatment for thyroid storm is to inhibit thyroid hormone synthesis completely, using the following agents:

- PTU blocks T4 to T3 conversion; give 200–300 mg four times per day via an NGT
- potassium iodide 60 mg four times per day via an NGT, started 6 hours after the initial PTU dose, to inhibit thyroid hormone release
- propranolol 160–480 mg/day in divided doses or as an infusion 2–5 mg/hour, for beta blockade (calcium-channel blockers may be used when beta blockade is contraindicated)
- colestyramine, to reduce enterohepatic circulation of thyroid hormones
- prednisolone 60 mg/day, or intramuscular hydrocortisone 40 mg four times per day

In addition, any precipitating illness should be addressed.

When all pharmacological therapies fail, plasmapheresis and peritoneal dialysis may be effective.

Thyroid adenoma and multinodular goitre

Definitions of thyroid adenoma and multinodular goitre

A thyroid adenoma is a solitary nodule present in the thyroid. In contrast, in a multinodular goitre, multiple nodules are present. These nodules may be palpable or non-palpable, and toxic or non-toxic.

Etiologies of thyroid adenoma and multinodular goitre

Thyroid adenoma

Thyroid adenomas are usually follicular; common types include colloid nodules, cysts, and benign neoplasms (Hürthle cell adenomas). Lymphocytic thyroiditis is a common cause of thyroid adenomas. Uncommon causes include granulomatous thyroiditis, infection, and malignancy (papillary, follicular, medullary, anaplastic, metaplastic; also lymphoma).

Multinodular goitre

Multinodular goitres are most commonly caused by autoimmune thyroid disease; sporadic, endemic iodine deficiency; pregnancy; and thyroiditis syndromes. They may also be drug induced.

Typical symptoms of thyroid adenoma and multinodular goitre, and less common symptoms

The thyroid mass may be discovered by the patient or clinician. Important symptoms to ask about include a rapidly enlarging mass or discrete nodule within the goitre; previous history of radiation to head or neck; family history of thyroid cancer; and hoarse voice, dysphagia, or dyspnoea. Fixation of the mass to adjacent tissue, lymphadenopathy, and a short history of the mass may indicate malignancy, depending on the age of the patient (see 'Demographics of thyroid adenoma and multinodular goitre').

Demographics of thyroid adenoma and multinodular goitre

The prevalence of non-toxic goitre is high (3.2% in the UK); the disease is more common in women (5.3%) than in men (0.8%). Thyroid nodules are common: the prevalence of thyroid nodules is 5%–50% and increases with radiation exposure, iodine deficiency,

and increasing age. Ten per cent of the population have clinically apparent nodules; these are four times more common in women than in men. Less than 5% of such nodules are cancerous, but they are more likely to be so if the patient is <20 years old, >60 years old, or male.

Natural history of thyroid adenoma and multinodular goitre, and complications of the disease

The generation of a non-toxic goitre is thought to occur when there is an intense growth stimulus over a short period of time, resulting in a diffuse goitre, whereas a mild stimulation over longer periods results in a nodular goitre. Expansion of thyrocytes may eventually ensue, along with autonomous thyroid function. Patients with multinodular goitre tend to be older and have larger goitres. The goitre size is negatively related to TSH levels; thus, the larger the multinodular goitre, the more suppressed the TSH and the higher the FT4. Solitary nodules without suspicion of malignancy generally change very little. Those that increase in size or are predominantly solid are more likely to be malignant. Those that are cystic may decrease in size or disappear.

Approach to diagnosing thyroid adenoma and multinodular goitre

With a multinodular goitre, thyroid function must be ascertained, as well as the presence of any pressure effects. With a solitary lesion, again check the biochemical thyroid status with TSH, and establish whether the nodule is benign or malignant. FNA should be used for this. Imaging in these lesions is controversial, and radionuclide and ultrasound scanning of the thyroid should be discussed with a specialist. A hot spot on the radioisotope scan makes malignancy less likely, as cancers are generally cold, but the specificity and positive predictive value of scanning is poor.

Other diagnoses that should be considered aside from thyroid adenoma and multinodular goitre

Other diagnoses that should be considered in addition to adenoma and multinodular goitre include multiple endocrine neoplasia, Gardner's syndrome, familial polyposis coli, and Cowden's syndrome.

'Gold-standard' diagnostic tests for thyroid adenoma and multinodular goitre

The gold-standard diagnostic tests for adenoma and multinodular goitre are TSH and FNA (Thy1 - Thy5 classification); these are the best and most cost-effective ways of making the diagnosis.

Acceptable diagnostic alternatives to the gold-standard tests for thyroid adenoma and multinodular goitre

Imaging is an acceptable diagnostic alternative to the gold-standard tests for adenoma and multinodular goitre (U1 to U5 classification).

Other relevant investigations for thyroid adenoma and multinodular goitre

Other relevant investigations for adenoma and multinodular goitre include pulmonary function tests, CT for suspected retrosternal goitre, and follow-up of malignant disease. In cases of medullary thyroid carcinoma, calcitonin may be measured, but this is only recommended in the case of positive family history.

Prognosis of thyroid adenoma and multinodular goitre, and how to estimate it

For benign adenoma and multinodular goitre, the prognosis is good. For tailored-treatment prognoses, see 'Prognosis of thyrotoxicosis, and how to estimate it'.

Treatment of thyroid adenoma and multinodular goitre, and its effectiveness

The optimal therapy for thyroid nodules depends on whether they are functioning or non-functioning, and benign or malignant. If they are functioning, see 'Treatment of thyrotoxicosis, and its effectiveness' for an outline of the medical and radioiodine therapies that may be used.

Surgery for the treatment of thyroid adenoma and multinodular goitre

Surgery for the treatment of adenoma and multinodular goitre is indicated when a lesion is malignant, or when the cytology has suspicious features. The success of surgery is high in specialist centres and, depending on the extent of the thyroidectomy, post-operative, life-long T4 is given.

187 Primary hyperparathyroidism

John Newell-Price, Alia Munir, and Miguel Debono

Definition of the disease

Primary hyperparathyroidism is a disorder of bone mineralization and renal physiology due to excess parathyroid hormone (PTH) secretion.

Aetiology of the disease

PTH is produced and released by the parathyroid chief cells. Its principal actions are stimulation of bone resorption; increased renal calcium reabsorption and phosphate excretion; and stimulation of the conversion of 25-hydroxy vitamin D to the active form 1,25-hydroxy vitamin D. PTH is under the regulation of the G-protein-coupled calcium-sensing receptor (CaSR), and primary hyperparathyroidism occurs when there is a loss of the inhibitory feedback of PTH release by extracellular calcium. The rise in PTH levels is initially associated with a normal serum calcium, and then over time with hypercalcaemia. The most common cause is a benign solitary adenoma (80%). Other causes include multiple adenomas and hyperplasia. Rare causes include parathyroid carcinoma, lithium therapy, thiazide diuretics, and mutation of the CaSR, such as occurs in familial hypocalcaemic hypercalcaemia or as part of the multiple endocrine neoplasia (MEN) type I or II spectrum. Head and neck irradiation maybe a risk factor. PTH levels will rise secondary to hypocalcaemia, vitamin D deficiency, or hyperphosphataemia and are blunted by magnesium deficiency.

Primary hyperparathyroidism is the most common cause of hypercalcaemia in ambulant patients, with 85% of cases being due to a single adenoma, and the remainder to parathyroid hyperplasia. Hyperparathyroidism is commonly found in patients with MEN types I or II. Chronically low vitamin D levels, and chronic renal failure with persistently low calcium levels, may stimulate the autonomous increased production of PTH, resulting in tertiary hyperparathyroidism, causing hypercalcaemia.

Typical symptoms of the disease, and less common symptoms

With the advent of widespread measurement of serum calcium within standard biochemical requests, most patients will be asymptomatic or complain of non-specific fatigue, feelings of weakness, and cognitive blunting. Fewer patients present with symptoms of hypercalcaemia, such as renal tract calculi, abdominal pain, constipation, and low mood.

Demographics of the disease

Primary hyperparathyroidism has a community prevalence of 0.5% to 0.1% but is a common diagnosis in patients presenting with hypercalcaemia. It is three times more common in women, and peaks in the sixth decade.

Natural history and complications of the disease

Approximately 15% of asymptomatic patients with primary hyperparathyroidism progress over years, in terms of increases in serum calcium and PTH. The complications are commonly low bone density, fragility fractures, and renal stones. While commoner in the past, peptic ulcers, myopathy, and pancreatitis are now rare complications. Severe protracted hyperparathyroidism results in multiple bone cysts

or brown tumours as part of osteitis fibrosa cystica. These can be a site of bone pain and pathological fracture. In protracted secondary hyperparathyroidism, a small proportion will develop tertiary hyperparathyroidism, where there is autonomous escape from regulation, and extreme hypercalcaemia.

Approach to diagnosing the disease

The key is to establish an inappropriately high or high normal level of circulating PTH with respect to serum calcium. The exclusion of other causes of raised calcium or secondary hyperparathyroidism is usually straightforward. Once a diagnosis of primary hyperparathyroidism is likely, and vitamin D deficiency either excluded or treated, it is essential to request a 24-hour urinary calcium and creatinine collection, with paired serum calcium and creatinine to exclude familial hypocalcaemic hypercalcaemia (FHH). A calcium:creatinine clearance ratio $((\text{urine calcium} \div \text{serum calcium}) \times (\text{serum creatinine} \div \text{urine creatinine})) < 0.01$ indicates FHH, not primary hyperparathyroidism. Where there is diagnostic uncertainty, family screening for hypercalcaemia is helpful. In cases of primary hyperparathyroidism in young adulthood, it is worth screening for other tumours of MEN type I or II.

Once a diagnosis is established, the most important step is to refer to an experienced endocrine surgeon for a minimally invasive exploration and excision. The surgical team will have a local protocol for then working up patients to identify the site of adenoma. This usually includes functional localization by sestamibi nuclear scan with anatomical localization by MRI, CT, or ultrasound. In cases with concomitant thyroid disease, subtraction-imaging ^{123}I may be needed. Additional diagnostic modalities include SPECT and selective venous sampling.

Other diagnoses that should be considered

Another diagnosis that should be considered is FHH. In addition, secondary hyperparathyroidism may be secondary to hypocalcaemia, vitamin D deficiency, and/or hyperphosphataemia, such as occurs in chronic kidney disease. Patients with primary hyperparathyroidism often have a concomitant vitamin D deficiency that can lower the serum calcium to within the normal range or lower the urine calcium. The diagnostic strategy is to treat the vitamin D deficiency and then remeasure the serum calcium. Even with high-dose replacement of vitamin D, the increment in serum calcium in patients with primary hyperparathyroidism is usually small and asymptomatic. Subsequent unmasking of hypercalcaemia in these patients reveals the diagnosis of primary hyperparathyroidism.

'Gold-standard' diagnostic test

The gold-standard diagnostic test for primary hyperparathyroidism is a blood test to confirm hypercalcaemia with elevated intact PTH. In addition, a technetium-99m sestamibi nuclear scan, with anatomical localization via either MRI or ultrasound, can be used.

Other relevant investigations

Other relevant investigations include blood tests to determine whether there is associated low serum phosphate and/or high alkaline phosphatase. It is also necessary to exclude vitamin D deficiency and renal disease, especially in patients with normocalcaemic hyperparathyroidism. Dual-energy X-ray absorptiometry should be performed, to exclude low bone density and increased fragility fracture

risk. In addition, a 24-hour urinary calcium and creatinine collection, with paired serum calcium and creatinine, should be carried out.

In those presenting in young adulthood, a screen to rule out MEN type I/II should be performed.

Prognosis and how to estimate it

Epidemiological studies have confirmed that untreated hyperparathyroidism leads to an excess mortality, reduced quality of life from cardiovascular disease, and bone fragility.

Treatment and its effectiveness

Surgery is the only definitive treatment for this disease. In Guidelines for the Management of Asymptomatic Primary Hyperparathyroidism: Summary statement from the Fourth International Workshop 2013 parathyroidectomy was recommended for patients with 1) serum calcium 0.25mmol/l > upper limit of normal, 2) creatinine clearance $<60\text{ml/min}$ and/or 24 hour urine calcium $>400\text{mg/day}$ and increased stone risk by biochemical stone analysis and/or nephrolithiasis or nephrocalcinosis on imaging, 3) BMD T-score <-2.5 at any site and/or vertebral fracture, 4) or age <50 years. In patients who do not undergo surgery an annual serum calcium and serum creatinine/eGFR is recommended and bone density every one to two years. If renal stones suspected do 24 hour biochemical stone analysis and imaging. The American Association of Clinical Endocrinologists and the American Association of Endocrine Surgeons also state that operative management should be considered and recommended for all asymptomatic patients with a reasonable life expectancy, and suitable operative and anaesthetic risk factors. When the operation is performed by a qualified surgeon, the disease is cured with low risk in 90%–95% of cases. Radiological imaging is usually performed only as part of the workup for surgery, and may include technetium-99m sestamibi scans, ultrasound scans, CT scans, and MRI scans, depending on tumour location.

If patients do not undergo surgery, they need biannual calcium levels and annual creatinine or creatinine clearance, blood pressure monitoring, and annual bone density scans. If the patient is not suitable for surgery, sex hormone replacement therapy and bisphosphonates should be considered to prevent bone loss. A more targeted approach is the use of calcimimetics, a group of

drugs which increase the affinity of the receptor for extracellular calcium, leading to an increase in intracellular calcium. This inhibits the secretion of PTH from the parathyroid cell. Rapid normalization of calcium levels have been achieved with the use of cinacalcet hydrochloride, with maintenance of normal calcium levels, but the drug is expensive.

Minimally invasive parathyroidectomy by an experienced endocrine surgeon is curative. Surgery is indicated in those who have skeletal complications (such as osteoporosis), renal complications (stones or impaired creatinine clearance), a history of parathyroid crisis, or presentation when under 50 years old. In those not meeting these criteria, a comparison of the risks and benefits of the curative procedure needs to be made on a case-by-case basis. Pre-surgical correction of vitamin D deficiency and dietary calcium repletion reduces the incidence of post-operative hungry bone syndrome. It is important to avoid use of potent parenteral anti-resorptive agents prior to surgery to minimize post-operative hypocalcaemia.

In those not eligible for surgery, medical management involves adequate hydration and a moderate dietary calcium intake of 600–800 mg/day. In those with evidence of osteoporosis, anti-resorptive therapy should be considered. In those with parathyroid carcinoma, and even inoperable patients with primary hyperparathyroidism the calcimimetic cinacalcet is indicated. Tests for serum calcium and the estimated glomerular filtration rate should be repeated annually, and bone mineral density should be measured every two years to check for progression.

Where the cause is thought to be lithium or thiazide related, the drug should be stopped for 3 months, and then PTH and calcium levels remeasured.

188 Adrenal disease

John Newell-Price, Alia Munir, and Miguel Debono

Adrenal insufficiency

Definition of adrenal insufficiency

Adrenal insufficiency (AI) is a disorder characterized by impaired adrenocortical function, with destruction of the adrenal cortex (primary AI (PAI)) resulting in a decreased production of glucocorticoids, mineralocorticoids, and/or androgens. Secondary AI (SAI) is due to disordered pituitary and hypothalamic function resulting in decreased secretion of adrenocorticotropic hormone (ACTH) or corticotrophin-releasing hormone, with consequent reduction in glucocorticoid and/or androgen secretion.

Aetiology of AI

The aetiology of AI is given in Table 188.1.

Typical symptoms of AI, and less common symptoms

Common symptoms of AI include fatigue; loss of energy; abdominal pain; anorexia; weight loss; weakness; hyperpigmentation (primary); myalgia; dizziness secondary to hypotension; and joint pains. Less common symptoms include impaired libido (women), salt craving (primary), axillary or pubic hair loss, and diarrhoea. In SAI, patients may have alabaster-coloured pale skin, and headaches or visual field defects secondary to a pituitary tumour. Hirsutism, acne, and oligomenorrhoea around the onset of puberty may indicate congenital adrenal hyperplasia (CAH).

Demographics of AI

The prevalence of PAI is 93–140 per million, with an incidence of 4.7–6.2 per million in Caucasian populations, while SAI has a prevalence of 190–280 per million. Women are affected more often than men in both PAI and SAI. AI may occur at any age but the autoimmune PAI is often discovered in the third to the fifth decade, while SAI peaks in the sixth decade.

Primary adrenal insufficiency (Addison's disease)	Secondary adrenal insufficiency
Autoimmune (commonest in UK; isolated or part of autoimmune polyendocrine syndrome type 1, 2, or 4)	Tumours of hypothalamus and pituitary gland (rare; granulomatous disease in these regions)
Malignancy (metastatic (lung, breast, kidney), infiltration, or lymphoma)	Long-term steroid-induced suppression of hypothalamic–pituitary–adrenal axis
Infiltration (amyloid, sarcoidosis)	Following cure of Cushing's syndrome
Infection (tuberculosis (commonest worldwide), histoplasmosis, AIDS, CMV, <i>Mycobacterium intracellulare</i>)	High-dose opioid analgesia
Vascular haemorrhage (meningococcaemia, anticoagulants, trauma)	
Congenital adrenal hyperplasia	
Congenital adrenal hypoplasia	
Adrenoleucodystrophy	
Bilateral adrenalectomy/drugs (steroid-synthesis inhibitors)	
Congenital unresponsiveness to adrenocorticotropic hormone	

Natural history of AI, and complications of the disease

The onset of AI is usually gradual and insidious, and may go undetected until an illness or stress precipitates an adrenal crisis. Patients with acute AI usually present unwell with hypotension, collapse, abdominal pain, fever, and a history or signs of a condition precipitating the event. Typically, these patients do not respond fully to fluid resuscitation unless glucocorticoids are given. If the condition is not treated, it may result in confusion, coma, and death.

As symptoms are non-specific in chronic AI, late diagnosis is common. In PAI, besides glucocorticoid deficiency, patients develop mineralocorticoid deficiency, with resultant electrolyte abnormalities and postural hypotension (may also occur with cortisol deficiency), and androgen deficiency with loss of axillary and pubic hair and loss of libido. Patients with AI may have poor quality of life despite being on conventional hydrocortisone treatment.

Approach to diagnosing AI

A thorough history and examination for symptoms and signs directly related to AI are mandatory. Further, history taking should also be directed to identifying a possible cause for AI, such as a history of autoimmune conditions or malignancy; a family history of endocrine disorders; use of drugs affecting cortisol production; or the use of long-term steroids. Social history should be directed towards the identification of risk factors, including risks for sexually transmitted disorders. Clinical examination should also focus on identifying signs of pituitary disease, such as visual field defects or signs of other hormone deficiencies. Signs of autoimmune disorders, such as vitiligo, or signs of underlying malignancy may also be useful in suggesting the diagnosis.

Other diagnoses that should be considered aside from AI

Autoimmune PAI may be associated with autoimmune polyendocrine syndrome 1 (rare; mainly hypoparathyroidism, chronic mucocutaneous candidiasis) or autoimmune polyendocrine syndrome 2 (mainly primary hypothyroidism, type 1 diabetes mellitus).

'Gold-standard' diagnostic test for AI

The gold-standard diagnostic test for AI is the short tetracosactide test: 250 µg of tetracosactide administered intramuscularly or IV. A serum cortisol level >550 nmol/l at 30 minutes afterwards indicates an adequate response—a 'negative result' (recent onset (<6 weeks) SAI may result in a false negative test).

Acceptable diagnostic alternatives to the gold-standard test for AI

The following tests are acceptable diagnostic alternatives to the gold-standard test for AI:

- 9 a.m. cortisol/ACTH:
 - a single 9 a.m. or random serum cortisol level >500 nmol/l almost always indicates adequate adrenal function
 - an inappropriately low cortisol with high ACTH is indicative of PAI
 - an inappropriately low cortisol with low or normal ACTH is indicative of secondary AI; high ACTH also present in uncontrolled CAH
- insulin tolerance test: rarely indicated unless pituitary disease known (a test for ACTH reserve; avoid if basal cortisol <100 nmol/l)

Other relevant investigations for AI

Other relevant investigations for AI include:

- plasma renin activity (elevated in aldosterone deficiency)
- dehydroepiandrosterone sulphate levels
- calcium levels (hypercalcaemia in PAI)
- electrolytes (hyponatraemia, hyperkalaemia—especially in PAI)
- urea (elevated)
- full blood count (FBC; normochromic, normocytic anaemia, eosinophilia)
- glucose (hypoglycaemia may occur)
- adrenal antibodies
- CT scan of adrenal glands (if adrenal antibodies negative)
- MRI pituitary (if SAI confirmed biochemically)
- thyroid function tests (cortisol deficiency may result in abnormal results that resolve on treating AI)
- very long chain fatty acids (adrenoleucodystrophy)
- other endocrine tests for associated pituitary hormone deficiencies or autoimmune endocrine disorders
- tests for 17-hydroxyprogesterone (at 9 a.m. and then 60 minutes after ACTH administration (diagnostic)), testosterone, and androstenedione (best for disease control monitoring in CAH)

Prognosis of AI, and how to estimate it

Patients with PAI, even if on full replacement therapy, have a mortality rate which is twofold greater than that of the background population, with the greatest number of deaths occurring from cardiovascular, malignant, endocrine, respiratory, and infectious diseases. It is possible that a major contributor to cardiovascular mortality is relative overdosing with hydrocortisone. The mortality rate for patients with secondary AI is up to seven times that of the normal population.

Treatment of AI, and its effectiveness

Glucocorticoid replacement in AI

For glucocorticoid replacement in AI, oral hydrocortisone is usually given three times per day: 10 mg on waking, 5 mg at midday, and 5 mg at 6 p.m. No definite method for monitoring treatment is available at present. Clinical assessment may be as effective as repeated day serum cortisol levels, the latter having particular benefit when patients are also on inducers or inhibitors of cytochrome P450 3A4, as these may result in lower or higher levels of circulating cortisol. Achieving physiological replacement is impossible with conventional glucocorticoid replacement. Oral formulations providing circadian cortisol profiles are being introduced.

Mineralocorticoid replacement in AI

For mineralocorticoid replacement in AI, fludrocortisone is given at a dose of 0.05–0.2 mg/day, with dose adjustment according to clinical status and plasma renin and electrolytes.

Androgen replacement in AI

Dehydroepiandrosterone replacement in patients with PAI may have beneficial effects on well-being.

Sick-day rules

- patient education
- double dose of glucocorticoids during febrile illness; in addition, a vial of 100 mg hydrocortisone is required if parenteral treatment is needed
- major illness should be covered with 50–100 mg hydrocortisone intramuscularly every 6 hours until the patient has recovered
- major surgery should be covered with 100 mg hydrocortisone intramuscularly every 6 hours for the first 3 days, and longer if prolonged post-op complications develop

Treatment of acute AI

Acute AI is a medical emergency and, if suspected, should be treated before biochemical confirmation of low serum cortisol. After a blood sample for serum cortisol and, if possible, plasma ACTH for later analysis is taken, large volumes of 0.9% saline are needed and hydrocortisone 100 mg should be given as an IV bolus, followed by 100 mg intramuscularly every 6 hours. On recovery, double-replacement

oral doses are given until the patient is well. Glucose supplementation may be necessary if hypoglycaemia develops. The precipitant should be identified and treated.

Treatment of CAH

In CAH, glucocorticoid therapy is used to replace low cortisol and control androgen excess. Hydrocortisone, prednisolone, and dexamethasone have been used. Androstenedione may be used to monitor disease.

Primary hyperaldosteronism (primary aldosteronism)

Definition of primary hyperaldosteronism

Aldosterone is produced in the zona glomerulosa of the adrenal cortex. Abnormal overproduction of aldosterone results in autonomous primary hyperaldosteronism, leading to hypertension and hypokalaemia.

Aetiology of primary hyperaldosteronism

The aetiology of primary hyperaldosteronism is shown in Box 188.1.

Typical symptoms of primary hyperaldosteronism, and less common symptoms

Common features of primary hyperaldosteronism are hypertension and hypokalaemia (9%–37%). Less commonly, myopathy, tetany, polyuria, abdominal distension, and cardiac arrhythmias may be evident.

Demographics of primary hyperaldosteronism

Primary aldosteronism is found in around 10% of resistant hypertensive patients. Studies report rates of between 0.05% and 14.4% in all patients with hypertension, the variability being due to differences in biochemical definitions. Conn's adenomas and adrenal carcinomas are more common in women than men, and adenomas usually present between the third to the sixth decade. Idiopathic adrenal hyperplasia is found in older people. Previous studies have shown that aldosteronomas are responsible for 70% of cases of primary aldosteronism but the incidence of bilateral adrenal hyperplasia is growing. Less than one per cent of cases are caused by the autosomal dominant condition, glucocorticoid-responsive aldosteronism (GRA).

Natural history of primary hyperaldosteronism, and complications of the disease

The clinical presentation of primary hyperaldosteronism is not distinctive, and a high index of suspicion is necessary. Hypertension is common amongst patients with primary hyperaldosteronism, and may be severe or refractory to therapy. Spontaneous hypokalaemia should warrant consideration of hyperaldosteronism, especially in patients who develop severe or persistent hypokalaemia in the setting of low to moderate doses of potassium-wasting diuretics. In view of resistant hypertension, patients may develop related complications, including cardiac failure, stroke, hypertensive encephalopathy, and retinal changes. Direct actions of aldosterone result in cardiac fibrosis and vascular smooth muscle hypertrophy, while persistent hypokalaemia causes neuromuscular symptoms and nephrogenic diabetes insipidus.

Box 188.1 Aetiology of primary hyperaldosteronism

- aldosterone-secreting adenoma of the adrenal cortex (Conn's adenoma)
- bilateral idiopathic adrenal hyperplasia
- primary adrenal hyperplasia
- adrenal carcinoma
- glucocorticoid-responsive aldosteronism

Approach to diagnosing primary hyperaldosteronism

The following patients should be screened for primary hyperaldosteronism:

- patients with a blood pressure >160–179/100–109 mm Hg or drug-resistant hypertension
- patients with hypertension and spontaneous or diuretic-induced hypokalaemia
- patients with hypertension with adrenal incidentaloma
- patients with hypertension and a family history of early onset hypertension or a cerebrovascular accident at a young age (<40 years old)

All hypertensive first-degree relatives of patients with primary aldosteronism should also be screened.

Other diagnoses that should be considered aside from primary hyperaldosteronism

Other diagnoses that should be considered aside from primary hyperaldosteronism are:

- secondary hyperaldosteronism: aldosterone hypersecretion occurs secondary to elevated renin levels (e.g. from cirrhosis of the liver, congestive heart failure, nephrotic syndrome, renal artery stenosis, or, very rarely, a renin-secreting tumour)
- other mineralocorticoid excess syndromes (e.g. low renin, aldosterone not high (apparent mineralocorticoid excess), liquorice ingestion, ectopic ACTH)

'Gold-standard' diagnostic tests for primary hyperaldosteronism

The following are gold-standard diagnostic tests for primary hyperaldosteronism:

- for screening: plasma aldosterone:renin activity ratio (ARR; hypokalaemia should be normalized prior to the test as this may impair circulating levels of aldosterone)
- for confirmation:
 - oral sodium loading test
 - saline infusion test
 - fludrocortisone suppression test
 - captopril challenge

NB: alpha antagonists and non-dihydropyridine calcium-channel blockers have minimal effects on ARR; other antihypertensives may need to be stopped 4 or 2 weeks prior to testing.

Acceptable diagnostic alternatives to the gold-standard tests for primary hyperaldosteronism

The following tests may be performed if primary aldosteronism is confirmed:

- adrenal CT (for subtype classification and to exclude carcinoma)
- adrenal vein sampling (when surgical treatment is considered and it is desirable to distinguish between unilateral and bilateral disease)
- genetic screening for GRA in those with a family history of strokes or hypertension at age <40 years or in those developing hypertension at age <20 years

Other relevant investigations for primary hyperaldosteronism

Other relevant investigations for primary hyperaldosteronism are:

- serum potassium levels
- bicarbonate levels (to exclude metabolic alkalosis)
- urine potassium excretion (to determine if >30 mmol/24 hours)
- sodium levels (to exclude reset osmostat with hypernatraemia)

Prognosis of primary hyperaldosteronism, and how to estimate it

In unilateral disease, surgical removal of the tumour results in improvement in hypertension and hypokalaemia, with cure of hypertension

in 50%. In patients with bilateral disease, the use of spironolactone results in a mean reduction in blood pressure of approximately 25%. The prognosis of adrenal carcinoma is extremely poor.

Treatment of primary hyperaldosteronism, and its effectiveness

For patients with unilateral primary aldosteronism, laparoscopic adrenalectomy is recommended. Blood pressure typically normalizes within 1–6 months.

For patients with bilateral disease, spironolactone (starting dose 12.5–25 mg/day) or eplerinone (25 mg once or twice daily) should be used and titrated against blood pressure levels

In patients with GRA, the lowest dose of glucocorticoid that can normalize blood pressure and potassium levels should be used. The aim is to suppress pituitary ACTH secretion. Prednisolone or dexamethasone may be used.

For adrenal carcinoma, surgery and post-operative use of mitotane is usually required.

Phaeochromocytoma

Definition of phaeochromocytoma

Phaeochromocytomas are rare tumours of the adrenal medulla, arising from chromaffin cells, and produce catecholamines. Tumours arising from extra-adrenal ganglia, both sympathetic and parasympathetic, are called paragangliomas. As the majority of sympathetic paragangliomas secrete catecholamines, they are also called extra-adrenal phaeochromocytomas.

Aetiology of phaeochromocytoma

The aetiology of phaeochromocytoma is shown in Box 188.2.

Typical symptoms of phaeochromocytoma, and less common symptoms

Common symptoms of phaeochromocytoma include headache (80%), sweating (>80%), palpitations (65%), nervousness, abdominal/chest pain, and constipation. Hypertension may be paroxysmal or persistent, while pallor and fever may also be present. Nausea, fatigue, dizziness, heat intolerance, anxiety, and postural hypotension are less common.

Demographics of phaeochromocytoma

Overall, phaeochromocytoma is rare (~1 per million per year) and usually benign. It has equal incidence in both sexes, and usually occurs between the third and the fourth decades. The 25% caused by inherited syndromes are much more frequently bilateral in the adrenal glands, extra-adrenal, or malignant, especially if caused by SDHB mutations. They account for <0.1% of cases of hypertension.

Natural history of phaeochromocytoma, and complications of the disease

Although the presence of symptoms and signs may raise suspicion of a phaeochromocytoma, many tumours go undiagnosed and are identified incidentally (incidentalomas) during investigation of other non-related complaints. The classic history of a phaeochromocytoma is characterized by headaches, palpitations, and sweating, together with persistent or episodic hypertension, and constipation.

Box 188.2 Aetiology of phaeochromocytoma

- 75% of cases are sporadic
- 25% of cases are inherited:
 - multiple endocrine neoplasia type IIa and type IIb
 - paraganglioma syndrome (mutations of subunits B–D of succinate dehydrogenase (SDHB, SDHC, SDHD))
 - von Hippel–Lindau syndrome
 - neurofibromatosis
 - Carney's triad

Episodes may vary in time, usually lasting less than an hour, but, rarely, may last for days. Some may occur weekly, several times daily, or sometimes every few months. Episodes increase in number as the tumour grows. Diverse symptoms may be related to the type of catecholamines secreted (e.g. postural hypotension secondary to adrenaline) or to co-secretion of other peptides (e.g. diarrhoea from vasoactive intestinal peptide). Although rare, the condition may be fatal if not diagnosed. Complications are mainly cardiovascular (arrhythmias, cardiomyopathy, myocardial infarction) and neurological (hypertensive encephalopathy, stroke); hyperglycaemia and hypercalcaemia can also occur.

Approach to diagnosing pheochromocytoma

The following patients should be screened for pheochromocytoma:

- patients with paroxysmal symptoms, especially palpitations, headaches, sweating, and hypertension
- patients who are well but with hypertension and tachycardia at rest
- patients with hypertensive crises induced by specific precipitants (e.g. tumour palpation; postural changes; exertion; trauma; drugs, including beta blockers, opiates, and tricyclic antidepressants; anaesthesia; tyramine-containing foods)
- patients with a family history of related syndromes
- young patients with hypertension
- patients with unexplained heart failure

Other diagnoses that should be considered aside from pheochromocytoma

Other diagnoses that should be considered aside from pheochromocytoma are associated syndromes, including multiple endocrine neoplasia (MEN) type IIa (hyperparathyroidism, medullary thyroid cancer), MEN type IIb (similar to MEN type IIa but with marfanoid habitus and mucosal and intestinal ganglioneuromas), von Hippel–Lindau syndrome (retinal and cerebellar haemangioblastomas; renal cysts and carcinoma; pancreatic cysts), and neurofibromatosis (café au lait spots, neurofibromas).

'Gold-standard' diagnostic tests for pheochromocytoma

The following are gold-standard diagnostic tests for pheochromocytoma:

- 24-hour urine metanephrines $\times 2$ (specificity 99.7%)
- plasma metanephrines (sensitivity 96%)

Acceptable diagnostic alternatives to the gold-standard tests for pheochromocytoma

An acceptable diagnostic alternative to the gold-standard tests for pheochromocytoma is the chromogranin A test. The following tests may be performed **after** diagnosis has been confirmed biochemically:

- MRI adrenal; if a pheochromocytoma is not detected, then body imaging (a pheochromocytoma appears hyperintense on T2-weighted images)
- CT adrenal
- ^{123}I -MIBG scan (ideal for multiple tumours, extra-adrenal tumours)
- venous sampling
- if pheochromocytoma is non-sporadic or extra-adrenal, consider FDG-PET scan (or DOPA PET, if available) or octreotide scan

Other relevant investigations for pheochromocytoma

Patients with pheochromocytoma and presenting <40 years of age or with multifocal disease should be screened for:

- MEN type II (via serum calcium, serum calcitonin, RET mutation analysis)
- von Hippel–Lindau syndrome (via ophthalmoscopy, MRI posterior fossa, ultrasound kidneys, VHL mutation analysis)
- paraganglioma syndrome (mutations in SDHB, SDHC, and SDHD)

Prognosis of pheochromocytoma, and how to estimate it

The 5-year survival rate for patients with non-malignant pheochromocytoma is $>95\%$, with a low recurrence rate. For malignant pheochromocytoma, the 5-year survival rate is $<50\%$.

Treatment of pheochromocytoma, and its effectiveness

As soon as diagnosis of pheochromocytoma is made, alpha blockade should be started, using phenoxybenzamine orally 10 mg two times daily, and then titrated against blood pressure. This may then be followed 72 hours later by beta blockade using beta blockers especially if palpitations are problematic.

The definitive treatment for pheochromocytoma is surgical excision. This may be open or laparoscopic. Careful control of blood pressure is essential. IV phenoxybenzamine may be used before surgery. Prognosis after surgery is excellent, although 25%–50% of cases may remain hypertensive. Repeat urine/plasma metanephrines 14–28 days post-operatively. Long-term follow-up is essential.

Hypertensive crisis

Endocrine causes of malignant hypertension are uncommon, but may be suggested by features in the history that indicate catecholamine excess or by biochemical abnormalities. Any patient with hypertension and tachycardia should be screened for pheochromocytoma. Look out for clinical features of Cushing's syndrome or acromegaly.

Features of hypertensive crisis

Features of hypertensive crisis are as follows:

- usually, very high BP $\geq 200/120$
- encephalopathy and coma may be present
- angina, with or without myocardial infarction, left ventricular dysfunction, and aortic dissection
- eclampsia
- renal failure, with proteinuria
- retinopathy, with or without papilloedema

Management of hypertensive crisis

In hypertensive crisis, secure IV access, ECG monitoring, and high-dose oxygen. Take blood for an FBC, to measure urea and electrolytes, and to assess calcium, glucose, and creatine kinase levels. Order a chest X-ray and get a 12-lead ECG. Also get a dipstick urine test and send a midstream specimen of urine for microscopy. In addition, check pulse symmetry, radiofemoral delay, and blood pressure in both arms and examine for renal bruits.

Reducing arterial pressure very rapidly can endanger watershed areas of the brain; aim for a smooth reduction over a few hours. In general, use oral therapy, unless there is encephalopathy or congestive heart failure. Usually prescribe bed rest with amlodipine 2.5 mg once daily to begin with.

Parenteral treatment should really only be attempted in an intensive care (or at least high-dependency unit) setting, with senior involvement. Appropriate parenteral agents include sodium nitroprusside, labetalol, and hydralazine, but are rarely needed.

Avoid beta-blocker treatment if pheochromocytoma is suspected: such patients should always receive adequate alpha blockade first with phenoxybenzamine. In addition, if a pheochromocytoma is suspected, at least two 24-hour urinary samples (preferably off all treatment) for metanephrines should be the routine screening test and should be collected in acid. A number of drugs may interfere with catecholamine or metanephrine concentrations. Tests for hyperaldosteronism should also be taken. Any patient with an abnormal screening test should be referred to an endocrinologist.

For all tests for pheochromocytoma or hyperaldosteronism, patients should preferably be only on an alpha blocker, as this causes little interference with investigations of pheochromocytoma and/or hyperaldosteronism.

189 Cushing syndrome

John Newell-Price, Alia Munir, and Miguel Debono

Definition of the disease

Endogenous Cushing's syndrome results from chronic, excessive, and inappropriately high cortisol exposure. It comprises a large group of signs and symptoms.

Pseudo-Cushing's syndrome is a state of hypercortisolaemia that may have some of the clinical features of Cushing's syndrome, but the clinical and biochemical features resolve when the underlying condition is treated: causes include alcohol dependence and depression.

Aetiology of the disease

By far, the most common cause of Cushing's syndrome is iatrogenic, from medically prescribed glucocorticoids.

Endogenous Cushing's syndrome may be caused by either:

- adrenocorticotrophic hormone (ACTH)-dependent Cushing's syndrome (80%); from pituitary adenoma (70%; termed 'Cushing's disease') or ectopic ACTH secretion (10%)
- ACTH-independent Cushing's syndrome (20%); from adrenal causes (adrenal adenoma; rarely, carcinoma or nodular hyperplasia)

Typical symptoms of the disease, and less common symptoms

Cyclical Cushing's syndrome may be particularly challenging to diagnose, as its features and biochemistry vary over time.

Demographics of the disease

Cushing's syndrome is uncommon, with an incidence of 2–3 per million per year. It is more common in women (3–15:1) and presents between 20 and 40 years of age.

Natural history, and complications of the disease

Glucocorticoid receptors are present in virtually all cells, reflecting the diverse actions of cortisol. Many of the symptoms are common and non-specific, such as obesity, lethargy, weakness, menstrual abnormalities, loss of libido, hirsutism, acne, depression, and psychosis. Those of greater specificity include proximal myopathy, easy bruising, purple striae, and thin skin. Development of diabetes mellitus, osteoporosis, and hypertension is common; 2%–5% of poorly controlled hypertensive patients with type 2 diabetes may have Cushing's syndrome. Seventy per cent of patients with Cushing's syndrome will have some form of psychiatric symptoms (often agitated depression).

Approach to diagnosing the disease

The following patients should be tested for Cushing's syndrome:

- patients who exhibit symptoms that are unusual for their age (e.g. osteoporosis)
- patients with multiple and progressive features that are predictive of Cushing's syndrome
- patients with adrenal incidentaloma compatible with adenoma
- children with a low height percentile and a high weight

Diagnosis is a two-step process: hypercortisolaemia must first be confirmed and **then** the cause can be searched for. Reliance is placed initially on biochemistry rather than imaging.

A biochemical hallmark of Cushing's syndrome is inappropriate cortisol secretion, with a loss of negative feedback and circadian rhythm.

For unknown reasons, some patients with Cushing's syndrome exhibit cyclical cortisol secretions that may fluctuate and remit spontaneously, sometimes over many years. This can cause considerable diagnostic difficulty; reinvestigation at intervals, and on several occasions, may be required.

Oral oestrogens increase cortisol-binding globulin and therefore lead to falsely elevated serum cortisol levels, and should be stopped for 6 weeks before investigation.

Other diagnoses that should be considered

Another diagnosis that should be considered aside from Cushing's syndrome is pseudo-Cushing's syndrome.

'Gold-standard' diagnostic tests

Step 1: Confirming Cushing's syndrome

For initial testing to confirm the presence of Cushing's syndrome, one of the following tests, based on the suitability for the patient, is used:

- urinary free cortisol (at least twice; NB: this is reduced in renal impairment)
- late-night salivary cortisol or plasma level (at least twice)
- 1 mg overnight dexamethasone suppression test (DST; in this test, dexamethasone 1 mg is given at 11:00 pm and serum cortisol is measured at 9:00 a.m. the next day)
- longer low-dose DST (2 mg/day for 48 hours; dexamethasone 0.5 mg is given at 9:00 a.m., 3:00 p.m., 9:00 p.m., and 3:00 a.m. and serum cortisol is measured at 9:00 a.m. at the start and end of the test)

For individuals with normal tests but progressive symptoms, re-evaluate in 6 months. For those with one or more abnormal test, further evaluation by an endocrinologist is recommended.

In healthy subjects, the serum cortisol level is less than 50 nmol/l (1.8 µg/dl) following any test; however, 5% of patients with Cushing's disease will show serum cortisol suppression <50 nmol/l. Thus, if the clinical index of suspicion is high, retest.

Both types of DST may give false-positive results if patients are taking drugs that increase the hepatic clearance of dexamethasone, including carbamazepine, phenytoin, phenobarbital, and rifampicin.

Midnight plasma cortisol

The normal circadian rhythm of cortisol level is lost in Cushing's syndrome. Following admission of the patient to hospital for 48 hours, a single, sleeping, midnight plasma cortisol level of >50 nmol/l is the most sensitive indicator of Cushing's syndrome, but this test is best left to dedicated endocrine centres.

Step 2: Isolating the cause of Cushing's syndrome

Once Cushing's syndrome is confirmed, the next step is to measure plasma ACTH. The sample needs careful handling, since ACTH is labile and, unless the sample is immediately processed and stored at -40°C, a falsely low level of ACTH may be recorded. A plasma ACTH level <5 pg/ml indicates a primary adrenal cause of Cushing's syndrome, and the adrenals should be imaged by CT or MRI. Levels of ACTH persistently more than 15 pg/ml can confidently be

ascribed to ACTH-dependent pathologies and require investigation as discussed in 'Plasma potassium'. Levels of 5–15 pg/ml require cautious interpretation, because individuals with Cushing's disease may have a plasma ACTH level <10 pg/ml. At least two or three estimations are made, to avoid inappropriate classification.

Plasma potassium

Ectopic ACTH secretion is usually associated with higher circulating levels of cortisol in Cushing's disease. These high levels overwhelm the 11-beta hydroxysteroid dehydrogenase type II enzyme, allowing cortisol to act as a mineralocorticoid in the kidney. Hypokalaemia is consequently more common in ectopic ACTH secretion, but it is also present in 10% of patients with Cushing's disease.

ACTH-dependent Cushing's syndrome

ACTH-secreting non-pituitary neuroendocrine tumours (carcinoid tumours) may mimic many of the clinical features of ACTH-dependent Cushing's disease caused by pituitary tumours. Biochemical evaluation, rather than imaging, should be relied on to differentiate pituitary from non-pituitary sources of ACTH, and it is strongly recommended that this is performed in major referral centres.

High-dose DST

In the high-dose DST, dexamethasone 2 mg is administered orally, strictly 6-hourly, and the plasma cortisol level is measured basally and at 48 hours. In about 80% of patients with Cushing's disease, cortisol is reduced to >50% of the basal level. This is, however, **lower** than the pretest likelihood of Cushing's disease in women (90%); thus, this test is no longer be recommended where there is access to **bilateral inferior petrosal sinus sampling** (BIPSS; see 'Corticotrophin-releasing hormone test').

Corticotrophin-releasing hormone test

Corticotrophin-releasing hormone (CRH) stimulates the release of ACTH from the corticotrophs of the anterior pituitary. Patients with Cushing's disease typically exhibit an excessive increase in plasma cortisol, whereas those with ectopic ACTH secretion usually do not.

BIPSS is a highly specialized, invasive investigation, but is the most reliable test for differentiating between pituitary and non-pituitary sources of ACTH. A basal central:peripheral ACTH ratio of more than 2:1, or a CRH-stimulated ratio of more than 3:1, is indicative of Cushing's disease.

Imaging

Pituitary MRI

Most corticotroph adenomas are <1 cm in diameter and, on MRI, give a hypo-intense signal that fails to enhance with gadolinium. When standard MRI protocols are used, 40% of corticotroph microadenomas are not visualized and incidentalomas are found in 10% of the healthy population; this emphasizes the importance of biochemical assessment.

Adrenal CT

Adrenal CT provides the greatest spatial resolution for the assessment of adrenal anatomy.

Imaging in ectopic ACTH secretion

The most common sites of ectopic ACTH secretion are small cell lung cancers and bronchial carcinoid tumours, but tumours may be in any tissue. High-definition multislice CT is required. Carcinoid tumours may be visualized on radiolabelled octreotide scintigraphy

Acceptable diagnostic alternatives to the gold standard

There are no acceptable diagnostic alternatives to the gold-standard tests for Cushing's syndrome.

Other relevant investigations

Other investigations that are relevant for Cushing's syndrome are tests for glucose and glycated haemoglobin, DEXA bone scan, and

investigations for associated conditions, such as multiple endocrine neoplasia.

Prognosis and how to estimate it

Untreated Cushing's syndrome (severe hypercortisolism) has a 5-year survival of 50%. If hypercortisolism persists, the SMR is increased 3.8–5.0-fold, compared with the population. Most deaths are caused by vascular (myocardial infarction, cerebrovascular accident) or infective complications.

Treatment and its effectiveness

Successful treatment reverses but may not normalize features of Cushing's syndrome. Bone mineral density and cognitive function improve. Quality of life improves (but remains below that of age- and gender-matched subjects).

Trans-sphenoidal surgery

Selective microadenectomy by an experienced surgeon is the treatment of choice in most patients with Cushing's disease. Long-lasting remission without other pituitary hormonal deficiency is achieved in 50%–60% of cases.

Adrenal surgery

Laparoscopic unilateral adrenalectomy is the treatment of choice in patients with an isolated adrenal adenoma. The prognosis following removal of adrenocortical cortisol-secreting adenomas is good. In contrast, the prognosis is almost always very poor in patients with adrenocortical carcinoma.

In ACTH-dependent Cushing's syndrome of any cause, bilateral adrenalectomy may be required to control cortisol levels. Nelson's syndrome (development of a locally aggressive pituitary tumour secreting high levels of ACTH, resulting in pigmentation) is a major concern following bilateral adrenalectomy in patients with refractory Cushing's syndrome. The tumour may be treated with further surgery and radiotherapy, but these seldom cure the disease.

When the syndrome is due to ectopic ACTH, complete excision of an ACTH-secreting tumour usually results in long-lasting remission.

Medical therapy

Medical therapy to lower cortisol may be used in preparation for surgery or after unsuccessful surgery. It is seldom a long-term solution, and is mainly used as an adjunctive treatment with other modalities such as pituitary radiotherapy. There is no **established** treatment to lower ACTH directly in Cushing's disease, and this is needed.

Metyrapone 500–1000 mg three or four times daily, increasing every 72 hours, and ketoconazole, 200–400 mg three times daily, increasing at 2–3-weekly intervals, are often used to inhibit cortisol synthesis, aiming for a mean plasma cortisol level of 150–300 mmol/l, or normalization of elevated urinary free cortisol levels. Metyrapone causes an increase in steroid androgenic precursors, and hirsutism is a major adverse effect in women; this does not occur with ketoconazole. In the UK, o,p'DDD (mitotane) is usually reserved for the treatment of adrenocortical carcinoma.

Pituitary radiotherapy

Following trans-sphenoidal surgery, persisting hypercortisolaemia may be treated with pituitary radiotherapy or gamma knife radiotherapy. Progressive anterior pituitary failure is the major side effect; growth hormone deficiency is present in almost all patients 10 years after treatment, and gonadotrophin deficiency in about 15%. About 4 years after treatment, 80% of patients are in remission with respect to circulating plasma cortisol levels.

190 Short stature

John Newell-Price, Alia Munir, and Miguel Debono

Definition of the disease

Short stature is defined as a height less than those in the second centile for age and sex on the appropriate growth chart. Abnormalities of growth may be detected earlier by assessing growth velocity. Specialists refer to an absolute height for which the z score is <-2 SDs for age, or a linear growth velocity with a z score <-1 SDs for age.

Aetiology of the disease

The aetiology of short stature is given in Box 190.1.

Typical symptoms of the disease, and less common symptoms

Features of the different causes of short stature are given in Table 190.1. The child or the child's parent(s) may complain of short stature; commonly, this may be in relation to peers or siblings. Ideally, collection of data from school, GP, health visitor, or home height and weight records can be used to help with calculating growth velocity. Notably, auxology is performed poorly by non-specialists.

Demographics of the disease

Organic disease is increasingly found as a cause of short stature; it is found in approximately 50% of cases. Twenty to thirty per cent of non-organic short stature has been attributed to social or environmental factors. Studies have shown that 80% of cases are due to familial short stature, constitutional delay, or both. Only 5% of cases are attributable to growth hormone (GH) deficiency, Turner syndrome, or hypothyroidism.

The prevalence of adult-onset GH deficiency is approximately 1 in 10 000. If adults who had childhood onset of GH deficiency

are included, the prevalence of GH deficiency amongst adults is increased to 3 in 10 000. In children, GH deficiency has a prevalence of 1 in 3480, with a male:female ratio of 3:1.

Natural history, and complications of the disease

The natural history of short stature, as well as the complications associated with it, depends on the cause of the short stature. Untreated systemic disease will result in failure to thrive in the paediatric group, and ongoing chronic disease in the older age group. In GH deficiency, untreated short stature and delayed puberty will result.

Approach to diagnosing the disease

Consistently slow-growing children require full systemic and endocrine assessment. If the growth velocity (measure in centimetres per year) is normal, there is unlikely to be a significant endocrine disease. If the growth velocity is low, without an underlying systemic cause, further investigation is warranted. Sudden cessation of growth suggests major physical disease. If there is no gastrointestinal, respiratory, renal, or skeletal abnormality, a cerebral tumour and hypothyroidism must be excluded. The diagnosis is guided by history, clinical signs, and growth performance.

History

When taking the history, assess the birthweight and the length of gestation, calculate the mid-parental height and the weight for height, and take note of any maternal illnesses, childhood illnesses, medication, and milestones. Also note any family history of short stature or delayed puberty.

Examination

For the examination, assess height and height velocity over at least 4–6 months. Low weight for height suggests a nutritional or gastrointestinal cause.

In addition, stage puberty, using Tanner staging. Also, observe for features of dysmorphism or chronic disease states.

Growth

The persistence of a poor growth rate (below the 25th percentile on a velocity chart over 12 months) would be indicative of the need for investigation. However, if the presentation includes signs or symptoms suggestive of intracranial pathology, urgent investigation is indicated.

Other diagnoses that should be considered

See 'Aetiology of the disease' and 'Approach to diagnosing the disease'.

'Gold-standard' diagnostic tests

Many tests are used in the assessment of short stature, depending on the clinical history and signs.

Basal tests

The following basal tests should be performed:

- full blood count
- erythrocyte sedimentation rate

Box 190.1 Aetiology of short stature

- familial short stature and constitutional delay in growth and puberty (40%)
- growth hormone deficiency: primary (idiopathic; accounts for 50%–70% of cases of growth hormone deficiency) or secondary (pituitary/hypothalamic) from malformation, brain tumours, cranial irradiation, or psychosocial deprivation (8%)
- intrauterine growth retardation (7.5%)
- skeletal dysplasia (e.g. achondroplasia, hypochondroplasia)
- dysmorphic syndromes (e.g. Turner syndrome, Noonan syndrome, Down's syndrome)
- chronic illness (e.g. coeliac disease, Crohn's disease, chronic renal failure, chronic respiratory conditions (cystic fibrosis, severe asthma); chronic infection (HIV, TB); haematological diseases, such as chronic anaemias (thalassaemia, Fanconi syndrome); congenital heart disease)
- malnutrition (anorexia nervosa; marasmus; kwashiorkor; rickets due to vitamin D deficiency)
- endocrine disorders (hypothyroidism, hypoparathyroidism, pseudohypoparathyroidism, Cushing's syndrome)
- metabolic bone disease (hypophosphataemic rickets)
- growth hormone resistance (rare)

Table 190.1 Features of the different causes of short stature

	Constitutional delay	Familial short stature	Growth hormone insufficiency	Primary hypothyroidism	Small bowel disease
Family history	Often present	Positive	Rare	Rare	Sometimes
Growth/clinical feature/puberty	Slow from birth/immature but appropriate, with late but spontaneous puberty	Slow from birth Clinically normal, with normal puberty	Slow growth Immature Often overweight Delayed puberty	Slow growth Immature Delayed puberty	Slow Immature Usually thin for height Delayed puberty
Bone age	Moderate delay	Normal	Moderate delay increasing with time	Marked delay	Delay
Comments	Often difficult to differentiate from growth hormone deficiency Growth velocity vital	Need family member heights	Early investigation vital, especially if plump child	Measure thyroid-stimulating hormone and free thyroxine in all cases of short stature Clear clinical signs may not be obvious in all cases	Diarrhoea Anaemia Macrocytosis

- urea and electrolytes
- thyroid function test
- bone profile
- coeliac serology
- insulin-like growth factor 1 (IGF-1), and insulin-like growth-factor-binding protein 3
- karyotype (in girls), for chromosomal anomalies
- urinalysis

Dynamic tests

There may be indication for anterior pituitary function testing, GH provocation testing (insulin tolerance test (ITT); clonidine or glucagon testing) and IGF-1 generation testing. The **gold standard for assessment of GH deficiency is an ITT**, but it should only be requested in specialist centres.

Imaging

Skeletal survey

A skeletal survey will enable the assessment of bone age: non-dominant hand and wrist X-rays allow comparisons that can be used to set standards (this may indicate that sex-steroid priming is required).

MRI pituitary

In a child, a GH peak <20 mU/l, on an ITT or another stimulatory test, is a classic sign of GH deficiency, and other pituitary deficiencies should be excluded. GH treatment is indicated.

If the basal GH is elevated or the level of growth hormone-binding protein is >2 SDs below the mean, the patient has GH insensitivity syndrome, which is a group of disorders including Laron syndrome and its variants; malnutrition; and chronic disease. In this case, IGF-1 treatment is effective.

Acceptable diagnostic alternatives to the gold standard

If ITT is contraindicated (e.g. in the case of epilepsy or ischaemic heart disease, or in children) to assess the GH axis, then tests for growth hormone-releasing hormone, arginine, or glucagon (if the patient is on steroids) may be used.

Other relevant investigations

A DEXA scan may be useful for investigation in short stature.

Prognosis and how to estimate it

If the short stature is due to a systemic disease, treatment of the systemic disease, such as a gluten-free diet for coeliac disease, results in complete recovery, and catch-up of lost height will occur.

If the short stature is due to GH deficiency, then, in general, growth rates are improved in children on GH replacement, although the effectiveness of GH replacement may decrease with prolonged treatment. If short stature due to GH deficiency is left untreated, extreme short stature and delayed puberty will result. If the diagnosis of GH deficiency is certain, normal height may be achieved in childhood and adolescence. A reduction in BMI, together with an improved body composition, will occur.

Treatment and its effectiveness

Any underlying systemic illness should be treated. In the case of primary hypothyroidism, replace levothyroxine at 50–200 µg/day.

In the case of GH insufficiency, injections of recombinant GH (this is synthetic GH, so there is no infection risk) should be given but only by specialists. Evidence suggests that this treatment leads to an improvement in quality of life, cardiac risk profile, body composition, and bone density. GH treatment in disorders such as Turner syndrome, Prader–Willi syndrome, and chronic renal insufficiency should also be done by specialists. A dose of 0.025–0.05 mg/kg per day for children, and 0.15–0.3 mg/day (or 0.6–0.9 IU/day) for adults may be used.

The aim of treatment for short stature is to correct growth failure and improve body composition. Data has shown an increase in growth velocity in response to treatment but there is some debate over whether there is also an increase in final height.

Wass J and Shalet S. *Oxford Textbook of Endocrinology and Diabetes*, 2002. Oxford University Press.

191 Infertility

John Newell-Price, Alia Munir, and Miguel Debono

Causes of female infertility

Polycystic ovary syndrome

Definition of polycystic ovary syndrome

Polycystic ovary syndrome (PCOS) is a disorder characterized by two of the following three characteristics: (1) chronic anovulation; (2) chronic hyperandrogenism; (3) and polycystic-appearing ovaries on ultrasound. A diagnosis should be made after exclusion of conditions which cause irregular menstrual cycles and androgen excess.

Aetiology of PCOS

PCOS is commonly polygenic but rarely may be monogenic. Genes involved with insulin and gonadotropin secretion and action and those involved with androgen biosynthesis, secretion, transport, and metabolism are responsible. Ethnic origin, race, and environmental factors also have an influence on the phenotype.

Typical symptoms of PCOS, and less common symptoms

Common features of PCOS are oligo/amenorrhoea (70%), hirsutism (60%), obesity (35%–70%), infertility (30%), and acne (25%). Male pattern hair loss and acanthosis nigricans are less common.

Demographics of PCOS

PCOS is one of the most common endocrine disorders of women in the reproductive age group, with a prevalence of around 5%–10%.

Natural history of PCOS, and complications of the disease

The symptoms of PCOS usually begin around menarche/puberty, but onset after puberty may occur in someone who gains weight, indicating both genetic and environmental influences. Menstrual irregularities occur mainly as oligomenorrhoea or amenorrhoea. Chronic anovulation results in infertility. The majority of women with PCOS have ovarian hyperandrogenism, with hypersecretion of luteinizing hormone (LH) occurring in about 70% of patients. This is thought to occur by an increased frequency of hypothalamic gonadotropin-releasing hormone (GnRH) pulses, which stimulate an increased frequency of LH pulses, which act on the ovarian theca cells to produce increasing amounts of androgens. Women with PCOS are hyperinsulinaemic and insulin resistant, probably because of defects in insulin-signalling pathways. Approximately 10% of patients with PCOS have type 2 diabetes, and 30%–40% have abnormal glucose tolerance. A significant number of patients are obese, and the incidence of the condition in different populations parallels the incidence of obesity. Hypertriglyceridaemia, high very-low-density lipoprotein, high LDL, low HDL, vascular endothelial dysfunction, and reduced vascular compliance increase the risk for cardiovascular disease and hypertension. There is a 43% prevalence of metabolic syndrome in patients with PCOS. In view of persistent unopposed oestrogen stimulation of the endometrium, endometrial hyperplasia or endometrial carcinoma may occur. Obstructive sleep apnoea is another complication of the disease.

Approach to diagnosing PCOS

To diagnose PCOS, a thorough menstrual history should be taken, including time of menarche, frequency of periods, onset of irregularities, and presence of inter-menstrual bleeding. Difficulties with conception should be elicited.

Cutaneous features such as hirsutism, acne, acanthosis nigricans, male pattern hair loss, and obesity are all suggestive of PCOS.

Hirsutism that is rapidly progressive and associated with virilization (deep voice, increased muscle size, clitoromegaly, frontal balding) are associated with ovarian and adrenal tumours. Include an external genitalia examination. In addition, patients may have a family history of PCOS.

Features of associated complications should be recorded, including chest pain, polyuria, polydipsia, high blood pressure, retinopathy, peripheral neuropathy, daytime somnolence, or frequent snoring. Enquire about risk factors for glucose intolerance (e.g. elevated BMI, race, family history of diabetes, gestational diabetes).

Other diagnoses that should be considered aside from PCOS

Other diagnoses that should be considered aside from PCOS are:

- non-classic congenital adrenal hyperplasia
- Cushing's syndrome
- hyperprolactinaemia
- premature ovarian failure (POF)
- virilizing adrenal or ovarian tumour
- drug-related causes

'Gold-standard' diagnostic test for PCOS

The best diagnostic test for PCOS is the serum testosterone level (no gold-standard test available).

Acceptable diagnostic alternatives to the gold-standard test for PCOS

Acceptable diagnostic alternatives are:

- the ratio of LH to follicle-stimulating hormone (FSH)
- sex hormone-binding globulin (SHBG) level (low in 50%)
- transvaginal ultrasound of ovaries and endometrium (>12 follicular cysts of <10 mm in diameter in at least one ovary; or increased ovarian volume (>10 ml); also exclusion of endometrial hyperplasia and ovarian tumours)

Other relevant investigations for PCOS

Other relevant investigations for PCOS are:

- prolactin (to exclude hyperprolactinaemia)
- 9 a.m. 17-hydroxyprogesterone \pm response to Synacthen test (to exclude non-classical congenital adrenal hyperplasia)
- androstenedione, dehydroepiandrosterone sulphate (DHEAS; both may be raised in PCOS; DHEAS is a marker for adrenal hyperandrogenism)
- overnight dexamethasone suppression test (if signs of Cushing's only)
- serum lipids and fasting glucose \pm an oral glucose tolerance test (OGTT)

Prognosis for PCOS, and how to estimate it

In obese patients with PCOS, endocrine–metabolic markers improve after 4–12 weeks of dietary restriction. With loss of 5% of their starting weight, women with PCOS show a 40% improvement in their hirsutism. In a meta-analysis, metformin therapy resulted in ovulation in 46% of patients compared with 24% who received placebo. Approximately three-quarters of women with PCOS ovulate on clomiphene citrate alone. In women who are resistant to clomiphene citrate alone, addition of metformin may increase ovulation.

Treatment of PCOS, and its effectiveness

Patients may be concerned about cosmetic issues, infertility, or menstrual irregularities. These should all be discussed in detail with the

patient, as will all influence the decisions regarding management. In view of long-term risks, all patients should be treated.

Weight loss

Diet and exercise should be recommended, as they may improve frequency of ovulation and fertility and lower diabetes risk and androgen levels.

Fertility

If fertility is the primary goal, consider clomiphene, metformin and, if these are unsuccessful, gonadotrophins. IVF or laparoscopic ovarian diathermy may also be considered.

Hirsutism

Treatment for hirsutism includes:

- short-term non-pharmacologic approaches, such as shaving and use of chemical depilatories and/or bleaching cream
- suppression of androgens (ovarian: oral contraceptive pills (OCPs), commonly co-cyprindiol; GnRH analogues for severe cases)
- androgen receptor blockers (e.g. cyproterone acetate, spironolactone, flutamide)
- 5-alpha reductase inhibitors (e.g. finasteride)
- eflornithine (Vaniqa; an ornithine decarboxylase inhibitor; available as a topical cream that can be used to slow the hair growth)

Amenorrhoea

It is important that women achieve a withdrawal bleed at least once every three months, to reduce the risk of endometrial hyperplasia. Use OCPs or metformin for this.

Premature ovarian insufficiency

Definition of premature ovarian insufficiency

Premature ovarian insufficiency (POI) is a disorder characterized by amenorrhoea, low oestradiol levels, and elevated gonadotrophins, developing in women <40 years. As the natural history of POI may begin with infertility but still have persistent follicular development at later stages, the name POI is more accurate than the commonly used POF.

Aetiology of POI

The aetiology of primary ovarian insufficiency is given in Box 191.1

Typical symptoms of POI, and less common symptoms

Patients with POI typically present with amenorrhoea (primary or secondary) and menopausal symptoms (flushes, night sweats, mood changes, low sex drive, sleeping problems).

Demographics of POI

Estimates of the prevalence of POI range between 0.3% and 1%. Age of onset may be as early as the teenage years but varies widely.

Natural history of POI, and complications of the disease

POI at any stage could result from a decrease in the initial primordial follicle number, an increase in follicle destruction, or a failure of the follicle to respond to gonadotrophin stimulation. The disease develops insidiously and the first sign of the disease may be unexplained

Box 191.1 Aetiology of primary ovarian insufficiency

- idiopathic causes (common)
- genetic associations: mutations in X-chromosomal or autosomal genes (e.g. Turner syndrome, fragile X syndrome, mutations in the receptors for follicle-stimulating hormone or luteinizing hormone)
- enzyme defects (galactosaemia, 17 alpha-hydroxylase deficiency (congenital adrenal hyperplasia))
- autoimmune causes (e.g. autoimmune polyendocrine syndrome types I and II, isolated; 20%)
- iatrogenic causes (e.g. chemotherapy, radiotherapy, pelvic surgery)
- infective causes (e.g. viral)

infertility in a patient failing to respond to gonadotrophin stimulation, although basal FSH levels may be normal (occult POI). As the disease progresses, FSH levels increase (biochemical POI). Following this stage, patients develop menstrual irregularities (overt POI) and, finally, amenorrhoea, permanent infertility, and elevated gonadotrophins (POF). Most patients who develop POI do so after undergoing normal puberty and establishing regular menses. Some do not develop regular periods, and progress to POI years later. Ten per cent of patients present with primary amenorrhoea. Menopausal symptoms may precede menstrual irregularities. Health concerns for patients with POI include osteoporosis, osteopenia, and heart disease.

Approach to diagnosing POI

When diagnosing POI, a thorough menstrual history should be taken, including time of menarche, frequency of periods, onset of irregularities, and presence of inter-menstrual bleeding. Difficulties with conception should be elicited. In addition, enquire about menopausal symptoms.

A history of chemotherapy, radiotherapy, pelvic surgery, or recent infections should be recorded. A family history of overt POI is an important clue to the diagnosis.

A review of systems and a full physical examination should be performed, to uncover other autoimmune disorders or genetic causes. In addition, examine external genitalia.

Other diagnoses that should be considered aside from POI

Other diagnoses that should be considered aside from POI are:

- Turner syndrome (short stature, webbing of the neck, a highly arched palate, short fourth metacarpals, widely spaced nipples)
- autoimmune polyendocrine syndrome types I (hypoparathyroidism, chronic mucocutaneous candidiasis, primary adrenal insufficiency, primary hypothyroidism) and II (adrenal insufficiency, primary hypothyroidism, type 1 diabetes mellitus, vitiligo)
- hyperandrogenic states

'Gold-standard' diagnostic test for POI

The gold-standard diagnostic test for POI is the basal serum FSH level (measured at two occasions on at least 1 month apart; may fluctuate; a high level indicates POI).

Acceptable diagnostic alternatives to the gold-standard test for POI

Acceptable diagnostic alternatives to the gold-standard test for POI are tests to measure:

- LH (high in POI)
- oestradiol (low in POI)

Other relevant investigations for POI

Other relevant investigations for POI include:

- a pelvic ultrasound (for uterine and ovarian anatomy assessment)
- karyotype analysis
- a screen for autoimmune disease (thyroid and adrenal antibodies, thyroid function test, fasting glucose test)

Consider a tetraoctactide test or other tests for autoimmune diseases, if they are clinically indicated. Also consider a bone density test, for osteoporosis.

Prognosis of POI, and how to estimate it

About 6%–8% of women with POF will become pregnant spontaneously. Sometimes this may occur years after diagnosis. Spontaneous remission may occur.

Treatment of POI

The following may be used in the treatment of POI:

- patient education and counselling
- sex hormone replacement therapy: conjugated oestrogens and oestradiol (add on progestogen for 12–14 days a month in a non-hysterectomized patient)
- oocyte donation and IVF

Causes of male infertility

Male hypogonadism

Definition of male hypogonadism

Male hypogonadism is the failure of testes to produce adequate amounts of testosterone, spermatozoa, or both. The term primary (hypergonadotrophic) hypogonadism refers to testicular disorders characterized by low serum testosterone despite high levels of FSH and LH. Secondary (hypogonadotrophic) hypogonadism is the deficient release of GnRH, characterized by low normal or low levels of LH, FSH, and testosterone.

Aetiology of male hypogonadism

The aetiology of male hypogonadism is given in Box 191.2.

Typical symptoms of male hypogonadism, and less common symptoms

Common features of male hypogonadism are absence and loss of secondary sexual characteristics; reduced libido; erectile dysfunction; low energy; depressed mood; increased irritability; hot flushes; and decreased muscle strength.

Demographics of male hypogonadism

In men with hypergonadotrophic hypogonadism, the more common cause is Klinefelter syndrome, which has an incidence of 1 per 500–1000 live births. Hypogonadism may occur at any age, and hypergonadotrophic hypogonadism is commoner in males.

Natural history of male hypogonadism, and complications of the disease

Hypogonadism will manifest differently depending on the time of onset, duration, and severity. If the onset is in prepubertal males, the patient will present with long arms, long legs, sparse body hair (eunuchoidism), and failure to progress through puberty, while, post puberty, erectile dysfunction and infertility are the chief concerning issues, together with non-specific symptoms of lethargy, irritability, and mood changes. Post puberty penile length and skeleton are of normal proportions, hair is of normal distribution but reduced in amount, and patients progressively claim to be shaving less frequently. Complications of low testosterone levels are loss of libido; decreased physical strength; increase in visceral fat; anaemia; and reduced bone density or osteoporosis. In addition, there is an important association with type 2 diabetes mellitus and the metabolic syndrome.

Box 191.2 Aetiology of male hypogonadism

Primary hypogonadism

- genetic (Klinefelter syndrome)
- anatomic defects (cryptorchidism)
- orchitis (infection, autoimmune causes)
- tumour
- trauma/torsion
- iatrogenic causes (e.g. chemotherapy, surgery, radiotherapy, trauma)
- chronic illness
- alcohol abuse
- varicocele
- systemic illness (e.g. cirrhosis, anaemia, chronic renal failure)

Secondary hypogonadism

- hyperprolactinaemia
- gonadotropin-releasing hormone deficiency (Kallmann syndrome; associated with anosmia)
- hypothalamic lesions or disorders
- pituitary lesions or disorders
- systemic illness (e.g. haemochromatosis, stress, myocardial infarction)

Numerous studies have established a close relationship between obesity and low serum free or total testosterone levels in healthy males. An inverse relationship exists between testosterone levels and insulin concentrations in healthy men. Importantly, free testosterone levels, independently of SHBG (also low in insulin resistance), are low in one-third of diabetic men, while obesity and visceral adiposity, as assessed by both BMI and waist circumference, are negatively associated with low levels of testosterone.

After the age of 50, mean serum testosterone levels decrease progressively. Associated with advancing age, there is an increase in the levels of SHBG, translating into a decrease in the bioavailable testosterone (both albumin-bound and free fractions). A combination of primary and secondary hypogonadism may be seen with ageing.

Approach to diagnosing male hypogonadism

When diagnosing male hypogonadism, enquire about the presence of developmental anomalies associated with the genital tract and elicit features of delayed puberty. If the hypogonadism is post pubertal, establish symptoms of testosterone deficiency. In addition, record:

- events leading to hypogonadism (trauma, infections, chemotherapy, radiotherapy)
- a drug history, including over the counter drugs and drugs of abuse
- a general medical history for systemic illnesses
- any family history of genetic disorders
- a thorough sexual history, for erectile function and frequency of intercourse

Also, perform an external examination for body hair distribution, muscle mass, sense of smell, visual fields, and gynaecomastia. In addition, examine external genitalia for reduced testicular volume or anomalies.

Other diagnoses that should be considered aside from male hypogonadism

Other diagnoses that should be considered aside from male hypogonadism are Klinefelter syndrome (small testis, gynaecomastia, eunuchoidism), Kallmann syndrome (anosmia, cleft lip or palate, sensorineural deafness), type 2 diabetes mellitus, and metabolic syndrome.

'Gold-standard' diagnostic test for male hypogonadism

The gold-standard diagnostic test for male hypogonadism is a fasting 9 a.m. serum total testosterone test (if the level is low, the test should be repeated).

Acceptable diagnostic alternatives to the gold-standard test for male hypogonadism

Acceptable diagnostic alternatives to the gold-standard test for male hypogonadism are:

- free testosterone levels (especially in patients with diabetes or who are obese)
- SHBG levels (high in elderly; low in type 2 diabetes and in obese patients)
- LH, FSH (high in primary hypogonadism; inappropriately low in pituitary or hypothalamic hypogonadism)
- prolactin levels

Other relevant investigations for male hypogonadism

Other relevant investigations for male hypogonadism are:

- oestradiol levels (especially if gynaecomastia is present or an adrenal or testicular tumour is suspected)
- human chorionic gonadotropin stimulation test (to examine for Leydig cell function)
- clomifene test (examining integrity of hypothalamic–pituitary–testicular axis)
- prostate-specific antigen (PSA), full blood count (FBC), and lipids, if considering testosterone replacement
- fasting glucose ± OGTT

Also consider bone density assessment.

Prognosis of male hypogonadism, and how to estimate it

Men with hypogonadism may live a normal life if on hormone replacement.

Treatment for male hypogonadism, and its effectiveness

Testosterone replacement therapy is used as treatment for male hypogonadism, as intramuscular, buccal, and transdermal formulations, as well as gels and implants. It improves well-being, libido, virilization, and sexual function, increases muscle mass, and prevents osteoporosis. Testosterone replacement therapy may also reduce cardiovascular risk by possibly improving markers of insulin resistance in patients with hypogonadism and type 2 diabetes. However, it is contraindicated in prostate or breast cancer and should be avoided in sleep apnoea.

During the course of the therapy, monitor PSA levels, FBCs (for polycythaemia), lipids, liver function tests (if on oral testosterone), and testosterone levels.

Androgen replacement therapy does not restore fertility. In secondary hypogonadism, if fertility is desired, this may be stimulated by pulsatile luteinizing hormone-releasing hormone or gonadotropins.

192 Pituitary disorders: Prolactinomas, acromegaly, and pituitary apoplexy

John Newell-Price, Alia Munir, and Miguel Debono

Prolactinoma

Definition of prolactinoma

A prolactinoma (a prolactin-secreting pituitary tumour) is defined as a macroprolactinoma when it is >1 cm in diameter, and as a microprolactinoma when it is <1 cm in diameter.

Aetiology of prolactinoma

The causes of hyperprolactinaemia are listed in Box 192.1. The pathogenesis of prolactinoma is unknown, but the rare malignant prolactinomas may harbour the Ras mutation.

Typical symptoms of prolactinoma, and less common symptoms

Patients with micro- or macroprolactinomas may develop galactorrhoea (up to 90% in women, and 10%–20% in men) and gonadal dysfunction (in women, menstrual disturbance in up to 95%; in men, loss of libido and erectile dysfunction). They also have a long-term risk of reduced bone mineral density. Further, patients with macroprolactinomas may develop mass effects such as headaches, visual field defects, hypopituitarism, and invasion of the cavernous sinus;

the latter may lead to cranial nerve palsies and, occasionally, erosion of bone, CSF leakage, and meningitis.

Demographics of prolactinoma

Prolactinomas are the commonest functioning pituitary tumour. Microprolactinomas are more common in females and are more common than macroprolactinomas.

Natural history of prolactinoma, and complications of the disease

Microprolactinomas are common post-mortem, and less than <17% show an increase in size. In one-third of women with hyperprolactinaemia, the condition resolves after pregnancy or menopause. Dopamine-agonist treatment can be titrated down after 2–5 years of treatment and withdrawn to assess whether resolution of hyperprolactinaemia has occurred.

For macroprolactinomas, dopamine-agonist dose reduction should only be considered >5 years of treatment, as tumour enlargement may occur and definitive treatment may be required (radiotherapy or surgery).

Approach to diagnosing prolactinoma

Hyperprolactinaemia is indicated by prolactin levels above the sex-specific normal range. Since stress can cause an elevation in prolactin levels, two to three cannulated prolactin measurements over 30–60 minutes can be used to confirm abnormal prolactin elevation.

In the context of a pituitary macroadenoma on MRI, a prolactin level >6000 mIU/l is diagnostic of a macroprolactinoma as opposed to a non-functioning tumour with stalk compression.

If history and biochemistry are consistent with disease, proceed to pituitary MRI with gadolinium contrast. Microadenomas appear hypodense on T1-weighted images. Macroadenomas are space-occupying lesions and are sometimes associated with invasion.

Other diagnoses that should be considered aside from prolactinoma

The following should be considered in the differential diagnosis of prolactinoma:

- rule out hypothyroidism and chronic renal failure, as these also cause elevations in serum prolactin
- the Hook effect: in some assays, a very high level of prolactin may be incorrectly reported as a low level, as the antibodies used in the assay may fail to bind all prolactin molecules
- macroprolactinaemia: macroprolactin ('big prolactin') is a non-bioactive isoform of prolactin that binds to the antibodies used in the prolactin assay and can cause the prolactin level to appear elevated; macroprolactinaemia presents biochemically as hyperprolactinaemia, but ovulatory cycles are normal
- idiopathic hyperprolactinaemia: this may be due to alterations in hypothalamic function, as MRI does not demonstrate a pituitary lesion in these patients; in one-third of cases, prolactin levels return to normal; in 10%–15% of cases, prolactin levels increase; in the remaining cases, prolactin levels remain stable

'Gold-standard' diagnostic test for prolactinoma

The gold-standard diagnostic test for prolactinoma is a cannulated prolactin measurement.

Box 192.1 Aetiology of hyperprolactinaemia

Physiological causes

- pregnancy
- sexual intercourse
- nipple stimulation/suckling
- neonatal
- stress

Pituitary tumours

- prolactinoma
- mixed growth hormone-secreting and prolactin-secreting tumour
- stalk compression (non-functioning pituitary tumour)
- empty sella
- hypothalamic disease
- infiltration
- stalk section
- cranial irradiation

Drugs

- dopamine-receptor antagonists
- neuroleptics
- antidepressants
- cardiovascular drugs
- opiates
- protease inhibitors
- others

Metabolic causes

- hypothyroidism
- chronic renal failure (reduced clearance)
- severe liver disease

Other causes

- polycystic ovary syndrome
- chest wall lesions (zoster, burns, trauma)

Acceptable diagnostic alternatives to the gold-standard test for prolactinoma

There are no acceptable diagnostic alternatives to the gold-standard test for prolactinoma.

Other relevant investigations for prolactinoma

Another relevant investigation for prolactinoma is a full anterior pituitary function tests (to rule out hypopituitarism and to check for co-secretion), including tests for:

- adrenocorticotrophic hormone (ACTH)
- luteinizing hormone (LH)
- follicle-stimulating hormone (FSH)
- testosterone
- growth hormone (GH)
- insulin-like growth factor 1 (IGF-1)
- oestradiol
- urea and electrolytes

In addition, liver function tests and a short Synacthen test should be carried out.

Prognosis for prolactinoma, and how to estimate it

Most prolactinomas are treated successfully with medical therapy, with minimal morbidity. Lack of normalization of prolactin levels can be found in 25%–50% of patients taking bromocriptine, and 5%–18% taking cabergoline. Regarding failure to achieve at least a 50% decrease in tumour size, resistance can be expected in about one-third of those taking bromocriptine, and 5%–10% of those taking cabergoline. Prolactinomas in multiple endocrine neoplasia (MEN) type 1 may act more aggressively. Dopamine-agonist resistance is commoner in macroprolactinomas, especially in men.

Treatment of prolactinoma, and its effectiveness

The aim of treatment for prolactinoma is to restore gonadal function (for both microprolactinomas and macroprolactinomas) and reduce tumour size and prevent expansion (in macroprolactinomas). Thus, definitive tumour treatment is necessary.

Medical therapy for the treatment of prolactinoma

Dopamine-agonist treatment is the mainstay of treatment for all types of prolactinomas and leads to suppression of prolactin in most patients, so that galactorrhoea ceases and gonadal function returns to normal. Tumour shrinkage is the norm and must be carefully monitored. Cabergoline is more effective than bromocriptine. If prolactin levels fall but no shrinkage of a macroadenoma is seen on an MRI scan, the diagnosis is likely to be that of a non-functioning pituitary adenoma, and surgery may be indicated. Dopamine-agonist resistance may occur.

Surgery for the treatment of prolactinoma

Trans-sphenoidal hypophysectomy for the treatment of microprolactinoma is only indicated in patients who are intolerant to or resistant to dopamine agonists. The surgical cure rate for macroprolactinoma is poor (<30%); therefore, drug treatment should be trialled for all tumours. For microprolactinoma, the surgical cure rate is high (>80%) but the risk of subsequent hypopituitarism is also high (25%), and recurrence occurs at a rate of 4% at 5 years.

Radiotherapy for the treatment of prolactinoma

Pituitary irradiation leads to a slow reduction of prolactin levels in the majority of patients with prolactinoma. It is useful in the treatment of macroprolactinoma, provided the optic chiasm is not involved. Stereotactic radiosurgery may be used in selected cases.

Acromegaly

Definition of acromegaly

Acromegaly occurs as a result of excessive secretion of GH and, consequently, insulin-like growth factor 1 (IGF-1) in adults. It is termed 'pituitary gigantism' in the paediatric setting when excessive GH secretion occurs prior to epiphyseal plate fusion.

Box 192.2 Aetiology of acromegaly

- pituitary adenoma, in the majority of cases (>99%)
- growth hormone-releasing hormone secretion (hypothalamic or ectopic; rare)
- ectopic growth hormone secretion (very rare)

Aetiology of acromegaly

The aetiology of acromegaly is given in Box 192.2.

Typical symptoms of acromegaly, and less common symptoms

Symptoms of acromegaly include increased sweating (>80%), headaches, tiredness and lethargy, joint pains, and change in ring size or shoe size. Signs of acromegaly include coarsening of facial features; oily skin; frontal bossing; an enlarged nose; prognathism; interdental separation; a deep voice; macroglossia; musculoskeletal changes such as degenerative joint disease (osteoarthritis; 70%) and generalized myopathy; and soft tissue swelling, such as carpal tunnel syndrome (40%), goitre, and organomegaly (see Figure 192.1).

Demographics of acromegaly

Acromegaly is rare, with a prevalence of 40–60 cases/million population and a new case incidence of 4/million per year. There is an equal sex distribution. Most cases are insidious in onset and diagnosed in middle age.

Natural history of acromegaly, and complications of the disease

Acromegaly is a chronic debilitating disease. Often there is a delay in diagnosis for up to 7–10 years. The clinical manifestation of acromegaly depends on the chronicity and severity of disease. Patients frequently experience hyperhidrosis and fatigue. Acral enlargement may also be an early feature. Thickening of the soft tissue of the hands and feet results in enlargement of ring and shoe sizes. Coarsening of the facial features has a deleterious effect on self-image, markedly affecting self-confidence and quality of life. Local pituitary tumour enlargement may cause headaches and cranial nerve defects; in particular, optic chiasm compression may cause visual field defects (typically, bitemporal hemianopia).

There is a two- to threefold increase in mortality in patients with acromegaly, with cardiovascular, cerebrovascular, and respiratory disease contributing to the reduced life expectancy. It has been shown that disease duration and GH levels are independent predictors of overall mortality. Excess GH and IGF-1 have major detrimental effects on the heart and vasculature. At diagnosis, 60% of patients have hypertension, arrhythmias, valvular heart disease, and, consequently, diastolic heart failure. In terms of respiratory disorders, upper airways obstruction caused by pharyngeal hypertrophy and macroglossia, with obstructive sleep apnoea, occurs in over 50% of patients. Mortality returns to normal when GH and IGF-1 levels are in their normal ranges.

Up to 70% of patients with acromegaly develop large-joint and axial arthropathy due to bone and cartilage overgrowth and peri-articular calcification. Clearly, these problems represent the most significant functional disability associated with acromegaly. Another serious consequence is the development of type 2 diabetes mellitus. GH blocks the action of insulin, inhibiting phosphorylation of the insulin receptor and the signalling molecule insulin receptor substrate 1. This results in impaired glucose tolerance and insulin resistance. Both peripheral glucose uptake and suppression of gluconeogenesis are reduced.

Twenty-five per cent of GH-producing adenomas co-secrete prolactin. This may contribute to the 40%–80% of menstrual irregularities seen in women with acromegaly. Tumour compression effects may also cause hypopituitarism in some patients, who may therefore require replacement hormonal therapy.

Patients with acromegaly have a twofold increased risk of developing colonic polyps; this is attributed to the effects of IGF-1 on proliferating epithelial cells. Interestingly, the incidence rate of colon

Figure 192.1 Hands of a patient with acromegaly. Please see colour plate section.

cancer is lower but the rate of death from colon cancer is higher in this patient group compared to the normal population.

Complications of acromegaly include:

- hypertension (60%)
- impaired glucose tolerance (40%)
- insulin resistance and diabetes mellitus (20%)
- obstructive sleep apnoea (50%)
- increased risk of colonic polyps
- ischaemic heart disease
- cerebrovascular disease
- congestive cardiac failure
- visual field defects
- hypopituitarism

Approach to diagnosing acromegaly

A high index of suspicion is required to consider a diagnosis of acromegaly. Key questions in the history and careful examination are essential. It is useful to ask about changes in appearance; often, patients do not notice, so asking for an old photograph of the patient for comparison and, in particular, asking about changes in ring, shoe, or hat size may be helpful. Biochemical confirmation of the disease should be the initial investigative approach.

Other diagnoses that should be considered aside from acromegaly

Acromegaly is associated with the following rare syndromes: MEN type 1, Carney complex, and isolated familial somatotrophinomas.

'Gold-standard' diagnostic test for acromegaly

The gold-standard diagnostic test for acromegaly is failure to suppress GH levels to $<1 \mu\text{g/l}$ in response to a 75 mg oral glucose tolerance test with at least five measures (normally, GH suppresses to undetectable levels); in addition, 30% of patients show a paradoxical rise. This test may diagnose glucose intolerance as well. However, note that failure to suppress GH may also be seen in advanced liver disease, anorexia nervosa, and opiate abuse; in addition, a paradoxical rise in GH levels may be seen in diabetes mellitus and renal failure.

After the biochemical test, it is essential to proceed to an MRI (with gadolinium) of the pituitary to demonstrate a tumour.

Acceptable diagnostic alternatives to the gold-standard test for acromegaly

An IGF-1 test alongside GH measurements during the oral glucose tolerance test can be useful, as a normal IGF-1 level with a GH level $<1 \mu\text{g/l}$ excludes acromegaly. It is also useful in disease monitoring.

Note that a random GH test will be unhelpful, as GH is secreted in a pulsatile fashion.

Other relevant investigations for acromegaly

Other relevant investigations for acromegaly are:

- serum prolactin; this is essential, as some tumours co-secrete
- serum calcium: some patients are hypercalcaemic due to increased levels of 1,25-dihydroxycholecalciferol, as GH stimulates renal 1-alpha hydroxylase
- full anterior pituitary function (i.e. ACTH, GH, prolactin, testosterone, LH, FSH), to exclude hypopituitarism
- a short tetracosactide test

In the absence of a pituitary lesion, a serum growth hormone-releasing hormone measure may be useful. Imaging the thorax and abdomen will also help demonstrate a carcinoid tumour (rare; $<1\%$ of cases).

Prognosis of acromegaly, and how to estimate it

If acromegaly is untreated, its mortality is double that of the normal population, with the cause of death usually being cardiovascular, cerebrovascular, or respiratory in origin.

Treatment of acromegaly, and its effectiveness

Treatment for acromegaly is tailored to the patient.

Surgical treatment of acromegaly

The first-line management of acromegaly is surgical resection of the pituitary tumour, usually through trans-sphenoidal surgery, although a transfrontal approach may be necessary, depending upon the tumour. More recently, endoscopic endonasal trans-sphenoidal surgery has been shown to be less invasive. Optimal surgical outcome depends on the surgeon. Cure is defined as a mean GH $<1 \mu\text{g/l}$. Surgery achieves biochemical control in 80% of acromegalics with microadenomas ($<1 \text{ cm}$), and 50% of those with macroadenomas. As over

70% of acromegalics have macroadenomas, adjunctive medical treatment is required in about half of all cases.

Medical treatment of acromegaly

Dopamine agonists

Cabergoline has been shown to be more effective than bromocriptine at reducing IGF-1 levels. Levels of GH and IGF-1 are reduced but not usually to the normal range. Tumour shrinkage may occur if prolactin is co-secreted. ECG is recommended prior to and as monitoring with this class of drugs.

Somatostatin analogues

Somatostatin analogues lead to GH suppression in 60% of patients with acromegaly. Up to 40% of patients are complete responders, with normalization of GH and IGF-1 levels.

GH receptor antagonists

Pegvisomant is a new drug that has been shown to reduce IGF-1 levels in >90% of patients.

Radiotherapy for the treatment of acromegaly

Radiotherapy is used following unsuccessful surgery, or, very occasionally, as a primary therapy. The greatest reduction in GH levels following radiotherapy usually occurs in the first 2 years but GH levels may continue to fall for many years after therapy. Selected patients may also undergo stereotactic radiosurgery but this procedure is only performed at a few centres.

Pituitary apoplexy

Definition of pituitary apoplexy

Pituitary apoplexy is infarction of the pituitary gland, via haemorrhage or ischaemia, with resulting hypopituitarism. The clinical syndrome is characterized by sudden-onset headache, vomiting, visual impairment, and decreased consciousness. This may be accompanied by neurological symptoms involving the second, third, fourth, and sixth cranial nerves. Classical pituitary apoplexy is a medical emergency. Prompt diagnosis and hydrocortisone administration may be life-saving. Referral should be made to a multidisciplinary team consisting of (amongst others) a neurosurgeon and an endocrinologist.

Aetiology of pituitary apoplexy

Apoplexy may occur in patients with pituitary adenomas, most commonly with macroadenomas. It occurs when bleeding into a necrotic area of a pituitary tumour which has outgrown its blood supply causes infarction. Other factors which predispose to pituitary apoplexy include radiation therapy, diabetes mellitus, anticoagulant therapy, reduced intracranial pressure, major surgery, and post-partum haemorrhage (Sheehan's syndrome, where the enlarged post-partum pituitary gland is infarcted following severe hypotension from blood loss).

Typical symptoms of pituitary apoplexy, and less common symptoms

Consider pituitary apoplexy in all patients who have severe headache and:

- subarachnoid haemorrhage and meningitis have been excluded
- the headache is of sudden onset (may be retro-orbital), with vomiting and meningism
- visual disturbance and cranial nerve palsies (neuro-ophthalmic symptoms) are present; most commonly, bitemporal hemianopia; at worst, blindness
- there are preexisting pituitary tumours
- hypopituitarism is present, with symptoms similar to those of target organ insufficiency; this may be clinically apparent

If blood bursts through the sellar diaphragm, subarachnoid haemorrhage will develop.

Demographics of pituitary apoplexy

Pituitary apoplexy is rare. In preexisting pituitary tumours, the risk is higher in macroadenomas and it has been reported that

0.6%–10.0% of such cases experience apoplexy. The average age of onset is 50 years. Men are more affected than women. The majority of the tumours involved in pituitary apoplexy are non-functioning adenomas. In most cases, the pituitary tumour was previously undiagnosed.

Natural history of pituitary apoplexy, and complications of the disease

After pituitary apoplexy, 80% of patients develop hypopituitarism; 60%–80% require hydrocortisone replacement, either permanently or when unwell; 50%–60% require thyroid hormone replacement; and 60%–80% of men require testosterone replacement therapy. GH deficiency is, however, a common problem in these patients and, if left untreated, may cause decreased muscle mass, obesity, and fatigue; in addition, 10%–25% of patients develop diabetes insipidus. Hypopituitarism should be identified, and patients informed, as glucocorticoid deficiency is a life-threatening complication.

Approach to diagnosing pituitary apoplexy

There must be a high index of suspicion to consider a diagnosis of pituitary apoplexy. Consider this diagnosis in patients with known pituitary tumours; patients who have had major surgery, such as a coronary artery bypass; patients who are on anticoagulation; patients who have undergone radiation therapy to the pituitary; patients with a traumatic brain injury; and patients who are pregnant or on oestrogen treatment. In addition, hormone stimulation tests have been reported to provoke apoplexy.

In the acute situation with sudden-onset headache, haemodynamic stability must be maintained through supportive means (fluids and steroids), and urgent tests for urea, creatinine, renal function, liver function, clotting, random serum cortisol, thyroid-stimulating hormone (TSH), free thyroxine (FT4), prolactin, IGF-1, LH, FSH, testosterone (men), and oestradiol (women), as well as a full blood count, are to be sent. MRI pituitary is the imaging of choice. Subarachnoid haemorrhage and meningitis must be excluded. Depending on the severity of illness, admission to a high-dependency unit may be indicated.

Other diagnoses that should be considered aside from pituitary apoplexy

Other diagnoses that should be considered aside from pituitary apoplexy are:

- subarachnoid haemorrhage
- bacterial/viral meningitis
- brainstem infarction
- cavernous sinus thrombosis

'Gold-standard' diagnostic tests for pituitary apoplexy

'Gold-standard' diagnostic tests for apoplexy in the anterior pituitary

The following are the gold-standard diagnostic tests for apoplexy in the anterior pituitary:

- basal hormones:
 - LH
 - FSH
 - 9 a.m. testosterone
 - oestradiol
 - TSH
 - FT4
 - 9 a.m. cortisol
 - prolactin
 - IGF-1
 - ACTH; deficiency leads to a low glomerular filtration rate (an inability to excrete water load will mask diabetes insipidus); replace corticotrophic function first and then TSH
- further dynamic testing if indicated (e.g. insulin tolerance test (ITT))
- MRI pituitary

'Gold-standard' diagnostic tests for apoplexy in the posterior pituitary

The gold-standard diagnostic tests for apoplexy in the posterior pituitary are paired urine and plasma osmolalities at baseline (usually enough).

Acceptable diagnostic alternatives to the gold-standard tests for pituitary apoplexy

The following are acceptable diagnostic alternatives to the gold-standard diagnostic tests for pituitary apoplexy:

- a glucagon test (if ITT is contraindicated)
- CT (if MRI pituitary is contraindicated)

Other relevant investigations for pituitary apoplexy

The following tests may be used if infiltration of the pituitary is suspected and further investigation is needed:

- angiotensin-converting enzyme levels (serum and CSF; to exclude sarcoidosis)
- ferritin level (to exclude haemochromatosis)
- pituitary biopsy

Prognosis of pituitary apoplexy, and how to estimate it

In a large case series, mortality in pituitary apoplexy was thought to be 1.6% overall, and 1.9% in those requiring pituitary surgery. If pituitary apoplexy is untreated, there is an increased mortality from hypopituitarism. Before the introduction of steroid replacement, mortality was 50%.

Treatment of pituitary apoplexy, and its effectiveness

Empirical steroids are indicated in the treatment of pituitary apoplexy if there is haemodynamic instability, altered consciousness, reduced visual acuity, and severe visual field defects. In adults administer a 100 mg intramuscular bolus of hydrocortisone and then 50–100 mg 6 hourly intramuscular injections; alternatively, administer a 100–200 mg IV bolus and then an IV infusion of 2–4 mg/hour. Ideally, blood samples for basal anterior pituitary blood tests should be taken

urgently for analysis; the tests should include random serum cortisol, TSH, FT4, prolactin, IGF-1, LH, FSH, testosterone (men), and oestradiol (women).

A bedside assessment of visual acuity and fields should be made, with further neuro-ophthalmic assessment when the patient is stable. CT brain (+/- lumbar puncture) to exclude subarachnoid haemorrhage and meningitis should be undertaken, if not done already. The imaging of choice is an MRI of the pituitary and will confirm diagnosis in 90%. After emergency care, refer to a joint neurosurgical/endocrine team for definitive management and arrange a formal visual field assessment when the patient is stable, preferably within 24 hours. Where visual acuity and field defects occur, early surgery (trans-sphenoidal hypophysectomy) significantly improves the neuro-ophthalmic outcome.

Consider surgery if any of the following is present:

- severely reduced visual acuity
- severe, persistent visual field defects
- a deteriorating level of consciousness

If urgent empirical steroids are not indicated, consider treatment if the 9 a.m. serum cortisol is <400–500nmol/L (depending on assay).

Repeat pituitary and visual assessments are required at 4–6 weeks post apoplexy. Long-term follow-up 6–12 monthly is required to optimize hormone replacement and monitor tumour progression or recurrence.

PART 8

Gastrointestinal disorders

193 Normal gastrointestinal function

Satish Keshav and Alexandra Kent

Introduction

The gastrointestinal (GI) system accomplishes the tasks of digestion, absorption of nutritional compounds, and removal of waste products. This is a complex process that involves the hollow GI tract and the hepatic, pancreatic, and biliary systems. Symptoms and signs of disease relate directly to the digestive and/or absorptive processes they interrupt.

In this section, we will follow the progress of food through the GI tract.

Swallowing

There is first an oral and then a pharyngeal phase of swallowing. When food enters the mouth, mastication helps break down the bolus while mixing liquids, solids, and saliva, which helps lubricate and dissolve solid boluses. Taste sensation is carried by afferent fibres from the anterior two-thirds of the tongue (Cranial nerve (CN) VII), the posterior third of the tongue (CN IX), and the epiglottis (CN X); these fibres terminate in the nucleus tractus solitarius. When the bolus is a suitable size for swallowing, it is voluntarily moved to the back of the oral cavity by the tongue. The tongue then presses its anterior, superior aspect against the hard palate to prevent the bolus from entering the anterior part of the oral cavity, and creates a pressure wave which propels the bolus into the oropharynx as the soft palate raises. The posterior dorsum of the tongue then presses against the soft palate, thus preventing the bolus from re-entering the oral cavity.

The pharyngeal phase of swallowing transports the bolus through the pharynx and upper oesophageal sphincter, while protecting the airway. The soft palate raises to seal off the nasopharynx; the vocal cords and arytenoids adduct; and the epiglottis swings down to protect the laryngeal vestibule. In addition, the larynx and hyoid bone move forwards and upwards to move the larynx under the tongue and out of the path of the bolus. Overall, the bolus moves through the oropharynx at a velocity of 20–40 cm/s, and usually ~15 ml of air is swallowed with the bolus. At rest, the upper oesophageal sphincter is naturally closed, and prevents air from entering the oesophagus during respiration. However, the pressure reduces during sleep and anaesthesia. The upper oesophageal sphincter opens due to a reduction in tone plus traction from associated muscles, allowing the bolus to pass through.

The muscles involved in the initiation of swallowing are all striated, while the lower oesophageal muscles are non-striated. CN V and VII are required for mastication, while movement of the tongue requires CN XII, and the overall swallowing process requires further input from CN IX, X, XI, and XII. Acetylcholine is the major neurotransmitter.

Oesophagus

The oesophagus lies behind the trachea and enters the abdominal cavity through an opening in the diaphragm, the oesophageal hiatus. The upper third is composed of striated muscle, and peristalsis is controlled by parasympathetic nerves originating from the vagus nerve. The lower two-thirds is composed of smooth muscle and is innervated by the myenteric plexus, which lies between the inner circular and outer longitudinal muscle layers. There is also input from Meissner's plexus within the submucosa.

Peristalsis within the oesophagus, alongside the natural effect of gravity, transports boluses from the upper oesophagus into the stomach, through the lower oesophageal sphincter. Peristalsis involves lumen-occluding contractions that travel the oesophagus at ~4 cm/s,

caused by alternating, vagally controlled inhibition and excitation. Secondary peristalsis (peristalsis without the swallowing reflex, pharyngeal contractions, or relaxation of the upper oesophageal sphincter) clears food debris from the oesophagus. Tertiary contractions are simultaneous (non-propagated) contractions, of which the relevance is not known. The basal resting tone of the lower oesophageal sphincter is high, and on manometry is seen as a high-pressure zone, which relaxes within 2 s of swallowing, to allow the bolus into the stomach.

Belching

During belching, gas passes from the stomach into the oesophagus, causing oesophageal distension. This distension causes neurally mediated reflex relaxation, which, along with the pressure of the gas, causes relaxation of the upper oesophageal sphincter and release of the gas.

Reflux events

Transient relaxations of the lower oesophageal sphincter are often seen and, although not all are associated with reflux events, most reflux episodes occur during these relaxations. Distension of the oesophagus from liquid occurs much more slowly than in belching, resulting in contraction of the upper oesophageal sphincter and thus preventing fluid from entering the pharynx and causing aspiration.

Vomiting

During vomiting, the upper oesophageal sphincter relaxes and is pulled open by suprahyoid muscles, and the vocal cords actively close to prevent aspiration.

Stomach

The stomach is divided into four sections: the cardia, the fundus, the body, and the antrum. The oesophageal and pyloric sphincters keep the contents of the stomach contained. The stomach receives its blood supply from several sources:

- the right gastric artery (supplies the inferior part of the lesser curvature)
- the left gastric artery (supplies the superior part of the lesser curvature, and the cardia)
- the right gastroepiploic artery (supplies the inferior part of the greater curvature)
- the left gastroepiploic artery (supplies the superior part of the greater curvature)
- the short gastric artery (supplies the fundus and the upper portion of the greater curvature)

The layers of the stomach are found throughout all luminal surfaces of the GI tract, and are shown in Table 193.1.

The stomach has three main functions:

- to store food and release it into the duodenum at a slow steady rate
- to 'churn' food, aiding its breakdown by gastric acid and enzymes
- to kill ingested pathogens

As digestive products enter the stomach and cause distension of the antrum, G-cells release gastrin, which stimulates the release of hydrochloric acid. This acid aids in killing bacteria, and initiates protein digestion by catalysing the conversion of pepsinogen to pepsin, which is a protease. Gastrin stimulates the release of pepsinogen from chief cells. Intrinsic factor is produced by parietal cells, and binds to dietary hydroxocobalamin (vitamin B₁₂), preventing its degradation, and aiding its absorption in the ileum. The production of gut hormones is controlled by the autonomic nervous system; details of

Mucosa	This layer is exposed to luminal contents; there are three layers within the mucosa: <ul style="list-style-type: none"> • epithelium • lamina propria (contains connective tissue and glands) • muscularis mucosa
Submucosa	This contains fibrous connective tissue, and Meissner's plexus
Muscularis externa	This muscular layer has two layers throughout the gastrointestinal tract: the inner circular layer and the outer longitudinal layer; Auerbach's plexus lies between these layers; the stomach has an additional inner oblique layer, which helps create motion and churn food
Serosa	This is a connective tissue layer, continuous with the peritoneum

this are listed in Table 193.2. Absorption is not one of the major roles of the stomach, although the stomach does absorb some lipid-soluble compounds, such as caffeine, alcohol, and aspirin.

Duodenum

The duodenum is the first part of the small intestine. It is approximately 25 cm long, and connects the stomach to the jejunum, ending at the ligament of Treitz. It is largely retroperitoneal. The duodenum is C-shaped, and is divided into four parts:

- the first part is the duodenal bulb, which passes laterally, superiorly, and posteriorly, before making a sharp downward turn into the second part
- the second part passes downwards, and contains the ampulla of Vater, where the pancreatic duct and common bile duct connect to the GI tract
- the third part passes transversely to the left, crossing the aorta and vertebrae
- the fourth part terminates at the duodenojejunal flexure, which is surrounded by a peritoneal fold called the ligament of Treitz

The duodenum represents the join between the embryological foregut and midgut, with the transition point at the level of the ampulla of Vater. As such, it has two blood supplies: the foregut is supplied by the gastroduodenal artery and its branch, the superior pancreaticoduodenal artery, and the midgut is supplied by the superior mesenteric artery and its branch, the inferior pancreaticoduodenal artery.

The duodenum is responsible for digestion and controls the rate of emptying food from the stomach. As food enters the duodenum,

fat and acid stimulate the release of secretin and cholecystokinin from duodenal epithelial cells. These hormones stimulate the gallbladder and liver to release bile, and the pancreas to release bicarbonate and digestive enzymes. These digestive enzymes include trypsin (breaks down proteins), lipase (breaks down fat), and amylase (breaks down carbohydrates). The bicarbonate neutralizes gastric acid, and Brunner's glands release mucus.

Jejunum and ileum

The jejunum is approximately 2.5 m long, and the ileum is 3–4 m long; overall, the small intestine is approximately 5–7 m long. The mucosal layer of the small intestine is permanently folded (plicae circulares), with further finger-like projections of the mucosa, and microvilli projections on the epithelial cells. Overall, this increases the absorptive surface area of the small intestine by 500-fold, to approximately 250 m². Each villus has a blood supply which transports nutrients to appropriate sites throughout the body. Most of the nutrients are absorbed in the jejunum, with the following exceptions:

- vitamin B₁₂ and bile salts are absorbed in the terminal ileum
- water and lipids are absorbed throughout the ileum
- iron is absorbed in the duodenum

The GI tract secretes approximately 8 l of fluid per day: 1–1.5 l of saliva, 2–3 l of stomach secretions, 2 l of pancreaticobiliary secretions, and 2 l of small intestinal secretions. However, the small intestine reabsorbs the majority of this fluid, so only ~1 l enters the colon. Any pathological process that affects this absorptive process (e.g. cholera) can lead to excess fluid loss. Water absorption is passive, but other electrolytes (e.g. sodium, chloride) have both active and passive transport mechanisms. The nutritional role of the small intestine is clearly affected by conditions affecting the small bowel (e.g. coeliac disease, Crohn's disease), and these can lead to malnutrition.

Pancreas

The pancreas is an organ that lies beneath the stomach, and secretes hormones and enzymes into the GI tract via the pancreatic duct. It is divided into the head (from which extends the uncinata process), neck, tail, and body and sits in the retroperitoneum. The blood supply is from the superior and inferior pancreaticoduodenal arteries and the splenic artery. The pancreas is both an endocrine gland and an exocrine gland. Islets of Langerhans produce hormones: alpha cells secrete glucagon, beta cells produce insulin, delta cells secrete somatostatin, and PP cells secrete pancreatic polypeptide. Table 193.2 provides information about these hormones. Acinar cells produce

Hormone	Site of production	Stimulus for secretion	Mode of action
Gastrin	G-cells in the stomach	Distension of the antrum and duodenum; pancreas	Increases secretion of gastric acid, pepsinogen, and intrinsic factor
Cholecystokinin	Duodenum	Acid and fat entering the duodenum	Release of bile; decreases gastric emptying; increases release of pancreatic juice; mediates satiety
Secretin	Duodenum	Low pH from acid entering the duodenum	Stimulates release of pancreatic enzymes, bile, insulin, pepsin, glucagon, pancreatic polypeptide, and somatostatin; stimulates water and bicarbonate release from Brunner's glands; inhibits gastrin release
Gastric inhibitory peptide	Duodenum and jejunum	Glucose in the duodenum	Decreases gastric acid and motility; increases insulin secretion
Somatostatin	Delta cells, islets of Langerhans, stomach, intestine		Inhibitory hormone; inhibits release of gastrin, cholecystokinin, secretin, motilin, vasoactive intestinal polypeptide, gastric inhibitory peptide, enteroglucagon, insulin, glucagon, and pancreatic enzymes; decreases gastric emptying
Pancreatic polypeptide	PP cells, islets of Langerhans	Protein meal; fasting; exercise; hypoglycaemia	Stimulates release of pancreatic hormones and enzymes
Glucagon	Alpha cells, islets of Langerhans	Hypoglycaemia, catecholamines, cholecystokinin	Stimulates liver to convert glycogen into glucose
Insulin	Beta cells, islets of Langerhans	Protein and glucose ingestion	Stimulates glucose absorption, and conversion into glycogen
Vasoactive intestinal polypeptide	Brain, gut, pancreas		Causes smooth muscle relaxation; stimulates water and electrolyte secretion; inhibits gastric acid secretion

digestive enzymes; these cells are regulated by hormones and via the sympathetic and parasympathetic innervation.

Biliary tree

The biliary tree provides the pathway by which bile secreted by the liver reaches the duodenum. The bile first travels from the bile canaliculi to the canals of Hering and then to the bile ductules (in portal tracts). From there, it goes to the intra-hepatic bile ducts and then to the left and right hepatic ducts, which join to form the common hepatic duct. This joins the cystic duct to form the common bile duct, which then joins the pancreatic duct. From there, the bile travels to the ampulla of Vater and then to the duodenum. The gallbladder is connected to the common bile duct via the cystic duct, and acts as a reservoir for bile when the bile does not need to be delivered into the duodenum.

Bile has three main functions:

- to increase the solubility of cholesterol, fats, and fat-soluble vitamins and aid in their absorption
- to stimulate the secretion of water, to help move the contents along
- to aid the excretion of drugs and other waste products

The term 'enterohepatic circulation' refers to the way bile salts are reabsorbed in the terminal ileum, extracted by the liver, and then resecreted into bile. Bile salts are recirculated about 10–12 times per day.

Colon

The colon is the most caudal part of the GI tract. It starts at the caecum and can be divided into the following regions: ascending, transverse, descending, and sigmoid. The ascending colon and

the proximal two-thirds of the transverse colon are supplied by the superior mesenteric artery, and the rest of the transverse colon, the descending colon, and the sigmoid colon are supplied by the inferior mesenteric artery. The main functions of the colon are:

- absorbing water
- storing waste
- absorbing some vitamins (e.g. vitamin K)

As chyme passes into the colon, most of the water is removed, and the chyme is mixed with bacteria and mucus to become faeces. Some fibre is broken down by bacteria to create butyrate, acetate, and propionate, which provide some nourishment for the mucosal lining.

Rectum and anus

The rectum acts as a reservoir for faeces. As the rectum becomes full, stretch receptors initiate the desire to defaecate; the increase in intra-rectal pressure forces the faecal matter into the anal canal, and peristaltic waves propel the faeces out of the body. The anus has an internal and external sphincter, with the external sphincter remaining in a constant state of tonic contraction. The rectum receives a blood supply from the rectal arteries.

194 Diagnosis in suspected gastrointestinal disease

Satish Keshav and Alexandra Kent

Symptoms of suspected gastrointestinal disease

The most frequent presenting complaints suggesting gastrointestinal disease are diarrhoea, constipation, nausea, vomiting, anorexia, and abdominal pain, which can localize to any of the quadrants of the abdomen observed from the front. Loss of weight is a feature of some gastrointestinal disease, and general symptoms such as fever, malaise, and arthralgia may also occur. According to the National Institute for Health and Care Excellence (NICE), alarm symptoms include unintentional weight loss, dysphagia, chronic gastrointestinal bleeding, iron deficiency anaemia, an abdominal mass, and/or persistent vomiting.

The characteristics of diarrhoea and vomiting are important: for instance, is the stool loose, liquid, fatty, or blood stained? Urgency in the need to defaecate is characteristic of pathological bowel movements. Steatorrhoea, with the passage of pale, floating, malodorous stool suggests malabsorption, which can arise from pancreatic insufficiency and coeliac disease, amongst other causes. Watery diarrhoea is usually due to hypersecretion, and can be caused by viral, parasitic, or bacterial infection; toxins; laxatives ingested deliberately or inadvertently; and hormonal excess, for example, from thyrotoxicosis or neuroendocrine tumours. Bloody stools usually indicate inflammatory, vascular, or neoplastic disease such as bacterial dysentery, inflammatory bowel disease, neoplasia, and so on. Haematemesis or vomiting of coffee grounds is a feature of peptic ulcer disease and oesophageal varices, which are major causes for emergency presentation in gastroenterology.

Abdominal pain is a common symptom and, when it is chronic, associated with bloating of the abdomen, and altered bowel habit; it is a diagnostic criterion for irritable bowel syndrome. Typically, abdominal pain is relieved by defaecation in irritable bowel syndrome. Pain felt in the epigastrium or left upper quadrant may indicate gastric or duodenal disease. Pain in the right upper quadrant may be associated with hepatobiliary disease. Epigastric pain that radiates through to the back may indicate a penetrating peptic ulcer or pancreatic disease. Periumbilical pain may indicate disease in any part of the midgut, that is, any structure from the duodenum to the splenic flexure of the colon. Pain in the right lower quadrant may arise from structures such as the appendix or the caecum, and pain in the left lower quadrant suggests pathology in the sigmoid colon, such as diverticulitis.

Other important symptoms include dysphagia and odynophagia, acid reflux, dyspepsia, rectal bleeding, and difficulties with defaecation. Conversely, many serious gastrointestinal diseases can remain asymptomatic, and are only suspected because of abnormal tests indicating, for example, anaemia or elevated inflammatory markers, or when complications occur.

Family history is important because many gastrointestinal conditions have genetic or familial associations. These include colorectal cancer, inflammatory bowel disease, and coeliac disease.

Reassurance is the key to the management of most benign conditions. However, patients have access to the internet and often attend the outpatient clinic with preconceived ideas about their underlying diagnosis. Identifying a patient's specific concern is vital to preventing recurrent hospital attendances. Discussing these concerns with the patient will often lead to a more honest portrayal of their symptoms, and prevents the patient purely presenting the symptoms that they feel will lead to what they consider to be the necessary investigation.

Signs of suspected gastrointestinal disease

General examination is as important in gastroenterology as in all specialities. Particular attention must be paid to:

Colour: Pallor and jaundice are important.

Weight: Is the patient underweight for height? Has their weight changed?

Evidence of being systemically unwell: Tachycardia, fever, and hypotension occur in varying combinations in intra-abdominal sepsis, inflammation, and haemorrhage.

Stigmata of chronic liver disease: clubbing, Dupuytren's contracture, loss of body hair, gynaecomastia, and spider naevi.

Finger clubbing: Finger clubbing is also a feature of inflammatory bowel disease.

Various unusual rashes, such as acanthosis nigricans, are associated with gastrointestinal malignancy. Carcinoid syndrome is characterized by flushing and sclerosis of the skin.

Abdominal examination is used to detect an enlarged liver or spleen, ascites, tumours, and inflammatory masses. Nausea, vomiting, and constipation may arise from an incarcerated hernia, and examination for herniae is part of the gastroenterological assessment. Examination of the perineum may show signs of perineal Crohn's disease, or excoriation of the anal skin from chronic diarrhoea. Digital rectal examination is used to detect distal rectal masses, and proctoscopy and sigmoidoscopy, performed at the bedside, can be used to detect haemorrhoids, fissures, and rectal inflammation. Mucosal biopsies of the rectum can be obtained at the same time.

Examination of the stool is frequently helpful—it is an essential part of the evaluation when the patient presents with reported melena or haematemesis, and blood-stained faeces can indicate the presence of neoplasia or inflammation in the colon and rectum.

Tests for suspected gastrointestinal disease

Blood tests

Routine test results will usually be available to the physician in secondary care, and are easily obtained in primary care. These are frequently very helpful.

Haematology

Anaemia may be the earliest and only indicator of gastrointestinal disease, particularly in non-menstruating individuals with no other comorbidity. Iron deficiency can be caused by reduced absorption in coeliac disease and inflammatory bowel disease, or by intestinal bleeding in peptic ulcer disease, excessive use of NSAIDs, and intestinal neoplasia. For these reasons, unexplained iron deficiency should prompt further gastrointestinal investigation. Iron deficiency should be suspected in patients with microcytosis, and the most helpful further test is to determine the ferritin level. Hypoferritaemia indicates iron deficiency. The ferritin may, however, be normal or even slightly elevated in iron-deficient patients with an inflammatory condition, because increased ferritin production is a feature of the hepatic acute phase response. In these cases, more careful examination of the full blood count, the transferrin level, and the clinical context is necessary.

In acute gastrointestinal haemorrhage, of course, the haemoglobin level will not be reduced immediately while bleeding is occurring.

Rather, the initially normal haemoglobin level is seen to fall in the subsequent hours as the circulating volume is replenished. Therefore, in such cases, the best guide to the extent of blood loss is the haemodynamic assessment of pulse and blood pressure rather than the full blood count.

Vitamin B₁₂ and folate levels are easily checked. Low vitamin B₁₂ may indicate atrophic gastritis (pernicious anaemia) or ileal disease such as Crohn's ileitis. Low folate levels may be due to dietary insufficiency or malabsorption, caused by, for instance, coeliac disease.

Biochemistry

Inflammatory markers such as C-reactive protein (CRP) and the erythrocyte sedimentation rate (ESR) are useful to detect inflammatory bowel disease, infection, pancreatitis, and so on. In ulcerative colitis, the CRP level and the ESR are typically normal or only slightly elevated whereas, in Crohn's disease, the CRP level is usually moderately elevated. Very high levels of CRP, usually accompanied by leucocytosis, typically indicate infection or severe systemic inflammation associated with, for example, acute pancreatitis, cholecystitis, or appendicitis. An elevated platelet count should make the clinician suspicious of intra-abdominal septic collections or an abscess.

Electrolyte disturbances may be seen in diarrhoeal diseases and vomiting, especially when severe or prolonged. Typical changes include hypokalaemia and hyponatraemia. Diarrhoea may cause a metabolic acidosis, while persistent vomiting of gastric contents may cause a metabolic alkalosis. In coeliac disease, there may be malabsorption of calcium and magnesium with hypocalcaemia, and hypophosphataemia due to secondary hyperparathyroidism. In upper gastrointestinal haemorrhage, the urea level may be elevated because of increased digestion, absorption, and degradation of blood protein, resulting in increased production of urea.

Liver dysfunction and disease produce characteristic alterations in the levels of circulating transaminases, indicating hepatocellular damage, and the alkaline phosphatase and gamma-glutamyl transferase enzymes, indicating biliary tract damage. Hyperbilirubinaemia may indicate hepatic or post-hepatic cholestasis. Reduced liver function is best demonstrated by a prolonged prothrombin time, provided that the patient is not deficient in vitamin K (vitamin K deficiency is an important cause of coagulopathy), or by a reduced serum albumin level, provided that this is not caused by poor nutrition, an exaggerated acute phase response, or loss of albumin from the intestine or kidneys (e.g. via protein-losing enteropathy or nephritic syndrome). In hepatic encephalopathy, serum ammonia levels may be elevated. However, ammonia levels only approximately relate to clinical severity and, in chronic liver disease, can be totally misleading.

Stool samples can be tested for excessive fat, indicating malabsorption, and for levels of pancreatic elastase, which are reduced in cases of pancreatic insufficiency.

Serology

Specific blood tests can be used to provide near-diagnostic information. These include antibodies to tissue transglutaminase, which indicate coeliac disease, anti-mitochondrial antibodies, which indicate primary biliary cholangitis, and antibody tests for viral hepatitis. The tumour markers carcinoembryonic antigen, alpha-fetoprotein, and CA-19-9 are associated, respectively, with colon, liver, and pancreatic cancer, although they are not diagnostic and can only be used to monitor progress.

Endoscopy

Endoscopy of the upper and lower gastrointestinal tract is a direct and highly accurate means of diagnosing gastrointestinal disease. Biopsies taken at the time of endoscopy can be used to detect helicobacter infection, coeliac disease, various gastrointestinal infections, cancer, and inflammatory bowel disease. Endoscopy is usually performed by gastroenterologists, and the specific test should be discussed in advance. Endoscopy can also be used therapeutically, for example to control bleeding from a peptic ulcer or to remove a colonic polyp. The reach of endoscopy is increasing, for example, with the development of enteroscopy, biliary endoscopy, and wireless capsule endoscopy.

Radiology

Radiological examination of the gastrointestinal tract, liver, and pancreas is also expanding rapidly. Barium swallow is an important modality used to study the function of the oesophagus, although upper endoscopy has almost completely replaced barium meals. Small bowel enema and small bowel follow-through allow visualization of the small intestine, and are used particularly for detection of strictures and diverticula rather than for evaluation of the mucosal surface. Colonic polyps and cancer can be detected without the need for colonoscopy, using CT scanning with or without tagging of faeces with radio-opaque material, and gas distention of the lumen. Ultrasound scanning of the liver is highly sensitive to gallstones and fatty infiltration of the liver. The liver and the biliary tract are also well visualized with MRI.

Histopathology

Liver biopsy, and biopsy and histological examination of tumours, are critically important diagnostic tests. A liver biopsy can be performed percutaneously, using ultrasound guidance, or via the jugular vein (transjugular liver biopsy).

Microbiology

Examination of stool and urine may also help the diagnosis. Diarrhoea is frequently due to microorganisms such as viruses, parasites, and bacteria that can be detected by microscopy and culture, for instance. Antibiotic-associated diarrhoea may be caused by toxin-expressing *Clostridium difficile* strains, and the toxin can be detected in the stool by ELISA. Porphyria is a rare cause of recurrent abdominal pain, and a urine sample is used to detect excessive porphyrin excretion.

Summary

Diagnosis in gastroenterology should still proceed along standard lines, with an emphasis on history and examination, and attention to simple tests such as the full blood count. Specific diagnoses can be reliably established by more specialized tests, including serology, endoscopy, radiology, histopathology, and microbiology. However, it is critically important that clinical judgement is used in deciding which tests to perform, and when and how to interpret the results in the context of the patient's presentation.

195 Investigation in gastrointestinal disease

Satish Keshav and Alexandra Kent

Blood tests

Blood tests used for investigation in gastrointestinal disease include a full blood count, haematinics tests, and tests for biochemistry, immunology, and microbiology.

Full blood count

Haemoglobin

Haemoglobin is reduced in occult blood loss and malabsorption. However, it may remain normal for some time even in iron, vitamin B₁₂, or folate deficiency and in acute haemorrhage.

White-cell count

The white-cell count is raised in infection. It is also raised in patients taking steroids (e.g. for inflammatory bowel disease (IBD)).

Platelets

The platelet level is raised in inflammatory disorders (e.g. IBD).

Mean corpuscular volume

The mean corpuscular volume is a measure of the average red blood cell volume; it differentiates between microcytic (iron deficiency) and macrocytic (B₁₂ and folate deficiency) anaemia and is normal in acute blood loss.

Haematinics tests

Serum iron

Serum iron measures circulating iron bound to transferrin; iron is predominantly absorbed in the duodenum and upper jejunum. The results of this test are highly variable diurnally and in relation to meals and so of little clinical use.

Transferrin

Transferrin is a circulating protein that transports iron around the body. It is high in iron-deficiency anaemia due to the liver producing more in order to maximize use of available iron. It is low in anaemia of chronic disease.

Transferrin saturation is the ratio of serum iron and total iron-binding capacity (TIBC). It is low in iron-deficiency anaemia, and normal in anaemia of chronic disease. TIBC measures the bloods capacity to bind iron and transferrin. It is high in iron-deficiency anaemia, and low in anaemia of chronic disease.

Vitamin B₁₂

Vitamin B₁₂ levels indicate the status of the stomach, the pancreas, and the ileum. First, proteases released by the exocrine pancreas digest R-proteins to release vitamin B₁₂. In order to be absorbed, vitamin B₁₂ must first bind intrinsic factor, which is produced by parietal cells in the stomach. This complex is then absorbed in the terminal ileum. Therefore, B₁₂ absorption requires that the stomach, exocrine pancreas, and terminal ileum be intact.

Folate

Folate is absorbed in the proximal jejunum and its status can be indicated by folate levels. Folate deficiency can also occur in small bowel disease such as coeliac disease, and in diets deficient in green leafy vegetables. Conversely, small bowel bacterial overgrowth may result in elevated folate concentrations, because bacteria produce folic acid.

Biochemistry

Calcium

Calcium absorption occurs mainly in the proximal small intestine. Calcium levels are reduced in vitamin D deficiency and coeliac disease.

Magnesium

Magnesium is absorbed from the upper small intestine. Its absorption is hindered by the presence of calcium, alcohol, protein, phosphates, or fats. Magnesium levels are also low in short-bowel syndrome.

Albumin

Albumin levels can be reduced via protein-losing enteropathy, due to an increase in its loss from the gastrointestinal tract. It can also be reduced in inflammatory states, as it is a negative acute phase protein and so is downregulated during inflammation, and in nutritional deficiency. It is produced by the liver; therefore, in severe liver failure, albumin levels fall.

Glucose

Hypoglycaemia can be a feature of acute liver failure. Chronic pancreatitis may be associated with diabetes mellitus and hyperglycaemia. In addition, diabetes mellitus is associated with autonomic neuropathy, which can manifest as gastroparesis and chronic diarrhoea; however, these usually occur in patients with a long-standing history of diabetes and associated complications.

Zinc and selenium

Zinc and selenium are trace elements absorbed by the small intestine (jejunum). They are usually only reduced in malnutrition/malabsorption.

Thyroid function

Thyroid dysfunction can be associated with diarrhoea (hyperthyroidism) and constipation (hypothyroidism).

Cortisol levels and the Synacthen test

Addison's disease can present with weight loss and diarrhoea.

Immunology

Antibodies positive in coeliac disease include anti-gliadin antibody, anti-endomysial antibody, anti-reticulin antibody, and anti-tissue transglutaminase. IgA levels should also be checked, as 2% of patients with coeliac disease have IgA deficiency.

Microbiology

Blood serum can be used for specific bacterial serology (e.g. salmonella, brucella, proteus, giardia, and campylobacter). *Helicobacter pylori* serology confirms exposure to the bacteria, and titres will reduce following eradication therapy. Table 195.1 lists available tests for helicobacter.

Stool investigations

Stool samples for microscopy and culture are the most important investigation for acute diarrhoea. It is important to state on the request form details regarding risk factors, as different bacteria require selective culture medium. Furthermore it is important to specify if testing for *Clostridium difficile* is required. If the patient has travelled abroad it is also important to send stool samples for ova, cysts, and parasites. If the stool sample is not received by the microbiologist within 2 hours it should be refrigerated at below 4°C.

Stool samples are also useful when assessing fat malabsorption. Previously, the laboratory required a 3-day collection to assess abnormal faecal fat content, but nowadays most laboratories can perform this test on a single sample. Faecal elastase is a simple and non-invasive method for detecting pancreatic exocrine insufficiency and is performed on a single stool sample.

Radiology

Abdominal plain X-ray

Normally, an abdominal plain X-ray (AXR) is taken in a supine position, although an erect AXR gives the added benefit of visualizing air–fluid levels. Normally, the gastric gas bubble is seen in the left upper quadrant, and air is seen through the large bowel. The large bowel is normally in the periphery of the film, has a diameter ≤ 5 cm, and has haustra that only partially cross the bowel wall. The small bowel sits centrally and should have a diameter ≤ 3 cm, with valvulae conniventes that traverse the whole bowel wall. The caecum may have a greater diameter (up to 9 cm). There should not be air in the biliary tree unless the patient has recently undergone endoscopic retrograde cholangiopancreatography (ERCP). Gas outside the bowel is invariably abnormal, and is best seen under the right diaphragm on a supine film. Faecal matter has a mottled appearance. Colitis can have a characteristic appearance on the AXR, with narrowing, loss of haustrations, and thumbprinting. Calcium is radiolucent and may be identified in blood vessels (in calcified vessels), the pancreas (in chronic pancreatitis), gallstones, the kidneys (renal calculi or nephrocalcinosis), and the pelvis. Usually, you can see the outline of soft tissues and organs.

The AXR is an excellent tool for rapid diagnosis in support of clinical findings, including emergency conditions such as bowel perforation, chronic pancreatitis, and colitis, as well as benign conditions such as constipation.

Barium studies

Barium studies utilize barium, which is radiolucent and coats the bowel lining. The integrity of the bowel wall can then be seen on plain AXR. It can be used to look at the oesophagus (via a barium swallow), the stomach (via a barium meal), the small bowel (via barium follow-through or enteroclysis), or the colon (via a barium enema). Contrast studies permit the detection of mucosal abnormalities, including diverticulosis, dilation, polyps, and cancers. Air can be instilled into the colon along with the barium contrast medium to enhance and further define structures of the large bowel and rectum. Polyps and small cancers are more readily found using this method, which is called a double-contrast barium enema. A barium study may also provide information about gastrointestinal motility (e.g. delayed transit, nutcracker oesophagus, etc.). Barium enemas are used far less commonly now, given the greater availability of colonoscopy and CT pneumocolon, which are invariably more detailed. Barium is an irritant to the mediastinum and the peritoneum so, in cases of possible perforation, alternative contrast media (e.g. Gastrografin®, Omnipaque®) are used.

Ultrasound

Ultrasound uses reflected sound waves to produce a picture of abdominal structures via a non-invasive and risk-free procedure. It can gain an image of all abdominal structures (unless prevented due to body habitus) and is particularly good at assessing:

- gallstones
- biliary dilatation +/- cause
- organ (liver, spleen, pancreas, kidneys) size, shape, and texture
- the presence of masses
- hepatic fatty infiltration
- blood flow (e.g. through the portal vein)
- renal stones
- cysts
- aortic aneurysms

It is also used for guiding biopsies and aspirations.

CT

CT combines multiple X-rays with a computer to generate three-dimensional images of the body. CT can provide far more information than plain X-rays, contrast radiography, or ultrasound can. There are multiple reasons to perform CT scans, but the commonest indications include:

- diagnosing or staging cancer
- infections (e.g. appendicitis, abscesses, or fluid collections)
- inflammatory processes (e.g. pancreatitis or pyelonephritis)
- kidney and bladder stones
- abdominal aortic aneurysms
- when combined with angiography, assessing for blood vessel diseases such as thrombosis and stenosis
- rapidly identifying trauma
- guiding therapeutic procedures such as biopsies and drain insertion

CT colonoscopy (CT pneumocolon) is widely used, especially in patients in whom a colonoscopy is felt to be high risk (e.g. patients with heart disease). Patients require bowel preparation beforehand with purgatives, and have carbon dioxide passed into the colon via a rectal tube. They then undergo a CT scan, which can be used to create three-dimensional endoluminal views of the colon. CT colonoscopies are generally less uncomfortable than conventional colonoscopy, and do not require sedation. However, they are less accurate for polyps < 5 mm, and do not allow mucosal biopsies. Patients in whom it is not necessary to identify polyps and in whom a CT is being performed to purely exclude colorectal cancer (e.g. the elderly, who would not benefit from polyp surveillance) are usually offered a CT colon with oral contrast alone. This is referred to as 'faecal tagging', and aids the radiologist in excluding faecal residue as pathology.

MRI

MRI utilizes magnets and radio waves to create three-dimensional images, and has the added benefit of not requiring ionizing radiation to produce images. Gadolinium is routinely used as a contrast agent and is usually well tolerated, with less risk of renal dysfunction, compared to the contrast agents used for CT scans.

The high-contrast resolution of MRI allows discrimination between two adjacent tissue types as well as between normal and abnormal structures, to a greater degree than in CT. This accounts for the common practice of performing an MRI in patients with equivocal CT findings. MRI is more sensitive and specific for the detection and characterization of small disease processes such as hepatocellular carcinoma and liver metastases. Phases of contrast enhancement allow hepatic lesions to be assessed when contrast is in the arterial, venous, and intermediate stages, aiding differentiation amongst vascular, benign, and malignant lesions in the liver. In much the same way, small pancreatic cancer is much better shown on MRI.

MR cholangiopancreatography allows clear images of the biliary system and is often used to clearly assess for biliary obstruction prior to referral for therapeutic ERCP. The uses of MRI are expanding rapidly, and MRI small bowel is often used to assess young people for small bowel Crohn's, while reducing their radiation exposure.

MRI can also combine images with physiological responses. For example, secretin-enhanced MRI pancreas involves the exocrine pancreas being stimulated to produce a fluid containing digestive enzymes which are released into the pancreatic duct.

Nuclear medicine

SeHCAT scan

In a SeHCAT scan, the patient takes, orally, a capsule containing radiolabelled bile salts (23-seleno-25-homo-tauro-cholate) and then undergoes a baseline scan. The scan is then repeated after 7 days. Normally, bile salts are reabsorbed as part of the enterohepatic circulation; a retention value less than 15% signifies bile salt malabsorption. This scan is not routinely used, as treatment with colestyramine (a bile acid sequestrant) is quicker and simpler. If patients have bile salt malabsorption, they will respond rapidly to colestyramine.

HIDA scan

A HIDA scan involves injection of a radioactive tracer (hydroxyiminodiacetic acid (HIDA)) into the bloodstream, from which it is preferentially taken up by the liver and excreted into the bile. The HIDA then enters the biliary tree and the gallbladder and then exits into the small intestine. A HIDA scan is used to identify biliary obstruction; if the gallbladder is not filled, this suggests blockage of the cystic duct +/- cholecystitis. When used in conjunction with an injection of cholecystokinin, a gallbladder ejection fraction (the percent of bile expelled) can be calculated. When this ejection fraction is very low, gallbladder disease may be present.

Gastric emptying study

A gastric emptying study is used to calculate the rate at which the stomach empties, and can be used to diagnose gastroparesis. This study requires the ingestion of a meal containing a radioactive tracer. The test is completed in approximately 1–2 hours and is painless.

Endoscopy

Endoscopy is a minimally invasive procedure which uses a fibre-optic telescope passed into the body via the mouth or anus. It provides a video image, allowing direct inspection of the mucosal surface. The instrument also has additional channels and equipment, to allow passage of the following instruments:

- biopsy forceps: for mucosal biopsies
- snares: for removal of polyps, either alone ('cold') or with electrodiathermy ('hot')
- injection needles: a needle is passed through the endoscopic channel and attached to a syringe held by an assistant; it can be used to inject bleeding points with adrenaline, inject gastric varices with glue or thrombin, mark colonic cancers with dye (tattoo) to aid surgeons to identify cancer sites at the time of surgery, or inject beneath flat polyps ('lifting') to aid their removal and reduce the risk of perforation
- cauterization instruments: heat probes or argon plasma coagulation probes can be passed through the biopsy channel to apply heat to bleeding lesions
- endoscopic basket: used to pick up and remove objects (e.g. polyps, foreign objects) from the lumen
- endoloops: these are ligatures that can be placed on long polyp stalks to reduce bleeding from any vessels within the stalk

Oesophagogastroduodenoscopy

Oesophagogastroduodenoscopy (OGD) can be performed with local anaesthetic sprayed into the throat, or under conscious sedation with a short-acting benzodiazepine. In this procedure, the endoscope passes into the second part of the duodenum. There are many indications for OGD. The main side effects and risks include a sore throat, bleeding, and perforation, although the latter two are rare in diagnostic OGD and usually only seen when the OGD is accompanied by therapeutic procedures.

Lower GI endoscopy

A flexible sigmoidoscopy can pass as far as 60 cm, which is enough to reach the transverse colon, although usually it is only used to view as far as the descending colon. A colonoscopy can view the entire colon and pass into the terminal ileum. Sigmoidoscopies are usually performed with the patient unsedated whereas a colonoscopy usually requires conscious sedation with a short-acting benzodiazepine with or without an opiate (usually pethidine or fentanyl). Prior to the procedure, the patient requires bowel preparation, which, for sigmoidoscopy, involves an enema and, for colonoscopy, requires a full bowel purge. Lower GI endoscopies are often accompanied with simple procedures such as polypectomy, especially in patients >50, when polyps are common. Perforations occur in ~1 in 1000 diagnostic colonoscopies and ~1 in 500 therapeutic colonoscopies (e.g. polyp removal), and are rare in sigmoidoscopies. Bleeding occurs in 0.001%–0.240% of colonoscopies, is usually related to polypectomy, and settles with conservative measures in the majority.

Endoscopic retrograde cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) is now only used as a therapeutic procedure, as radiology is able to give clear visualization of the biliary tree. However, an ERCP is performed with radiological guidance. Initially, an endoscope is passed into the duodenum in a similar way as in an oesophagogastroduodenoscopy. However, an ERCP utilizes a side-viewing endoscope, allowing clearer visualization of the ampulla of Vater. Initially, the ampulla is cannulated so that radiolucent dye can be injected into the biliary tree, which is visualized via radiological images so that any obstruction to biliary flow can be identified. Operators can then treat the biliary obstruction according to the underlying pathology. Treatment can include sphincterotomy (cutting the sphincter of Oddi to open the exit into the duodenum and allow passage of gallstones), clearing of the bile ducts, dilatation of strictures, and placement of biliary stents. Samples can also be taken to aid diagnosis. ERCP usually requires heavier sedation with benzodiazepines and opiates.

Therapeutic endoscopy

There are several procedures that can be performed endoscopically:

Endoscopic mucosal resection: This is the removal of large polyps, by injecting saline underneath the polyp to lift, snare, and retrieve it. More recently, endoscopic submucosal dissection has been introduced, allowing lesions to be removed in one section.

Dilatation: This is most often used for oesophageal strictures, whether benign or malignant, although it is occasionally used for colonic fibrotic strictures. Balloon dilatation is most commonly used, allowing direct visualization of the mucosa as it is stretched. Bougie dilatation involves passing bougies of increasing size over an endoscopically placed guidewire. The risk of perforation should be clearly explained to the patient, at approximately 1%–2% for benign strictures and 4%–6% for malignant strictures.

Stent insertion: Self-expanding metal stents can be endoscopically placed within GI tumours to prevent obstruction and provide some palliation to symptoms. These can also be placed on a temporary basis in benign recurrent strictures in an attempt to prevent strictures reforming. Furthermore, stents are occasionally used to cover small mucosal tears (usually oesophageal) to prevent leakage as the perforation heals.

Laser therapy: This can be used for oesophageal cancers to reduce obstruction.

Radiofrequency ablation: This is used for Barrett's oesophagus associated with high grade dysplasia or early cancer in specialist centres. A balloon-mounted coil is passed into the oesophagus, and a controlled emission of radiofrequency energy is delivered. This ablates the abnormal tissue to good effect.

Photodynamic therapy: This is used in some specialist centres for oesophageal and gastric cancers. The basis behind photodynamic therapy is that a photosensitive drug is given to the patient, which is attracted to cancer cells. When the light is directed at the cancer, the drug is activated.

Capsule endoscopy

In capsule endoscopy, a capsule containing a camera, a light source, batteries, and a transmitter is swallowed. The capsule is approximately 1.5–2.0 cm long, and images are taken every 2 seconds and relayed to a data recorder worn by the patient. The commonest indications for this procedure include:

- iron-deficiency anaemia with normal OGD and colonoscopy, for suspected obscure gastrointestinal bleeding
- diagnosis of early or suspected small bowel Crohn's disease
- diagnosis of benign and malignant small intestinal lesions
- diagnosis of small bowel abnormalities identified via other investigations (e.g. CT, MRI, or barium X-rays)

Side effects are rare, and capsule retention occurs in <0.75% of cases.

Breath tests

Lactulose/glucose-hydrogen breath test for small bowel bacterial overgrowth

In a lactulose/glucose-hydrogen breath test for small bowel bacterial overgrowth, baseline expired air samples are taken to assess the patient's basal hydrogen concentrations, prior to consuming 75 g lactulose or 50 g glucose. Repeat expired air samples are taken every 15 minutes for 3 hours following this. A positive test is defined as a rise in hydrogen concentration >10 ppm over basal values within the first 2 hours, suggesting bacterial colonization of the small intestine. This initial peak will be followed by a much larger peak signifying the colonic response. Glucose (unlikely lactulose) is absorbed and so is less accurate for determining distal end bacterial overgrowth.

Lactose/hydrogen breath test for lactose intolerance

In a lactose/hydrogen breath test for lactose intolerance, following baseline samples, the patient consumes ~20 g lactose.

If the expired hydrogen concentration rises >20 ppm over the baseline value, the patient is typically diagnosed as having lactose intolerance.

Urea breath test for *H. pylori*

In a urea breath test for *H. pylori*, following baseline samples, patient consume a solution containing ¹³C- or ¹⁴C-labelled urea, which is broken down by the *H. pylori* bacteria to release CO₂. This is absorbed into the bloodstream and excreted in the breath, which is measured for the radiolabelled carbon 10–20 minutes later. This test is >90% accurate for the presence of *H. pylori*.

196 Immunology and genetics in gastrointestinal and hepatic medicine

Satish Keshav and Alexandra Kent

Introduction

Immunology

The gut has a pivotal role in immune homeostasis. It is constantly exposed to a wide array of antigens in food, and resident and consumed microorganisms. It is estimated that the number of bacterial cells in the gastrointestinal tract is tenfold greater than the number of cells in the human body. The gut needs to recognize harmful bacteria and, consequently, contains the largest number of immune cells in the body. However, it must remain tolerant to commensal bacteria. Bacteria express antigens that stimulate an immunological response via the gut-associated lymphoid tissue (GALT). The GALT includes the appendix, tonsils, Peyer's patches, and mesenteric lymph nodes. Therefore, the intestinal immune system is finely balanced between tolerance and reactivity. An example of an abnormal response that generally the individual should be tolerant to is gliadin peptides in coeliac disease. An example of excessive tolerance to an otherwise controllable infection is cryptosporidiosis, which causes diarrhoea in patients with HIV infection.

Genetics

The understanding of genetics in disease has progressed rapidly with the introduction of genome-wide association studies. The Wellcome Trust Case Control Consortium has performed extensive research on the genetics of many illnesses, including Crohn's disease, ulcerative colitis, Barrett's oesophagus, oesophageal adenocarcinoma, and primary biliary cholangitis. Although these studies have increased our understanding of the molecular basis of disease, they have had little impact on clinical management. This may change as studies associate genotype and phenotype.

Several gastrointestinal diseases have an aetiology based on immunological or genetic aberrations, and these immunological mechanisms and genetic mutations can be utilized for diagnostic purposes. However, there is no genetic or immunological marker that is 100% specific to a disease and, consequently, the markers are used to support clinical, histological, and/or radiological findings. Immunological and genetic tests that can be done for specific gastrointestinal conditions are listed in Tables 196.1 and 196.2, respectively.

Inflammatory bowel disease

Inflammatory bowel disease (IBD) is caused by an aberrant immune response in genetically susceptible individuals. The genetic component of IBD is confirmed by the increased concordance in monozygotic twins (50%–70%) compared to dizygotic twins (5%–10%); 15%–20% of IBD patients have an affected family member. Genome-wide scanning has identified a number of genes that alter the risk of developing IBD. Some genes, including the one with the strongest effect, NOD2, affect bacterial recognition. The NOD2 gene is on Chromosome 16, and the gene product is expressed in Paneth cells, which are specialized intestinal epithelial cells that have an anti-bacterial role, and in mononuclear phagocytes, including monocytes. Other genes are the IRGM and ATG16L autophagy-related genes, the interleukin 23 receptor gene, and PTPN2 (protein tyrosine phosphatase, non-receptor type 2) gene, which is also associated with other autoimmune diseases. Certain HLA types affect the exact type of IBD that is manifest, and affect prognosis. Many more genes have been identified, but the results concerning their roles in IBD are

Table 196.1 Immunological tests in gastrointestinal disease

Disease	Autoantibodies
Coeliac disease	Anti-tissue transglutaminase IgA Anti-endomysial IgA Anti-reticulin IgA
Autoimmune pancreatitis	Raised IgG4 levels
Autoimmune hepatitis	Type 1: ANA, anti-SMA, anti-actin antibody, anti-SLA, anti-liver-pancreas antigen, pANCA, AMA Type 2: anti-LKM, anti-liver cytosol-1 Raised IgG
Primary biliary cholangitis	AMA (raised in 90%–95%) ANA (raised in 20%) Raised IgM
Primary sclerosing cholangitis	pANCA Anti-biliary epithelial cells (60%) AMA, ANA, anti-SMA

Abbreviations: AMA, anti-mitochondrial antibody; ANA, antinuclear antibody; anti-LKM, anti-liver kidney microsomal type 1 antibody; pANCA, perinuclear antineutrophil cytoplasmic antibody; anti-SLA, anti-soluble liver antigen antibody; anti-SMA, smooth muscle antibody.

less well replicated, although studies are ongoing. Studies are now directed at correlating genotype and phenotype; for example, mutations in the NOD2 gene are associated with small bowel disease.

The underlying mechanism of inflammation in IBD is driven by immunological responses, including macrophage activation, leucocyte trafficking, and production of inflammatory cytokines such as tumour necrosis factor alpha (TNF α). Cytokines are inflammatory mediators which interact with the colonic mucosa and associated immune cells, resulting in colonic inflammation and ulceration. IBD patients have raised TNF α levels in inflamed mucosa, and this has led to the development of anti-TNF α therapy (e.g. infliximab, adalimumab). TNF α levels are not routinely measured. However, studies have suggested measurements of anti-TNF α trough levels or antibodies to anti-TNF α may allow for more accurate dosing, checking for adherence, and provide a rationale for switching to alternative therapies.

Table 196.2 Diagnostic genetic tests in gastrointestinal disease

	Disease	Gene	Chromosome
Colon cancer	Familial adenomatous polyposis	APC	5
	Hereditary non-polyposis colorectal cancer	MLH1	3
		MSH2	2
		MSH6	2
Liver disease	Haemochromatosis	HFE	6
	Wilson's disease	ATP7B	13
	Alpha-1-antitrypsin deficiency	Alpha-1-antitrypsin	14
Pancreatitis	Cystic fibrosis	CFTR	7
Luminal disease	Coeliac disease	HLA DQ2	6
		HLA DQ8	6

Coeliac disease

Coeliac disease, also known as gluten-sensitive enteropathy, is due to an immunologically mediated reaction to gliadin, leading to intra-epithelial lymphocyte infiltration, loss of intestinal villi, and lengthening of the intestinal crypts. Loss of the intestinal villi significantly reduces the absorptive capacity of the small bowel, leading to malabsorption. This immunological component is reflected in the presence of autoantibodies, which form part of the diagnostic workup. The most sensitive and specific antibodies are the anti-tissue transglutaminase IgA, anti-endomysial IgA, and anti-reticulin IgA, and these antibodies have been shown to correlate with the degree of mucosal damage. It is important to remember that approximately 1 in 500 people are deficient in IgA; therefore, the routine, IgA-based serological tests for coeliac disease will be falsely negative. A routine check on IgA levels will avoid this diagnostic pitfall. In any case, cases of suspected coeliac disease should undergo endoscopic biopsy of the duodenum to confirm the diagnosis.

There is a hereditary component with a prevalence of 10% in first-degree relatives and 75% concordance between monozygotic twins. Coeliac disease is almost never seen without an appropriate, permissive HLA background: DQ2 or DQ8.

Colon cancer

Colorectal cancer is associated with specific genetic mutations which are now well-characterized and which are usually acquired by somatic mutation, although they may also be inherited in the germline. An individual colorectal cancer has an average of nine mutant genes per tumour. These mutations are not tested for routinely, but a strong family history should initiate genetic testing for specific mutations; this testing should be done in specialist centres, alongside genetic counselling. Even without a specific inherited mutation, the risk of colorectal cancer is increased in family members. One first-degree relative with colorectal cancer will increase an individual's risk of colorectal cancer (relative risk (RR) 2.3), with additional first-degree relatives increasing the risk further (RR 4.3). Familial conditions associated with a significant increase in colorectal cancer include familial adenomatous polyposis coli, which is very rare, hereditary non-polyposis colorectal cancer, which is less rare, and juvenile polyposis and Peutz-Jeghers syndrome. Genes associated with specific conditions are listed in Table 196.2.

Haemochromatosis

Haemochromatosis is a common autosomal recessive genetic disorder in certain Western European populations, and is caused by two common mutations in the HFE gene. This gene is located within the HLA Class I region on Chromosome 6, and affects iron homeostasis. Identifying the gene responsible has made diagnosing cases easy, by virtue of genetic testing, although clinical and biochemical testing, for instance, for a very high ferritin level, is also reliable. Most cases are caused by mutations C282Y or H63D, which block the normal HFE activities, leading to enhanced iron accumulation. C282Y homozygotes account for 95% of cases, and C282Y/H63D compound heterozygotes account for 3%. More unusual causes of haemochromatosis have been mapped to Chromosome 2 (HFE2; juvenile haemochromatosis) and Chromosome 7 (HFE3).

Wilson's disease

Wilson's disease is an autosomal recessive disease characterized by excessive copper absorption from the small intestine. This abnormality is caused by a mutation in the ATP7B gene, with over 40 different mutations found, including small deletions, insertions, and missense mutations. This variety of mutations means genetic testing is not feasible as a diagnostic test for this disease.

Autoimmune hepatitis

Autoimmune hepatitis (AIH) is more common in women than men, and can cause cirrhosis and liver failure rapidly. It is characterized by

the presence of elevated levels of circulating IgG, and autoantibodies. It is likely that liver damage is a consequence, however, of the activation of T-lymphocytes, and consequent release of cytokines in the liver. Histologically, there is interface hepatitis, and a tendency to for rapid progression to cirrhosis. There are two types of AIH, according to serology: type 1 is characterized by the presence of antinuclear antibodies and/or anti-smooth muscle antibodies, whereas type 2 has anti-liver kidney microsomal type 1 antibody. AIH is associated with other autoimmune diseases and usually responds well to corticosteroid and immunosuppressive therapy. There is a genetic component to the disease. In Europe and the USA, susceptibility to AIH type 1 is conferred by the presence of HLA DR3 and DR4, and AIH type 2 by HLA DR7 and DR3. HLA DR7 confers a more aggressive disease.

Primary biliary cholangitis

In primary biliary cholangitis (PBC), increased expression of HLA Class II antigens makes hepatocytes more vulnerable to CD4 and CD8 lymphocyte-mediated attack, leading to the progressive destruction of small and medium bile ducts. It is also characterized by circulating autoantibodies (anti-mitochondrial antibodies), which are directed against the pyruvate dehydrogenase enzyme, raised levels of circulating IgM antibodies, and granuloma formation in the liver and regional lymph nodes. Genetic factors play an etiological role, as there is a significantly increased risk in first-degree relative (500–1000-fold), although no specific gene has been identified as yet. PBC has been associated with haplotype HLA-DR8 and, for some populations, HLA-DPB1.

Primary sclerosing cholangitis

Primary sclerosing cholangitis occurs mainly in the context of ulcerative colitis, although it may also occur in patients with Crohn's colitis, and in some cases with no apparent IBD. It is probably due to immune-mediated damage to large, medium, and, occasionally, small bile ducts. Circulating levels of IgG and IgM may be raised in some patients, and 60%–82% of patients are positive for pANCA (perinuclear antineutrophil cytoplasmic antibody). Studies have suggested a genetic component, with increased incidence in first-degree relatives, and it is strongly associated with HLA-B8 and HLA-DR3.

Viral hepatitis

Hepatitis B virus (HBV) has been classified by the genetic variation in a partial sequence of the HBV genome, with nine genotypes (A, B, C, D, E, F, G, H, J) identified to date. However, only four of these genotypes are tested for in routine clinical practice. These genotypes vary between populations and have been associated with differences in disease progression and response to therapy. Many doctors use genotyping to guide therapy, and educate the patient on the likelihood of a sustained response. However, there is disagreement between major national and international organizations as to whether genotyping should be part of routine management or simply used as a research tool. Further details regarding HBV genotypes can be found in Chapter 212. Eleven hepatitis C virus (HCV) genotypes have been identified throughout the world, designated 1–11, with further subtyping and strains identified according to the genomic sequence heterogeneity. This heterogeneity has hindered the development of vaccines, although this research is ongoing. The genotype may influence response to treatment.

The immune response to viral inoculation allows diagnosis from simple serological tests. An antibody to HCV confirms exposure, with further tests required to confirm ongoing infection. Presence of the hepatitis B surface antigen means HBV infection, with further tests required to assess whether infection is acute or chronic. Chapter 212 gives further information regarding serological testing in viral hepatitis.

Variations in the gene for interleukin 28 (interferon lambda) have an apparently profound effect on the outcome of infection and treatment for HCV. This relatively new discovery may also alter our understanding of the pathogenesis of this disease.

197 Gastrointestinal infections

Satish Keshav and Alexandra Kent

Definition of the disease

Gastrointestinal infections includes diarrhoeal diseases that are major causes of morbidity and mortality worldwide; viral hepatitis; and infections such as *Helicobacter pylori* infection in the stomach, and intestinal tuberculosis. Here, only luminal gastrointestinal infections causing gastroenteritis, manifested by diarrhoea and/or vomiting, are considered.

Aetiology of the disease

Gastrointestinal infections can be caused by viral, bacterial, or parasitic infections. Risks include contact with infected individuals, travel to areas with endemic infection, poor sanitation, eating uncooked or poorly cooked food, and immunocompromise. Table 197.1 lists the most common pathogens.

Table 197.1 Pathogens causing gastrointestinal disease

Pathogen	Risk factors	Incubation period	Duration	Symptoms	Treatment
Bacteria					
<i>Escherichia coli</i>	Enterotoxigenic <i>Escherichia coli</i> is the commonest cause of traveller's diarrhoea <i>Escherichia coli</i> O157 is found in undercooked meat (especially beef) and milk	1–7 days	3–5 days	Bloody diarrhoea Severe abdominal cramps	Co-trimoxazole Second or third generation cephalosporin Avoid antibiotics in <i>Escherichia coli</i> O157
<i>Campylobacter</i> spp.	Dairy products Undercooked meat, especially poultry	2–5 days	7 days	Abdominal pain Bloody diarrhoea Malaise Myalgia Fever	Erythromycin Ciprofloxacin
<i>Salmonella</i> spp.	Uncooked food Eggs	8–48 hours	10 days	Nausea Vomiting Diarrhoea (watery, +/- blood) Fever	Ciprofloxacin Co-trimoxazole Third generation cephalosporins
<i>Shigella</i> spp.	Shellfish Fruit Vegetables	2–4 days	7 days	Bloody diarrhoea Fever	Ampicillin Co-trimoxazole Ciprofloxacin
<i>Yersinia</i> spp.		3–7 days	1–3 weeks	Fever Watery diarrhoea, Abdominal pain	Ciprofloxacin Tetracycline
<i>Vibrio cholerae</i>	Seafood Contaminated water	6–48 hours	5–7 days	Rice-water diarrhoea	Tetracycline Co-trimoxazole Erythromycin Doxycycline
<i>Listeria monocytogenes</i>	Dairy products, especially soft cheese	3 weeks	48 hours	Fever Myalgia Nausea Diarrhoea	Ampicillin
<i>Staphylococcus aureus</i>	Undercooked meat	1–6 hours	1 day	Vomiting and diarrhoea Mediated by toxin production	
<i>Clostridium perfringens</i>	Inadequately reheated or undercooked meat	6–24 hours	1 day	Watery diarrhoea Abdominal pain Fever Nausea Vomiting Caused by enterotoxin	Supportive
<i>Clostridium difficile</i>	Occurs in hospitals, after antibiotics	Variable	Variable	Fever Profuse watery (green) diarrhoea Abdominal pain Leucocytosis	Stop broad-spectrum antibiotics Vancomycin Metronidazole

Table 197.1 (Continued)					
Pathogen	Risk factors	Incubation period	Duration	Symptoms	Treatment
<i>Aeromonas</i> spp.	Fresh water and fish	1–7 days	>10 days	Fever Abdominal cramps Diarrhoea Vomiting	Third and fourth generation cephalosporins
<i>Bacillus cereus</i>	Food, especially rice	1–24 hours	12–24 hours	Vomiting Diarrhoea	Usually self-limiting Vancomycin or clindamycin in severe disease
Viruses					
Rotavirus	Occurs in outbreaks	1–3 days	3–8 days	Vomiting Watery diarrhoea	Supportive
Norovirus	Occurs in outbreaks Commonly in hospitals, nursing homes, and schools	1–3 days	24–48 hours	Diarrhoea Vomiting Myalgia Headaches Spreads rapidly	Supportive
Astrovirus	More common in the winter Affects the extremes of age	1–3 days	3–4 days	Vomiting Diarrhoea	Supportive
Enteric-type adenovirus	Mainly in children <2 years	1 week	3–4 days	Vomiting Diarrhoea	Supportive
Hepatitis A	Water Shellfish Raw vegetables	2–6 weeks	10–30 days	Flu-like illness Myalgia Diarrhoea Vomiting Abdominal pain Jaundice	Supportive
Parasites					
<i>Entamoeba histolytica</i>	Exotic travel	1–2 weeks	1–3 weeks	Amoebic dysentery Can cause liver abscesses	Metronidazole, followed by a luminal agent to prevent colonization (paromomycin, diloxanide furoate)
Giardia	Contaminated food or water	2–12 days	Variable	Abdominal pain Diarrhoea Can cause a chronic illness with malabsorption	Metronidazole Tinidazole
Microsporidia	Immunosuppression	1 week	Variable	Chronic diarrhoea Weight loss Abdominal pain Nausea Vomiting	Albendazole
Cryptosporidia	Untreated water Unpasteurized milk	7 days	5–10 days	Profuse diarrhoea	Nitazoxanide Paromomycin
Schistosomes	Still-water bathing in Africa, the Caribbean, South and Central America (<i>Schistosoma mansoni</i>), or the Far East (<i>Schistosoma japonicum</i>)	Variable	Variable	Acute or chronic diarrhoeal illness	Praziquantel

Bacterial

Bacteria exert pathological responses via various mechanisms. Non-invasive bacteria adhere to the luminal wall, causing an inflammatory response, whereas invasive bacteria cause mucosal ulceration and inflammation. Bacteria can also produce toxins that can cause diarrhoea, inflammation, and systemic toxicity. For example, the verotoxin produced by enterohaemorrhagic *Escherichia coli* leads to complications such as haemolytic–uraemic syndrome (HUS).

Viral

Viral gastroenteritis is highly contagious, and is spread by direct contact or via food (contaminated water, shellfish). Norovirus can be spread via droplets.

Parasitic

Entamoeba histolytica is responsible for amoebiasis, and causes 40 000–100 000 deaths worldwide annually. Humans acquire microsporidiosis through ingestion or inhalation of microsporidia spores. Cryptosporidiosis and microsporidiosis rarely cause problems in immunocompetent hosts.

Helminthic

Helminthic infections include ascariasis, trichuriasis, hookworm infection, enterobiasis, strongyloidiasis, filariasis, and trichinosis. Worms are prevalent in warm moist climates. Worms can infect humans via ingestion, larval penetration, or the introduction of larvae by a vector (usually mosquitoes or flies).

Typical symptoms of the disease, and less common symptoms

Gastrointestinal infections usually manifest as mild to severe diarrhoeal illness, often with associated nausea, vomiting, and abdominal pain. Infections are often accompanied by non-specific flu-like symptoms, such as myalgia and headaches. Bacterial and viral illnesses are usually self-limiting, but parasitic infections (e.g. giardia or helminth infections) can cause chronic illnesses, leading to malabsorption and/or nutritional deficiencies.

Gastrointestinal parasitic infections, such as schistosomiasis, microsporidiosis, and cryptosporidiosis can cause chronic illness with diarrhoea and weight loss, especially in immunocompromised individuals.

Helminth infections can cause abdominal pain, weight loss, diarrhoea, malaise, or can be asymptomatic. *Trichuris trichiura* can cause bloody diarrhoea when there is a heavy parasite load. *Enterobius vermicularis* infection (pinworm) causes nocturnal perianal pruritus and, occasionally, appendicitis or ulceration in the bowel. Ascariasis can cause small bowel obstruction if a mass of worms obstructs the lumen, although this is usually observed in children with heavy infections. The major manifestations of hookworm disease include iron deficiency anaemia and chronic protein–energy malnutrition. Worm attachment to the small intestine mucosa can cause abdominal pain, diarrhoea, and weight loss. Malabsorption has also been reported in children and, less commonly, in adults. *Strongyloides stercoralis* infection can cause abdominal pain and diarrhoea, nausea, vomiting, weight loss, and a protein-losing enteropathy.

Demographics of the disease

Gastrointestinal infections affect both genders and all ages and races, but certain groups are more susceptible, including returning travellers, children, elderly, and the immunocompromised.

Natural history and complications of the disease

The majority of bacterial and viral infections are self-limiting, without long-term sequelae. Parasitic and helminth infections respond well to specific treatments. The commonest complication is dehydration with or without associated prerenal failure, and is a leading cause of death in developing countries. However, specific complications for infection by the following microorganisms should be kept in mind:

- *Escherichia coli*: HUS, caused by *Escherichia coli* O157:H7; seen in 10% of cases, with an overall mortality of between 1% and 5%
- *Yersinia* spp.: erythema nodosum, reactive polyarthritides
- *Listeria monocytogenes*: septicaemia and meningitis
- *Clostridium difficile*: pseudomembranous colitis, toxic dilatation, and paralytic ileus
- *Campylobacter* spp.: peritonitis, pancreatitis, cholecystitis, bacteraemia, meningitis, Reiter's syndrome, Guillain–Barré syndrome
- *Salmonella* spp.: osteomyelitis, meningitis, bacteraemia, endocarditis, Reiter's syndrome
- *Shigella* spp.: Reiter's syndrome, HUS
- *Entamoeba histolytica*: fulminant colitis, toxic megacolon, cerebral amoebiasis
- schistosomes: disseminated disease
- helminths: anaemia, protein-losing enteropathy

It is important to recognize that salmonella and *Clostridium difficile* can result in asymptomatic carriage and so patients should continue to follow strict hygiene.

Approach to diagnosing the disease

Epidemics in the UK are usually caused by rotavirus, especially in children. However, norovirus is a common cause of 'winter vomiting', and rapidly spreads. It is important to ask about recent travel abroad, as the country of travel may give clues to the causative organism:

- Africa (*Entamoeba histolytica*, *Vibrio cholerae*, *Schistosoma mansoni*, *Strongyloides* spp., *Loa loa*)

- Central and South America (*Entamoeba histolytica*, *Vibrio cholerae*, *Schistosoma mansoni*)
- the Caribbean (*Schistosoma mansoni*, *Strongyloides* spp.)
- the tropics (*Entamoeba histolytica*, *Trichuris trichiura*, *Ascaris* spp.)
- Asia (*Vibrio cholerae*, *Schistosoma japonicum*, *Strongyloides* spp., *Trichinella* spp.)
- India (*Entamoeba histolytica*, *Vibrio cholerae*)
- Mexico (*Aeromonas* spp., *Entamoeba histolytica*, *Plesiomonas shigelloides*, *Yersinia* spp.)
- New Guinea (*Clostridium* spp.)
- Japan (*Vibrio parahaemolyticus*)
- Australia (*Yersinia* spp.)
- Canada (*Yersinia* spp.)
- Europe (*Yersinia* spp., *Giardia* spp.)

If a number of people who ate together are affected, specific foods consumed and the incubation period may give an indication of the responsible organism (see Table 197.1). Bloody diarrhoea should arouse suspicion of bacterial infection, which is commonly caused by *Escherichia coli*, salmonella, campylobacter, or shigella. Fever in adults suggests an invasive organism; children are often febrile irrespective of the underlying pathogen. Notably, campylobacter and salmonella are the commonest causes of bacterial gastroenteritis in the UK. If diarrhoea lasts for more than a fortnight, the aetiology is likely to be different from that of shorter duration.

Other diagnoses that should be considered

Gastrointestinal infections are usually easily identified, characterized by an acute onset, and often associated with systemic signs of infection (e.g. fever). The differential diagnoses include all causes of diarrhoea, including drugs, inflammatory bowel disease, coeliac disease, diverticular disease, microscopic colitis, colorectal cancer, bile acid malabsorption, pancreatic insufficiency, ischaemic colitis, bacterial overgrowth, lactose intolerance, toxin ingestion, vitamin deficiencies, and endocrine disorders.

'Gold-standard' diagnostic test

Stool microscopy and culture are the critical investigations. Light microscopy can identify ova, cysts, and parasites, including *Entamoeba histolytica*, *Cryptosporidium parvum*, microsporidia, and *Giardia lamblia*. One gram of faeces contains >10¹¹ bacteria; however, selective media must be used to identify specific pathogens. Blood agar is suitable for *Plesiomonas shigelloides*, *Listeria monocytogenes*, *Staphylococcus aureus*, *Bacillus cereus*, and *Salmonella*, *Shigella*, *Aeromonas*, and *Vibrio* spp. *Campylobacter* spp., *Clostridium difficile*, *Escherichia coli*, and *Yersinia* spp. require selective culture mediums. Unfortunately, stool cultures have a low yield, especially if the sample is not cultured within 2 hours of collection or is refrigerated at below 4°C.

Acceptable diagnostic alternatives to the gold standard

Treatment for gastrointestinal infections is largely supportive, but septic patients are often treated empirically with suitable antibiotics until the organism is identified. Antibiotic choice should be based on risk factors and travel history. Microsporidiosis has the greatest parasitic burden in the proximal jejunum, and diagnosis can be made from biopsies and/or jejunal fluid retrieved at endoscopy.

Other relevant investigations

Leucocytosis and faecal leucocytes are seen in enteroinvasive organisms but are unusual with enterotoxin-producing bacteria. Persistent diarrhoea may require endoscopic evaluation via flexible sigmoidoscopy, and mucosal biopsies may identify organisms and can exclude differential diagnoses. Endoscopic evaluation can also diagnose pseudomembranous colitis as seen in *Clostridium difficile* infection. Serological tests are available for *Entamoeba histolytica*, *Escherichia coli* O157:H7, enteroviruses, *Salmonella typhi*, *Salmonella paratyphi*, Q fever, and campylobacter, but are usually reserved for patients who fail to respond to treatment and in whom the pathogen has not been

identified. *Staphylococcus aureus* enterotoxin and *Clostridium difficile* toxin can be identified in stool samples. *Salmonella typhi* and *Salmonella paratyphi* are found in the blood <10 days after infection, and in urine and bone marrow >10 days after infection. Helminth infections are associated with eosinophilia and elevated serum IgE.

Prognosis and how to estimate it

The prognosis from gastrointestinal infections should be good when medical help is available, as the illness is responsive to supportive and specific therapy. Unfortunately, diarrhoeal illnesses are a massive cause of morbidity and mortality worldwide where medical and supportive care is lacking and where patients live in poverty. In the UK, mortality is rare except in very young, very old, or frail patients and those with significant comorbidities such as compromised immunity and renal, hepatic, cardiac, or respiratory disease.

Treatment and its effectiveness

The mainstay of treatment is the following procedure:

1. Rehydrate.
2. Correct electrolyte disturbances.

3. Isolate infective diarrhoea.
4. Notify the CDC about cases of infective diarrhoea.

The use of antibiotics for bacterial infections is not straightforward. Unnecessary antibiotic use has been seen to prolong symptoms, and may increase the risk of complications (HUS in infection with *Escherichia coli* O157). Furthermore antibiotics may have gastrointestinal side effects and increase the risk of concomitant *Clostridium difficile* infection. Generally, antibiotics should be reserved for the immunocompromised, the elderly, and those with bacteraemia or prolonged symptoms. Patients with severe ischaemic heart disease are also often treated with antibiotics.

Anthelmintic treatments include albendazole, mebendazole, ivermectin, piperazine, pyrantel, and diethylcarbamazine citrate.

198 Benign oesophageal disease

Satish Keshav and Alexandra Kent

Definition of the disease

Benign oesophageal disease includes several conditions, including:

- gastro-oesophageal reflux disease (GORD), which is reflux of gastric juices into the oesophagus with or without mucosal injury (oesophagitis)
- achalasia, which is an oesophageal dysmotility disorder characterized by aperistalsis in the distal oesophagus, and failure of lower oesophageal sphincter (LOS) relaxation
- motility disorders, such as:
 - oesophageal spasm, which is characterized by simultaneous, non-propagated contractions
 - nutcracker oesophagus, which is diagnosed by high-amplitude (≥ 180 mm Hg) contractions associated with chest pain
 - ineffective oesophageal motility, which is characterized by low-amplitude contractions (≤ 30 mm Hg) in the distal oesophagus
- eosinophilic oesophagitis, which is diagnosed on a combination of clinical features and oesophageal biopsies confirming the presence of >15 eosinophils per high-powered film

Aetiology of the disease

GORD has been associated with a hypotensive LOS, or transient relaxations of the LOS. Certain substances increase GORD by either decreasing the LOS pressure (caffeine, alcohol, nitrates, theophyllines, beta blockers, and calcium channel blockers) or increasing gastric acid (citrus fruits, spicy food). Reflux is more likely to occur in the presence of a hiatus hernia as it disrupts the synergistic action of the diaphragmatic crura and LOS. Obesity increases the intra-abdominal pressure, precipitating reflux.

Achalasia is due to degeneration of inhibitory neurons of the myenteric plexus and oesophageal wall. The cause is unknown, although studies have suggested there are associations with HSV-1 infection and HLA-DQw1.

The aetiology of motility disorders is unknown. Similarly, the exact cause of eosinophilic oesophagitis is unknown, although its association with allergic conditions such as asthma and rhinitis suggests it is a response to environmental antigens.

Typical symptoms of the disease, and less common symptoms

Symptoms in benign oesophageal disease have an insidious onset (see Table 198.1).

Table 198.1 Typical and less common symptoms of benign oesophageal disease

Disease	Common symptoms	Less common symptoms
GORD/h hiatus hernia	Heartburn Acid reflux Regurgitation	Cough, wheeze, hoarseness, laryngitis, odynophagia, water brash, nausea
Achalasia	Dysphagia Regurgitation/vomiting	Chest pain, heartburn, weight loss
Motility disorders	Heartburn Chest pain Dysphagia	Regurgitation
Eosinophilic disorders	Dysphagia Food impaction	Heartburn, reflux

Abbreviations: GORD, gastro-oesophageal reflux disease.

Demographics of the disease

Symptoms of GORD affect 14%–20% of the population, although only 20%–40% of patients with symptoms have diagnostically proven GORD. It affects all age groups and races, with no gender predilection.

Motility disorders and achalasia have an incidence of ~ 1 – 3 in 100 000 population and affect the genders equally. They can affect all age groups but more commonly affect those aged 25–60.

To date, eosinophilic oesophagitis is a disease of the developed world, mainly affecting children and young adults. Its incidence is currently estimated at 10–40 per 100 000 population in the Western world and is increasing, although the increase is likely to be due to increasing recognition of the condition.

Natural history and complications of the disease

Persistent exposure of the lower oesophagus to gastric acid, and the associated mucosal inflammation, can lead to the development of peptic strictures. These usually present with dysphagia and are treated with a soft diet +/- endoscopic balloon dilatation.

Persistent exposure of the oesophagus to gastric acid can lead to oesophagitis, peptic strictures, replacement of the squamous epithelium with columnar epithelium (Barrett's oesophagus), and adenocarcinoma. Barrett's oesophagus and adenocarcinoma are more common in men. Barrett's is found in $\sim 1\%$ of all endoscopies, and $\sim 12\%$ endoscopes performed for symptoms of GORD. Five per cent of these patients will develop low-grade dysplasia, with 10%–50% of these patients progressing to high-grade dysplasia and adenocarcinoma over 4–5 years. For this reason, endoscopic screening is performed for patients with histologically proven Barrett's oesophagus.

Achalasia has a gradual onset, with patients often suffering for years before seeking medical attention. Patients have an increased risk of squamous cell carcinoma of the oesophagus.

Motility disorders have no long-term complications aside from discomfort related to symptoms.

Many patients will suffer with eosinophilic oesophagitis for years prior to presentation. Complications include oesophageal ulceration and strictures.

Approach to diagnosing the disease

The insidious onset of symptoms is compatible with the benign nature of these conditions. It is often difficult to distinguish GORD from functional dyspepsia on symptoms alone, although response to treatment is compatible with true GORD. In patients with typical symptoms of GORD who respond to medication, no further investigations are necessary. Achalasia and motility disorders are usually only considered once endoscopy has ruled out mechanical obstructive lesions or eosinophilic oesophagitis.

Other diagnoses that should be considered

The common symptoms that occur in benign oesophageal disease are associated with all diagnoses: GORD, achalasia, motility disorders, and eosinophilic oesophagitis. Therefore, the initial differential diagnosis will include all of these conditions. Chagas disease, due to infection with *Trypanosoma cruzi*, can cause neuronal degeneration and symptoms consistent with achalasia. Other diseases associated

with achalasia-like motor abnormalities include sarcoidosis, amyloidosis, juvenile Sjögren's syndrome, Fabry's disease, and neurofibromatosis. Often, patient demographics and risk factors will clarify the most likely diagnosis. Secondary causes of oesophageal dysmotility include scleroderma, diabetes mellitus, alcohol consumption, psychiatric disorders, and presbyesophagus.

Eosinophilic oesophagitis is diagnosed on a combination of clinical symptoms and histology. Other conditions associated with oesophageal eosinophilia include GORD, parasitic and fungal infections, congenital rings, Crohn's disease, periarteritis, allergic vasculitis, drug injury, connective tissue diseases, and bullous pemphigoid.

'Gold-standard' diagnostic test

Oesophageal physiology tests are the gold-standard diagnostic tests for GORD and motility disorders. GORD is most accurately diagnosed by pH monitoring, which will detect exposure of the lower oesophagus to pH <4. This can be performed using standard pH-monitoring probes or, as is the case more recently, by pH-monitoring capsules which are attached to the oesophageal mucosa at the time of endoscopy. Oesophageal manometry is the gold-standard diagnostic test for motility disorders. Achalasia is characterized by aperistalsis and failure of LOS relaxation. The LOS is often hypertensive with a raised oesophageal-body resting pressure. The diagnostic findings of the other motility disorders are as described in their definitions. Oesophageal impedance testing and high-resolution manometry are not yet in widespread use. Multichannel intra-luminal impedance testing measures electrical resistance and can more accurately monitor bolus transit and gas or fluid reflux. Manometry probes normal contain 4–8 pressure sensors. High-resolution manometry utilizes up to 36 pressure sensors, thereby providing far more information about oesophageal motility.

Eosinophilic oesophagitis is diagnosed histologically from oesophageal biopsies.

Acceptable diagnostic alternatives to the gold-standard tests

A barium swallow can easily diagnose the presence of a hiatus hernia, and may demonstrate reflux of barium into the oesophagus. Endoscopy cannot diagnose GORD unless there are associated complications, such as peptic strictures or Barrett's oesophagus. Therefore, patients should ideally only be referred for endoscopy in the presence of alarm symptoms (unintentional weight loss, chronic gastrointestinal bleeding, dysphagia, persistent vomiting, iron-deficiency anaemia, epigastric mass, suspicious barium meal), or in patients ≥ 55 years with persistent symptoms.

Achalasia has a virtually diagnostic appearance on barium swallow, with a dilated oesophagus and beak-like narrowing due to the contracted LOS, although a normal appearance does not exclude the diagnosis. Gastroscopy will often confirm the dilated oesophagus with food residue, and a tight LOS.

Motility disorders cannot be diagnosed by alternative methods. Eosinophilic oesophagitis is diagnosed by oesophageal biopsies,

but endoscopic appearances can show characteristic oesophageal mucosal 'rings'

Other relevant investigations

There are no further investigations required to diagnose these symptoms. It is important to state that *Helicobacter pylori* is not associated with oesophageal disease.

Prognosis and how to estimate it

Prognosis in benign oesophageal disorders is dependent on response to treatment and presence of complications. Oesophageal symptoms can significantly impair quality of life, and treatments can result in dramatic improvements. In GORD, 80%–90% patients will respond to medications; however, recurrence is common on discontinuing therapy. Long-term prognosis in eosinophilic oesophagitis is not yet known, but the disease remains confined to the oesophagus, with studies confirming the persistence of oesophageal eosinophilia and symptoms. Hopefully, increasing recognition and implementation of therapy should improve the long-term prognosis.

Treatment and its effectiveness

Lifestyle measures for GORD include weight loss, alcohol reduction, smoking cessation, raising the head of the bed, avoiding tight garments, avoiding large meals, and not consuming meals 3 hours prior to bedtime. Proton-pump inhibitors (PPIs) are more effective at treating oesophagitis (83% response) than H₂ antagonists (52% response). Patients with persistent symptoms are commonly offered prokinetics, to increase gastric emptying, although evidence for this approach is lacking. Nissen's fundoplication is equally efficacious as PPIs, but 60% of patients will have recurring symptoms after 10–12 years. The occurrence of Barrett's and adenocarcinoma is equal between medically and surgically treated groups.

Peptic strictures causing dysphagia are treated with endoscopic balloon dilatation and high-dose PPIs. Repeat dilatations are often required, and patients may require a Nissen's fundoplication to reduce acid reflux precipitating the stricture.

Achalasia has three main treatment strategies, which are shown in Table 198.2.

Motility disorders are difficult to treat. Reflux and heartburn are usually controlled with antisecretory agents. In patients with chest pain due to spastic disorders, clinical trials support the use of smooth muscle relaxants (nitrates, calcium channel blockers) and pain modulators (tricyclic antidepressants and selective serotonin reuptake inhibitors). Further treatments, with less evidence, include sildenafil and botulinum toxin.

Eosinophilic oesophagitis can be treated with elimination diets, with a 77% response seen when elimination is guided by skin prick or atopy patch testing. Milk, wheat, soy, and egg are the most common allergens associated with this disorder. Elemental diets have been successfully used in children, with smaller studies in adults showing a 94% symptomatic response and a 78% histological response. Topical steroids have been used widely, using steroid inhalers, but instructing

Table 198.2 Treatment of achalasia

Treatment	Procedure	Short-term response (1 year)	Long-term response (5–10 years)
Medications	Calcium channel blockers/nitrates	10%	Overall poor response; reserved for patients refusing further treatment options
Botulinum toxin	Endoscopic injection into the LOS; response lasts only 6–12 months	30%	N/A
Pneumatic dilatation	Endoscopic dilatation; associated with 5% perforation rate and 25% post-procedure GORD	70%–80%	45%–60%
Surgical myotomy	Post-operative GORD in 10%–15%; reduced by simultaneous partial fundoplication	85%–95%	70%–85%

Abbreviations: GORD, gastro-oesophageal reflux disease; LOS, lower oesophageal sphincter.

the patient to swallow rather than inhale the medication. There is an 80%–100% response to topical steroids, although up to 90% of symptoms recur off therapy. Small preliminary studies have shown a response to the following therapies: montelukast (leukotriene inhibitor), mepolizumab (a monoclonal antibody against interleukin 5), and azathioprine.

199 Peptic ulcer disease

Satish Keshav and Alexandra Kent

Definition of the disease

Peptic ulcer disease (PUD) describes ulceration limited to the stomach and duodenum and characterized by mucosal damage related to pepsin and gastric acid.

Aetiology of the disease

Helicobacter pylori and NSAIDs are the predominant cause of peptic ulcers. *H. pylori* is associated with >90% of duodenal ulcers (DUs), and >70% of gastric ulcers (GUs); 10%–15% of patients with *H. pylori* develop ulceration. NSAIDs confer an annual risk of 1%–4% in those taking long-term therapy. NSAIDs inhibit prostaglandin synthesis and cyclooxygenase-2, reducing mucus and bicarbonate secretion, mucosal blood flow, and epithelial cell proliferation. Other causes of peptic ulcers include steroids, bisphosphonates, malignancy, critical illness, surgery, or hypovolaemia (due to splanchnic hypoperfusion).

Chronic renal failure, cirrhosis, and sarcoidosis have an increased incidence of PUD. In addition, Zollinger–Ellison syndrome presents with multiple ulcers due to gastrin-producing tumours (gastrinomas).

Typical symptoms of the disease, and less common symptoms

The typical symptom associated with PUD is a gnawing or burning epigastric pain, occurring on an empty stomach or 2–5 hours after meals. Less common symptoms include nausea, vomiting, heartburn, bloating, anorexia, or haematemesis/melaena due to underlying bleeding.

Demographics of the disease

The worldwide incidence rates of PUD are closely related to the presence of *H. pylori* and NSAID-prescribing habits. Approximately 10% of the population have a lifetime risk of PUD. However, incidence and prevalence rates may be underestimated due to many patients self-medicating with antacids. Incidence is equal between genders, with the majority of patients between 25 and 64 years of age. Zollinger–Ellison syndrome is a rare condition, affecting ~1 per million population, but is the cause of peptic ulceration in 0.1%–1% of cases.

Natural history and complications of the disease

Ulcers will heal when the injurious agent is removed, although antacid therapy will accelerate healing. However, significant morbidity and mortality are associated with PUD, with older patients having a significantly higher mortality risk.

Mortality is related to associated perforation and gastrointestinal (GI) bleeding. Approximately 30 in 100 000 patients require hospitalization, with an overall mortality of 1 in 100 000 cases of PUD. Fifteen to twenty per cent of patients with PUD will develop GI bleeding. The mortality rate is higher in older patients, of whom 20% present with asymptomatic ulcers. Two to ten per cent of peptic ulcers will perforate, with 60% duodenal, 20% in the gastric antrum, and 20% on the gastric lesser curve. Recurrent duodenal or pyloric canal ulceration may lead to pyloric stenosis, with resultant gastric outlet obstruction. In addition, 10% of GUs are malignant.

Approach to diagnosing the disease

Symptoms of PUD are difficult to distinguish from those of gastritis and non-ulcer dyspepsia, with only 20%–25% of patients with

symptoms consistent with PUD actually having an ulcer. The presence of associated symptoms can provide more information, suggesting the presence of complications, for example persistent vomiting, in gastric outlet obstruction; haematemesis, in bleeding ulcers; and severe abdominal pain radiating through to the back, in gastric or duodenal perforation. In patients <55 years old, with no alarm symptoms, it is standard practice to give a trial of proton-pump inhibitor (PPI) and 'test and treat' for *H. pylori*. Referral for further investigations should be performed on older patients (≥55 years old), in the presence of alarm symptoms (weight loss, anaemia, persistent vomiting, haematemesis) or in patients who have persistent symptoms despite antisecretory therapy.

Other diagnoses that should be considered

The differential diagnosis for patients presenting with right upper quadrant/epigastric pain includes:

- gastric carcinoma
- biliary colic
- cholelithiasis
- cholecystitis
- gastritis/duodenitis
- functional dyspepsia
- gastro-oesophageal reflux disease
- pancreatitis
- pancreatic carcinoma
- mesenteric ischaemia
- Crohn's disease affecting the upper GI tract

'Gold-standard' diagnostic test

The only investigation that can absolutely confirm the presence of peptic ulceration is an upper GI endoscopy (oesophagogastroduodenoscopy). This allows accurate recording (including photographs) of ulcer size, depth, features, and stigmata of haemorrhage. It allows for biopsies to be taken, especially from GUs, which have a 10% malignancy risk. Gastric biopsies can also be taken for an *H. pylori* urease test. Endoscopy is fundamental in patients with possible GI bleeding, as bleeding lesions can be treated endoscopically by sclerosant injections, cauterization, and/or application of haemoclips.

Acceptable diagnostic alternatives to the gold standard

In patients in whom endoscopy is considered to be high risk, a barium/Gastrografin meal and follow-through will provide information regarding mucosal integrity. If abnormalities are seen on the barium studies, a more accurate risk–benefit assessment can be applied. CT can be used to identify abnormal, usually thickened, mucosa, which is often found in association with peptic ulcers. However, CT is less accurate than barium or endoscopic investigations and is usually reserved for patients with symptoms or signs suggestive of visceral perforation, when it should be performed immediately.

Other relevant investigations

Young patients without alarm symptoms or suggestion of complications can be treated empirically with antisecretory therapy and tested and treated for *H. pylori*. All patients diagnosed with peptic ulcers should be tested for *H. pylori* and treated as necessary. In patients with bleeding ulcers, when *H. pylori* tests are not available or results are delayed, treatment should be given empirically.

Table 199.1 Diagnostic tests for *Helicobacter pylori*

Diagnostic test	Sensitivity (%)	Specificity (%)
<i>Helicobacter</i> serology	92	83
<i>Helicobacter</i> stool antigen	96	97
<i>Helicobacter</i> /urea breath test	95	96
Urease test	96	96

Hospitals vary in modes of *H. pylori* tests, but available tests are listed in Table 199.1.

In patients with multiple ulcers or in whom ulcer healing is unresponsive to antisecretory therapy, a fasting serum gastrin level should be measured to exclude Zollinger–Ellison syndrome as an underlying cause. PPIs and H2 antagonists should be stopped 3 and 7 days, respectively, prior to this test.

Prognosis and how to estimate it

Peptic ulceration can inflict substantial morbidity and mortality if left untreated. True peptic ulcers response well to treatment and removal of precipitants, but recurrence is not uncommon. In patients with a previous history of PUD, care should be taken when prescribing medications (e.g. aspirin or NSAIDs) associated with peptic ulceration. The benefits and risks of such medications should be balanced, and prophylactic antisecretory medication considered, in the following groups:

- patients with NSAID-induced ulcers but who require chronic, daily NSAID therapy
- patients over the age of 60
- patients with a history of PUD or a complication such as GI bleeding
- patients taking concomitant steroids or anticoagulants
- patients with significant comorbid medical illnesses

Treatment and its effectiveness

H. pylori eradication reduces ulcer recurrence from 69% to 6% in DU and from 59% to 4% in GU, and has been shown to be cost-effective.

Treatment of *H. pylori* infection is more effective than antisecretory therapy in preventing recurrent bleeding from PUD. Consequently, the most important and efficacious treatments for peptic ulcers are *H. pylori* eradication and avoidance of precipitants (e.g. NSAIDs). All patients who have undergone *H. pylori* eradication should be retested to ensure eradication has been effective.

PPIs bind to and inhibit the H⁺/K⁺-adenosine triphosphatase pump of the parietal cell, resulting in a marked decrease in acid secretion. In those patients who need to remain on NSAIDs, co-treatment with PPIs can reduce ulcer recurrence from 67% to 11%.

H2 antagonists selectively block H2 receptors on parietal cells, resulting in diminished acid secretion and ulcer healing. Both H2 antagonists and PPIs can reduce the incidence of duodenal and gastric ulceration as primary and secondary prophylaxis, in ulcers that are not associated with *H. pylori*.

Misoprostol inhibits gastric mucosal release of endogenous prostaglandin E2 and thromboxane B2, and reduces gastric ulcer recurrence from 7.7% to 1.9%.

Visceral perforation is treated surgically.

All patients with GUs should undergo repeat endoscopy at 8–10 weeks, to ensure healing and obtain biopsies from persistent ulcers, to ensure there is no underlying malignancy.

200 Gall bladder disease

Satish Keshav and Alexandra Kent

Definition of gall bladder disease

The gall bladder is a sac which lies underneath the liver and stores and concentrates bile produced by the liver. As food enters the duodenum, it stimulates the release of cholecystokinin, which in turn stimulates the release of bile, which passes via the cystic duct to the common bile duct, which connects to the duodenum at the sphincter of Oddi. Bile is required in digestion, especially for the emulsification and absorption of fat. Biliary disease can take several forms:

- cholelithiasis, which is the presence of gallstones in the gall bladder
- choledocholithiasis, which is the presence of gallstones in the biliary tree
- cholecystitis, which is inflammation and infection of the gall bladder
- cholangitis, which is inflammation and infection of the biliary tree
- sphincter of Oddi dysfunction (SOD), which is characterized by symptoms of biliary obstruction, with no structural cause
- gall bladder polyps
- primary biliary cholangitis (see Chapter 213)
- primary sclerosing cholangitis (see Chapter 218)

Approach to diagnosing gall bladder disease

Gall bladder disease is easily diagnosed on a combination of history and examination, and radiology will clarify the exact underlying condition. SOD is more difficult to diagnose and requires the exclusion of structural causes of symptoms. An ampullary tumour is found in approximately 4% of patients suspected of having SOD, so multiple investigations may be required prior to establishing the diagnosis. The presence of associated functional or psychiatric symptoms may correlate with type III SOD. However, this should not defer the doctor from excluding structural causes, especially given the complications that can occur with a delay in diagnosis.

Other diagnoses that should be considered aside from gall bladder disease

The differential diagnosis of biliary pain includes:

- hepatitis
- pancreatitis
- gastroenteritis
- right lower lobe pneumonia
- mesenteric ischaemia
- myocardial infarction
- small bowel obstruction
- renal calculi
- abdominal aneurysm

'Gold-standard' diagnostic test for gall bladder disease

An ultrasound scan (USS) of the biliary tree is considered to be the gold-standard test for gall bladder disease. A USS can clearly identify the presence of gall bladder polyps and gallstones as small as 1–2 mm and determine whether they are impacted in the biliary tree, as well as detect any associated biliary dilatation. Normally, the common bile duct is <8 mm. Cholecystitis is characterized by gall bladder distension, wall thickening, and pericholecystic fluid, and Murphy's sign is often duplicated when the USS probe is pushed down on the gall bladder. Air in the gall bladder wall indicates gangrenous cholecystitis.

USS is also advantageous in that it can identify complications, for example abscesses, empyemas, and perforations. It can also image other abdominal structures, such as the pancreas and the aorta, helping to exclude differential diagnoses. Sphincter of Oddi manometry is considered the gold standard for diagnosing SOD, although this test is only available at specialized centres. An elevated sphincter pressure of >40 mm Hg is diagnostic and corresponds to the obstruction seen in SOD. Manometry results correlate well with the type of SOD, with raised pressure seen in 60%–85% of patients with type I SOD, 18%–55% of patients with type II SOD, and 7%–28% of patients with type III SOD.

Acceptable diagnostic alternatives to the gold-standard test for gall bladder disease

MRI

Magnetic resonance cholangiopancreatography (MRCP) can give clear information about the biliary tree, including biliary dilatation and choledocholithiasis. It is often more sensitive for biliary sludge and tiny gallstones. The use of MRCP with secretin-stimulating pancreatic flow is being evaluated in diagnosing SOD, but studies are still needed to verify the usefulness of the technique.

Biliary scintigraphy

A HIDA scan is performed in the nuclear medicine department. A radioisotope is injected intravenously and is naturally removed by the liver and excreted into the bile. A two-dimensional image is then produced that shows where the isotope is located. Failure to see the isotope in the liver suggests a diseased liver. Blockages within the biliary system can be clearly seen, as only clear ducts will show up on the image. A gall bladder that is not visualized (i.e. no isotope seen within it) suggests a blockage in the cystic duct, supporting a diagnosis of acute calculus cholecystitis.

HIDA scans will show obstruction to biliary flow in SOD, especially in types I and II. However, reproducibility is uncertain and, therefore, scintigraphy is not yet used consistently.

CT

CT is not usually useful for evaluating biliary disease, and should only be used to identify complications (perforation, empyema) or in patients with failed USS (usually due to body habitus).

Other relevant investigations for gall bladder disease

Liver function tests

Uncomplicated gallstones and biliary colic will have normal blood parameters, and abnormal liver function tests (LFTs) should alert the physician to an alternative diagnosis. LFTs may be raised in cholecystitis, but normal parameters do not exclude the diagnosis. Cholangitis and biliary colic will result in raised LFTs, with the bilirubin and alkaline phosphatase levels rising to a greater extent than the transaminase levels. Type I and type II SOD patients may have raised alkaline phosphatase and transaminases, with levels of up to three times the upper limit of normal.

Full blood count

Cholangitis will cause leucocytosis, whereas only 60% of patients with cholecystitis will have a raised white-cell count.

C-reactive protein

C-reactive protein levels will be raised in inflammatory conditions, such as cholecystitis and cholangitis.

Amylase

Amylase levels may rise in cholecystitis and cholangitis, but usually no higher than three times the upper limit of normal. An amylase level higher than this should alert the physician to the possibility of gallstone pancreatitis.

Blood cultures

All febrile patients should have blood cultures taken to help identify any bacterial pathogens.

Gallstones

Aetiology of gallstones

Gallstones are formed when there is an imbalance in the composition of bile, and can be formed from cholesterol (75%–80%), pigment (15%), or a mixture of both. Cholesterol stones form when there is too much cholesterol in the bile, and pigment stones form when there is too much bilirubin. Biliary stasis and impaired gall bladder motility increase the risk of gallstone formation. Gallstones can range in size from millimetres to centimetres. Cholecystitis and cholangitis invariably occur as a consequence of gallstones obstructing the cystic or common bile duct, respectively, impairing biliary flow. Inflammation of the gall bladder is usually chemically mediated by lysolecithin, although 20% of cases are complicated by bacterial infection: *E. coli* (41%), *Enterococcus* spp. (12%), *Klebsiella* spp. (11%), and *Enterobacter* spp. (9%).

Typical symptoms of gallstones, and less common symptoms

Gallstones are asymptomatic in the majority and are often coincidental findings. Pain related to the gall bladder or biliary tree is usually constant and located in the upper abdomen (right upper quadrant or epigastrium) and is worsened by eating, especially fatty meals. The nature of the pain can vary, being described as a dull, gnawing, aching, band-like burning or tightness. Simple gallstones often cause mild-to-moderate pain, whereas cholecystitis or cholangitis can produce a more severe pain lasting for days. Gallstones impacted in the biliary tree cause biliary colic, which is usually severe, lasting for 1–5 hours on average. Biliary pain can radiate through to the back or be referred to the right shoulder or scapula, and can be associated with nausea and vomiting. Cholangitis is more likely to be accompanied by signs of sepsis, including fever, tachycardia, and hypotension. Fever can occur in cholecystitis, but is less common. Tenderness in the right upper quadrant ('Murphy's sign') is indicative of cholecystitis. Jaundice will only be seen when there is an obstructed biliary tree causing a blockage to the flow of bile.

Demographics of the gallstones

In the UK, approximately 3.5 million people have gallstones, although only 30% will develop symptoms. The highest prevalence is in fair-skinned Northern Europeans, and gallstones are more common in females. It has been proposed that the reason for the female preponderance is oestrogens causing increased cholesterol secretion and progesterone promoting biliary stasis. Pregnancy increases the risk of gallstones. Other risk factors include obesity, rapid weight loss, diabetes mellitus, haemolysis (e.g. sickle cell disease), cirrhosis, exogenous oestrogens, and medications (e.g. octreotide, fibrates). The risk of gallstones increases with age. The classic presentation is with the '3 F's': 'fat, female, and forty'!

Natural history of gallstones, and complications of the disease

Seventy per cent of patients with asymptomatic gallstones will have no complications. The majority of patients with complications related to gallstone will recover with standard therapy. Seventy per cent of patients would have suffered with a recurrence of their symptoms,

but laparoscopic cholecystectomy has significantly improved the prognosis for patients.

Complications of gallstones include:

- sepsis
- choledocholithiasis (10%)
- acute cholecystitis
- cholangitis
- gallstone pancreatitis
- gall bladder perforation (10%)
- a gall bladder-enteric fistula caused by a gallstone eroding through the gall bladder wall into the small bowel
- gall bladder ileus: following formation of a gall bladder-enteric fistula, a gallstone ≥ 2.5 cm can obstruct the ileocaecal valve
- conversion of a laparoscopic cholecystectomy to an open procedure (5%)

Prognosis of gallstones, and how to estimate it

Uncomplicated acute cholecystitis has a low mortality. However, complications significantly increase the mortality: there is 25% mortality in patients with a gangrenous gall bladder or gall bladder empyema, and up to 60% in patients with a gall bladder perforation. Complications are more common in the elderly or immunocompromised.

In patients treated with a cholecystectomy, post-cholecystectomy syndrome affects ~10%–15% of patients. This condition is thought to be due to the continuous passage of bile into the upper gastrointestinal tract, due to the loss of the gall bladder reservoir. This can result in gastritis, duodenitis, abdominal pain, or diarrhoea.

Treatment of gallstones, and its effectiveness

Incidental asymptomatic gallstones do not require treatment.

Laparoscopic cholecystectomy has revolutionized treatment for gallstones, being a procedure with fewer complications and quicker recovery than an open cholecystectomy. It is the commonest treatment strategy, resolving symptoms in approximately 90%.

In patients unable to undergo the operation for medical or personal reasons, medical therapy can be offered. Ursodeoxycholic acid can promote dissolution of cholesterol stones, but requires treatment for a minimum of 6 months, and trials have shown wide-ranging results, achieving complete dissolution of gallstones in 20%–75%. Furthermore, it does not prevent new stone formation once the treatment is stopped.

Lithotripsy utilizes extracorporeal ultrasonic waves to shatter gallstones. It has a reported success rate as high as 90%, although it is more successful in patients with few, small non-calcified gallstones.

Treatment of cholecystitis

When treating cholecystitis, fluid losses should be replaced with IV fluids. Patients normally remain 'nil by mouth' until symptoms are settling and complications are excluded. Analgesia should be given: opiates are often necessary, although morphine should be avoided as it can increase sphincter of Oddi tone. Anticholinergic antispasmodics (dicyclomine, Buscopan) can be useful for biliary colic. Gall bladder distension can be effectively treated with anti-inflammatory drugs (indomethacin). Anti-emetics should be given as required.

Although bacterial infection only complicates 20% of cases, antibiotics are usually given to all patients with cholecystitis. The antibiotic choice should depend on each individual hospital policy. However, commonly used antibiotics include penicillin or cephalosporin plus metronidazole, or piperacillin and tazobactam.

Cholecystectomy should be performed on all patients with complications from gallstones, as gallstones have a high risk of recurrence (~70%). However, it is no longer performed during an acute attack of cholecystitis, unless complications develop (perforation, gall bladder gangrene). If a cholecystectomy is performed for acute cholecystitis, it is preferable for it to be performed immediately once the diagnosis has been established. Following admission, the inflammation will often progress, making a laparoscopic procedure more difficult, and more often requiring conversion to an open procedure. Emergency drainage of a distended gall bladder can be performed using a radiologically placed drain. Cholecystectomy is usually performed when the patient has fully recovered from the cholecystitis, on an elective basis.

Treatment of cholangitis

Cholangitis treatment mirrors that of acute cholecystitis. However, since its aetiology is due to a blockage in the biliary tree, treatment is required to relieve this. Usually, endoscopic retrograde cholangiopancreatography (ERCP) is performed, when a sphincterotomy can be performed; the ducts are trawled to clear stones, and stents placed, if required, to maintain drainage. When ERCP cannot achieve drainage, a percutaneous biliary drain can be placed under radiological guidance and, once inflammation has settled, an ERCP is often more successful.

SOD

Aetiology of SOD

The aetiology of SOD is not entirely known. Biopsies from the ampulla have shown inflammation or fibrosis in ~40%, and this would fit with the papillary obstruction seen in some patients with SOD. Biliary dyskinesia, causing a motor abnormality of the sphincter of Oddi, has been considered, and would correspond with studies that have shown increased frequency of phasic contractions, retrograde propagation of contractions, and a paradoxical response to cholecystokinin. Visceral hyperalgesia has also been proposed as an underlying cause, with increasing incidence of anxiety, depression, and psychiatric problems being seen in patients with type III SOD.

The three types of SOD are defined as follows:

- type I: biliary pain with elevated LFTs and a dilated common bile duct (CBD); thought to be related to sphincter of Oddi stenosis
- type II: biliary pain and either elevated LFTs or dilated CBD; represents an overlap of type I and type III
- type: biliary pain alone; thought to be a functional disorder with sphincter of Oddi dyskinesia

Typical symptoms of SOD, and less common symptoms

SOD has three distinct clinical scenarios: (1) post-cholecystectomy syndrome, (2) acalculus biliary pain, and (3) recurrent pancreatitis. Patients suffer with biliary-type pain, as described, with no structural abnormalities to explain their symptoms.

Demographics of SOD

SOD can affect any age or gender, but classically affects women between the ages of 20 and 50.

Natural history of SOD, and complications of the disease

The main complications of SOD are persistent pain, requiring continuing use of analgesia, and the risk of recurrent pancreatitis. Sphincterotomy in patients with SOD carries a much higher risk of associated pancreatitis, which occurs in over twice as many SOD patients undergoing sphincterotomy as those undergoing sphincterotomy for biliary pathology.

Prognosis of SOD, and how to estimate it

SOD can have a very variable prognosis. Type I SOD patients and many type II SOD patients will respond to a sphincterotomy, although symptoms may recur after time. Type III SOD is far more difficult to treat, with no benefit from a sphincterotomy and medications being poorly tolerated or poorly effective.

Treatment of SOD, and its effectiveness

Medical therapy, including calcium channel blockers (nifedipine) and nitrates, has been used, but studies are often small and therapy is limited by side effects. Studies are ongoing into the use of

octreotide and prostaglandin analogues, aimed at reducing sphincter pressures.

Sphincterotomy, performed endoscopically, can relieve symptoms in 85% of patients with type I SOD, and 69% of patients with type II SOD. It is usually only offered to type II SOD patients who have high sphincter pressures. It is far less effective in type III SOD.

Botulinum toxin, injected endoscopically into the sphincter, can give relief of symptoms, and the procedure is relatively easy to perform. However, it is limited by its short duration of action (3–6 months). Response to botox can also be used to predict those who will respond to a sphincterotomy.

Gall bladder polyps

Aetiology of gall bladder polyps

Gall bladder polyps are common, with a prevalence of 4%–9%, but have an unknown aetiology. Cholesterol polyps are the most common (70%), and other types of polyps include inflammatory polyps, hyperplastic polyps, lymphoid polyps, fibrous polyps, granulation tissue, and adenomas.

Typical symptoms of gall bladder polyps, and less common symptoms

The majority of polyps are asymptomatic and diagnosed on a USS incidentally. Large polyps may cause abdominal pain, which is thought to be due to hypercontraction of the gall bladder, or intermittent obstruction of gall bladder emptying. Occasionally, the polyp can break off and cause obstruction of the CBD.

Demographics of gall bladder polyps

Benign gall bladder polyps affects all ages equally. They are slightly more common in men and in patients of Indian origin, with an increased incidence in patients with primary sclerosing cholangitis and hepatitis B.

Natural history gall bladder polyps, and complications of the disease

The main concern with polyps is the adenoma-to-cancer sequence which is seen in colonic adenomas. Polyps <5 mm are unlikely to be malignant, whereas those >15 mm have a much higher risk; for this reason, gall bladder polyps should remain under surveillance.

Prognosis of gall bladder polyps, and how to estimate it

The overall prognosis of gall bladder polyps is unknown, and the benefit of surveillance USS to monitor growth has not yet been established.

Treatment of gall bladder polyps, and its effectiveness

Generally, gall bladder polyps ≥ 1.0 –1.5 cm are removed via a cholecystectomy. Smaller polyps usually are monitored closely for 2 years, with 6–12 monthly USS, to assess the rate of growth. When there is no clear growth, USS can be done yearly; however, it has not yet been established how long these polyps should be monitored for.

201 Pancreatic disease

Satish Keshav and Alexandra Kent

Acute pancreatitis

Acute pancreatitis is an acute inflammatory process of the pancreas and is potentially reversible. It is characterized by oedema and necrosis of peripancreatic fat and may progress to necrosis of glandular and surrounding tissue. Activation of pancreatic enzymes leads to pancreatic autodigestion and systemic effects.

Aetiology of acute pancreatitis

Fifty to fifty-five per cent of cases of acute pancreatitis are caused by gallstones impacted in the common bile duct, and 20%–25% of cases are caused by alcohol. Other causes include drugs (e.g. azathioprine, pentamidine, didanosine), endoscopic retrograde cholangiopancreatography (ERCP), hypercalcaemia, hyperlipidaemia, pancreatic tumours, familial pancreatitis, ischaemia, trauma, vasculitis, pregnancy, viral infection, venom (e.g. scorpion bite), intra-ductal parasites (e.g. ascariasis), mycoplasma, and end-stage renal failure; alternatively, acute pancreatitis may be idiopathic.

Typical symptoms of acute pancreatitis, and less common symptoms

Pancreatic pain is classically described as epigastric in origin, radiating through to the back, and worsened by lying down or eating. The pain can be severe, and be associated with nausea and vomiting. Cullen's sign and Grey Turner's sign, respectively, describe periumbilical and flank bruising seen with haemorrhagic pancreatitis, and are uncommon features. Patients with acute pancreatitis usually have severe pain, which is relieved only by opiates, and are often systemically unwell, with fever, tachycardia, dehydration, and leucocytosis.

Demographics of acute pancreatitis

Acute pancreatitis has an annual incidence of 2 per 100 000 population, with an increasing incidence with age. It affects the genders equally.

Natural history of acute pancreatitis, and complications of the disease

Approximately 10%–30% of patients will develop severe disease, and account for the over 2%–10% mortality associated with acute pancreatitis. Severe inflammation can lead to the systemic inflammatory response syndrome and multi-organ failure. Mortality from acute pancreatitis is almost exclusively due to patients with necrotizing pancreatitis, which has a mortality rate of 20%–40%. Infected pancreatic necrosis has a mortality reaching almost 100% if not debrided.

Approach to diagnosing acute pancreatitis

The differential diagnosis of any patient presenting with acute abdominal pain and with an underlying history of excess alcohol consumption should include acute pancreatitis. A raised amylase level in a patient with typical symptoms is virtually diagnostic, and a CT scan should simply confirm the diagnosis. A history of gallstones or a change in medication may aid in the diagnosis. Infectious causes may have prodromal illness.

Diagnostic tests for acute pancreatitis

A rise in the serum amylase level, which peaks in the first 24 hours of acute pancreatitis, combined with clinical signs and symptoms, is virtually diagnostic of acute pancreatitis. Serum lipase levels also rise in the first 24 hours of acute pancreatitis, and may remain elevated longer than amylase levels, due to the longer half-life

Box 201.1 Balthazar grading system for acute pancreatitis

A: Normal pancreas

B: Heterogeneous attenuation, focal or diffuse glandular enlargement, irregular contour of the gland, no peripancreatic inflammation

C: Grade B plus peripancreatic inflammation

D: Grade C plus a single fluid collection

E: Grade C plus multiple fluid collections or abscess formation

Data from Balthazar EJ, Robinson DL, Megibow AJ, Ranson JH; Robinson; Megibow; Ranson. Acute pancreatitis: value of CT in establishing prognosis, *Radiology*, volume 174, issue 2, pp. 331–336. Copyright © 1990

of lipase in serum. However, the lipase test is less readily available in hospital laboratories. Other pancreatic enzymes have no diagnostic value.

CT can be used to confirm acute pancreatitis and can be evaluated with the Balthazar grading system, which can be correlated with mortality (see Box 201.1). However, the optimal timing of CT is open to discussion. Early scans may confirm the diagnosis, but the use of IV contrast media can worsen necrosis and renal failure, and early scans may be too early to identify developing necrosis. A scan at 4 days will invariably detect necrosis.

MRI has been evaluated as an alternative to CT, but as yet is not in widespread use for diagnosing acute pancreatitis. Ultrasound may show inflammation of the pancreas and is especially good for identifying biliary obstruction or gallstones.

The APACHE scoring system lists the blood parameters that should be checked in patients with acute pancreatitis. These include a full blood count and tests for urea, creatinine, electrolytes, C-reactive protein (CRP), and arterial blood gas. Liver function tests should be checked, as the vast majority of patients have a history of excess alcohol consumption, and these results may confirm concurrent hepatic damage, inflammation, and synthetic function. Calcium and triglyceride levels also should be checked to ensure they are not etiological factors for acute or chronic pancreatitis.

Prognosis of acute pancreatitis, and how to estimate it

Amylase and lipase levels have no prognostic role in pancreatitis. Scoring systems have been developed to predict outcomes. The Ranson and Glasgow scoring systems have been used in the past, but can only be applied at 48 hours. Subsequently, the APACHE II score has come into widespread use, and can be applied from 24 hours. The variables used in the APACHE system are listed in Table 201.1. A score of >8 at initial presentation or 24 hours later is considered in keeping with severe pancreatitis. CRP levels can reflect disease severity, rising with the degree of inflammation. However, there may be no rise for 48 hours, reducing the usefulness of CRP levels in initial assessment.

Treatment of acute pancreatitis, and its effectiveness

The initial approach to acute pancreatitis is to assess severity, using scoring systems (Ranson, APACHE, Glasgow), serum markers (CRP, haematocrit), and clinical assessment (blood pressure, pulse, and dehydration). Fluid resuscitation is integral to restore intravascular volume and third-space losses, with placement of a urinary catheter

Table 201.1 The APACHE II scoring system

Physiological variables	Age	Pancreatic history
Rectal temp (°C)	<44	Non-operative patients
Mean arterial pressure (mm Hg)	45–54	Post emergency operation
Heart rate (bpm)	55–64	Post elective operation
Respiratory rate (bpm)	65–74	
Oxygen delivery (ml/min)	>75	
PO ₂ (mm Hg)		
Arterial pH		
Sodium (mmol/l)		
Potassium (mmol/l)		
Creatinine (mg/dl)		
Haematocrit (%)		
White-cell count (10 ³ /ml)

to monitor urine output. Pain should be controlled and usually requires opiate analgesia.

Patients with moderate-to-severe pancreatitis, or any suggestion of organ failure (respiratory, circulatory, renal, etc.), should be monitored in a high-dependency or intensive care unit. Those with milder disease should still have close monitoring in view of the risk of rapid deterioration.

Patients are usually kept 'nil by mouth', as any oral intake further stimulates the pancreas, causing the release of pancreatic enzymes and potentially worsening pain. Nutrition is extremely important, given the hypercatabolic state of the patient; usually, nasojejunal feeding is implemented early via endoscopically placed nasojejunal tubes. Total parenteral nutrition is an alternative, particularly in patients who develop an ileus. However, the higher costs and increased rate of septic complications preclude the routine use of parenteral nutrition.

If patients fail to respond to treatment within 72 hours, a repeat CT scan should be performed to assess for pancreatic necrosis or abscess formation.

The use of antibiotics in acute pancreatitis is contentious, with studies showing variable results, and recognition of the increased risk of developing antibiotic-resistant bacterial strains. However, the general consensus is that pancreatic necrosis requires treatment with prophylactic broad-spectrum antibiotics, with doctors being advised to refer to their hospital's antibiotic policy when it comes to choice. If antibiotics are given, a minimum of 14 days treatment should be advocated. Fine-needle aspiration of the necrotic area can be cultured and used to guide antibiotic therapy.

ERCP has only been shown to be useful when performed early (within 72 hours) in patients with evidence of biliary obstruction, with a sphincterotomy performed to allow biliary drainage. The use of magnetic resonance cholangiopancreatography (MRCP) allows clear views of the biliary system, and has led to the avoidance of unnecessary ERCP. In general, sterile necrosis will be treated conservatively, whereas infected pancreatic necrosis requires surgical debridement by open surgical techniques. However, minimally invasive procedures (laparoscopic or endoscopic) may hold promise for the future.

Chronic pancreatitis

Chronic pancreatitis is characterized by progressive inflammation and fibrosis, leading to the irreversible loss of pancreatic structure and function.

Aetiology of chronic pancreatitis

Sixty to eighty per cent of cases of chronic pancreatitis are related to alcohol and, conversely, 10% of alcoholics develop chronic pancreatitis. Idiopathic chronic pancreatitis is responsible for ~20% of cases; other causes include recurrent acute pancreatitis (and all causes thereof), gallstones, trauma, and autoimmune pancreatitis

(AIP). Chronic pancreatitis has also been associated with primary biliary cholangitis, Sjögren's syndrome, SLE, and renal tubular acidosis. Genetic studies have suggested several genetic mutations may be associated with hereditary and idiopathic chronic pancreatitis.

Typical symptoms of chronic pancreatitis, and less common symptoms

Chronic pancreatitis can present with constant discomfort, or with recurrent episodes of severe pain. Postprandial pain may lead to food avoidance and subsequent weight loss. Persistent pancreatic destruction may lead to the patient presenting with symptoms of exocrine insufficiency (diarrhoea and/or weight loss) or endocrine insufficiency (diabetes).

Demographics of chronic pancreatitis

Chronic pancreatitis affects men twice as often as women and is more common in the fourth to the sixth decades.

Natural history of chronic pancreatitis, and complications of the disease

The natural history of chronic pancreatitis is highly variable, but the overall survival is approximately 70% at 10 years and 45% at 20 years. In the majority, the pain will gradually resolve or reduce over the course of years to decades, although, in alcohol-related disease, abstinence may expedite pain relief. Endocrine dysfunction may lead to a reduction in insulin secretion and subsequent diabetes, with all associated complications.

The exocrine pancreas produces digestive enzymes, including trypsin, chymotrypsin, lipase, and amylase, and lack of these leads to malabsorption and resultant diarrhoea, steatorrhoea, and/or weight loss. However, nutritional deficiencies are not seen until 90% of exocrine function is lost. Chronic pancreatitis is also associated with pseudocyst (10%) and pseudoaneurysm formation, biliary and duodenal obstruction (5%–10%), venous thrombosis, and pancreatic cancers. The cancer risk is 4% after 20 years of disease.

Approach to diagnosing chronic pancreatitis

Chronic pancreatitis is less straightforward, since the pain is often chronic, but an alcohol history may be a clue to the diagnosis. The presence of symptoms of pancreatic insufficiency (diarrhoea or diabetes) may help confirm chronic damage to the organ.

Diagnostic tests for chronic pancreatitis

Amylase is less useful in chronic pancreatitis as there is often no rise in serum levels, due to atrophy and fibrosis, with overall destruction of exocrine cells which normally produce this enzyme. Chronic pancreatitis is often diagnosed on the clinical history of recurrent abdominal pain, commonly in a setting of alcohol excess.

A CT scan of chronic pancreatitis may appear normal in mild disease, but moderate-to-severe disease will produce an atrophic fibrotic gland with dilated ducts and calcifications. CT has an overall sensitivity of 80% and a specificity of 85%.

A plain abdominal X-ray will reveal pancreatic calcification in ~30% of cases. Anterolateral and oblique views should be performed to ensure the vertebral column does not conceal small calcifications.

MRCP can provide clear views and is growing in popularity, as it is safe, fast, and accurate. It can also be combined with a secretin-stimulation test to provide information on pancreatic function (so-called functional MR).

Criteria have been produced for diagnosing chronic pancreatitis from features seen from endoscopic ultrasound (EUS), including the presence of stones, irregular ducts, lobularity, and cysts. Pancreatic exocrine insufficiency can be assessed by a taking a stool sample to measure faecal pancreatic elastase. This will be reduced in advance pancreatic exocrine insufficiency (loss of ≥90% exocrine function). Other pancreatic function tests have been superseded by the simple faecal elastase test, but previously included the non-invasive para-aminobenzoic acid (commonly known as PABA) and pancreolauryl tests, and the invasive secretin-stimulation test and Lundh test.

As with acute pancreatitis, liver function tests, calcium levels, and triglyceride levels should be checked.

Treatment of chronic pancreatitis, and its effectiveness

Patients should be encouraged to stop drinking alcohol and smoking, as this can reduce pain and further pancreatic damage. Analgesics are required for pain relief; often, simple analgesics do not suffice and opiates are required. In extreme cases, a celiac ganglion block can relieve pain in ~50% of patients, but the relief is often short term, and complications (haemorrhage, transverse myelopathy) preclude regular use.

Pancreatic enzyme supplements can reduce symptoms of exocrine insufficiency and may reduce pain in some patients, by allowing the pancreas to 'rest'. Vitamin supplements (especially vitamin B₁₂) should be given where necessary, and low-fat meals may reduce symptoms.

Pancreatic duct strictures can be treated endoscopically by stent insertion and sphincterotomy, with resolution of pain in 65%. Pancreatic pseudocysts can often be treated endoscopically in specialist centres. Surgical procedures include a pancreaticojejunostomy to relieve pancreatic duct obstruction, or a pancreatic resection. However, the operative mortality is 3% and 10%, respectively, so it is reserved for patients who are severely affected but have an otherwise healthy pre-morbid status.

AIP

AIP is a relatively newly recognized disorder characterized by pancreatitis and biliary and/or pancreatic duct strictures and with autoimmune aetiology.

Aetiology of AIP

AIP has an autoimmune aetiology, and has been associated with other autoimmune conditions, including rheumatoid arthritis, primary biliary cholangitis, primary sclerosing cholangitis, Sjögren's syndrome, and inflammatory bowel disease. Recent studies have suggested that genetic factors related to the HLA complex may play a role in the development of this condition.

Typical symptoms of AIP, and less common symptoms

AIP can present with a variety of features, including mild acute pancreatitis, biliary or pancreatic strictures, and a pancreatic mass. Subsequently, symptoms are in keeping with those of acute pancreatitis, and also include jaundice and weight loss.

Demographics of AIP

AIP is more common in elderly men.

Natural history of AIP, and complications of the disease

Most patients with AIP will respond to either medical treatment, or endoscopic therapy of biliary strictures, and exocrine dysfunction is rarely detected after treatment. The long-term complications, including the potential increased risk of pancreatic cancer, are, as yet, unknown.

Approach to diagnosing AIP

Several criteria have been developed to aid diagnosis of AIP. The Mayo Clinic criteria state diagnosis can be made when ≥1 of the following are present:

- a diagnostic histology consistent with lymphoplasmacytic sclerosing pancreatitis
- response to steroid therapy
- a characteristic appearance on CT, with elevated IgG4 levels

Diagnostic tests for AIP

A diagnosis of AIP usually requires a histological sample and raised IgG4 levels. Increased serum levels of other autoantibodies, including rheumatoid factor, antinuclear antibody, and antibodies against lactoferrin and carbonic anhydrase, are often seen and can aid the diagnosis.

The CT appearance of the pancreas in AIP includes pancreatic enlargement, irregular narrowing of the pancreatic duct, sclerosing cholangitis, and/or stenosis of the intra-pancreatic duct. MRCP and EUS can also be used, but their usefulness is restricted by the limited availability of personnel with the technical skills needed to perform these techniques, and the difficulty of differentiating abnormalities from pancreatic or biliary cancer.

Prognosis of AIP, and how to estimate it

The overall prognosis is difficult to ascertain in AIP, due to it being a relatively new rare condition.

Treatment of AIP, and its effectiveness

The main treatment for AIP is steroid therapy. First, this can confirm the diagnosis, but the treatment also can relieve symptoms, improve structural abnormalities, and improve endocrine function in the short term. Steroids have been shown to help biliary strictures biochemically and structurally, although many patients undergo endoscopic therapy for biliary strictures before the diagnosis is confirmed. The long-term benefit of steroids is, however, not yet known.

Further treatment options require trials before they can be advocated.

Diabetes

Type 1 diabetes mellitus is caused by the autoimmune destruction of pancreatic beta cells, which normally produce insulin. Diabetes mellitus is dealt with in more detail in Chapter 184.

Cystic fibrosis

Cystic fibrosis is a condition caused by abnormalities in exocrine gland function and leads to the production of thick secretions affecting the lungs in 90% of patients with cystic fibrosis. It also leads to pancreatic exocrine insufficiency.

Aetiology of cystic fibrosis

Cystic fibrosis is an autosomal recessive genetic disorder caused by mutations in the cystic fibrosis transmembrane conductance regulator gene and disrupts chloride transport at the cellular level. Chloride ions, and associated sodium ion and water, are not secreted into the lumen, leading to the development of thick secretions in the airways and impaired mucociliary clearance. The pancreatic duct is lined with cells similar to those in the airways and, consequently, there is also a reduction in bicarbonate-related water secretion. As in the airways, this leads to the production of thick secretions which cause obstruction, dilatation, cellular damage, and fibrosis. Cystic fibrosis is the major cause of pancreatic insufficiency in childhood, and 85% of cystic fibrosis patients develop pancreatic insufficiency.

Demographics of cystic fibrosis

In the UK, cystic fibrosis affects over 8000 people, with a current life expectancy of 31 years.

Natural history of cystic fibrosis, and complications of the disease

Most complications and fatalities from cystic fibrosis are related to progressive lung disease. The pancreatic disease in cystic fibrosis can present as acute or chronic pancreatitis or progressive malnutrition due to malabsorption from pancreatic exocrine insufficiency.

Approach to diagnosing cystic fibrosis

Cystic fibrosis is usually diagnosed in childhood in a child with recurrent respiratory illnesses, failure to thrive, or diarrhoea.

Pancreatic cancer

Please see Chapter 204 for details about pancreatic cancer.

Other diagnoses that should be considered aside from pancreatic cancer

Upper abdominal pain has various differential diagnoses, including biliary colic, cholangitis, cholecystitis, gastritis, peptic ulcer disease, intestinal perforation, mesenteric ischaemia, Crohn's disease, and myocardial infarction.

202 Malabsorption

Satish Keshav and Alexandra Kent

Definition of the disease

Malabsorption is defined as a defect in the digestion and absorption of nutrients by the gastrointestinal tract. It can lead to a specific nutritional deficiency ('selective' malabsorption, such as vitamin B₁₂ deficiency) or a general nutritional deficiency (global malabsorption, such as that due to diseases affecting the mucosa diffusely, such as Crohn's disease).

Aetiology of the disease

Causes of malabsorption are listed in Table 202.1, and many of these diseases are dealt with elsewhere in this book. The commonest causes are coeliac disease and pancreatic exocrine insufficiency. Pancreatic insufficiency is dealt with in Chapter 201.

In coeliac disease, also known as gluten-sensitive enteropathy, an immunologically mediated reaction to gliadin peptides in cereals such as wheat, rye, and barley causes damage to the intestinal mucosa. Pathological features of coeliac disease include increased numbers of intra-epithelial lymphocytes, reduced height of intestinal villi, and increased length of the intestinal crypts. Loss of intestinal villi reduces the absorptive capacity of the small bowel, leading to malabsorption. There is a strong association with two HLA haplotypes: HLA-DQ2 and HLA-DQ8. Furthermore there is a hereditary component, with a prevalence of 10% in first-degree relatives, and 75% concordance between monozygotic twins.

There is an increased incidence of coeliac disease in patients with type 1 diabetes mellitus, Down's syndrome, Turner's syndrome, autoimmune thyroid disease, primary sclerosing cholangitis, primary biliary cholangitis, autoimmune cholangitis, autoimmune adrenal disease, Sjögren's syndrome, rheumatoid arthritis, and SLE.

Typical symptoms of the disease, and less common symptoms

Symptoms of malabsorption include diarrhoea, steatorrhoea, weight loss, anaemia, oedema, abdominal pain/bloating, defective bone metabolism, neurological manifestations, and others.

Diarrhoea

Diarrhoea is the most common presenting symptom, and is due to the reduced absorption of nutrients leading to an increased osmotic load reaching the colon, resulting in watery diarrhoea.

Steatorrhoea

Steatorrhoea is caused by fat malabsorption. It is characterized by the passage of pale, bulky, and often malodorous stools which are often difficult to flush. It is usually caused by pancreatic insufficiency, and may also be seen in severe coeliac disease.

Weight loss

Weight loss is more common in conditions affecting a larger surface area of the gastrointestinal tract, such as coeliac disease. Patients may increase their oral intake masking the reduced absorption of nutrients.

Anaemia

Anaemia can be caused by iron deficiency, vitamin B₁₂ deficiency, or folate deficiency. Iron is absorbed in the duodenum and upper jejunum, folate is absorbed in the proximal jejunum, and vitamin B₁₂ is absorbed in the terminal ileum after it is bound to intrinsic factor

Table 202.1 Causes of malabsorption

Mechanism	Cause
<i>Defects in digestion</i>	
Enzyme deficiency	Pancreatic insufficiency (e.g. chronic pancreatitis, cystic fibrosis) Lactase deficiency Alpha-glucosidase deficiency
Bile salt deficiency	Cirrhosis Cholestasis Small bowel bacterial overgrowth
<i>Defects in absorption</i>	
Damage to the intestinal wall	Coeliac disease Crohn's disease Eosinophilic gastroenteritis IgA deficiency Radiation enteritis Autoimmune enteropathy Intestinal lymphangiectasia Systemic mastocytosis Abetalipoproteinaemia Acrodermatitis enteropathica Enterokinase deficiency Small bowel lymphoma Short bowel syndrome
Circulatory defects	Mesenteric ischaemia Venous insufficiency (e.g. thrombosis, portal stasis, infiltration, trauma) Chronic heart failure ('cardiac cachexia') Constrictive pericarditis (due to dilated lymphatics leading to excessive protein loss)
Small bowel overgrowth	Small bowel diverticulosis Gastric atrophy Fistulae Diabetic neuropathy Scleroderma Obstruction
Microbial agents	Intestinal parasitosis (e.g. giardiasis) Tropical sprue Whipple's disease HIV
<i>Miscellaneous</i>	
	Achlorhydria Hyperthyroidism Drug related (e.g. orlistat, acarbose, colchicines) Amyloidosis Autonomic neuropathy Zollinger–Ellison syndrome (leads to inactivation of pancreatic enzymes)

produced by gastric parietal cells. Disease processes affecting any of these parts of the bowel can lead to anaemia. Small intestinal bacterial overgrowth can cause impaired B₁₂ absorption, but bacteria produce folate, so folate deficiency is rare.

Oedema

Chronic protein malabsorption leads to hypoalbuminaemia, with resultant oedema. This often affects the peripheries initially, but can cause ascites as it progresses. Intestinal lymphangiectasia can cause obstruction of the lymphatic system, with resultant oedema.

Abdominal pain/bloating

Bacterial fermentation of unabsorbed food substances releases gaseous products such as hydrogen and methane and this can cause bloating, abdominal discomfort, and excess flatulence.

Defective bone metabolism

Osteopenia and osteoporosis are caused by vitamin D and calcium malabsorption, and are well-recognized complications of coeliac disease.

Neurological manifestations

The following nutritional deficiencies may lead to the specific neurological manifestations listed, although these are rare:

- hypocalcaemia: tetany
- hypomagnesaemia: tetany
- thiamine deficiency: peripheral neuropathy
- vitamin A deficiency: night blindness
- vitamin D deficiency: hypocalcaemia, hypomagnesaemia, bone pain, and muscle weakness
- vitamin B₁₂ deficiency: anaemia, and loss of vibration sense and joint position sense

Other symptoms

Other symptoms recognized in coeliac disease include fatigue, alopecia, mouth ulcers, dyspepsia, headaches, dermatitis herpetiformis, infertility, amenorrhoea, and miscarriage.

Demographics of the disease

Approximately 1% of the UK population has coeliac disease, although it is estimated that only 1 in 8 have their condition diagnosed. Approximately 3 million people in Europe have coeliac disease, and it is more common in temperate climates, with the highest incidence in Ireland, Finland, and North America. However, the incidence is increasing in the Indian and Middle Eastern population. It has a bimodal age distribution, with peaks at 8–12 months and again in the third and fourth decades. It affects women slightly more than men.

Natural history and complications of the disease

Generally, patients respond rapidly to a gluten-free diet, with resolution of symptoms and a return to a normal small bowel mucosa. Complications can arise due to malabsorption, and nutritional deficits should be supplemented. There is a greater incidence of osteoporosis seen in coeliac patients, especially those with a low BMI and poor compliance with a gluten-free diet. Current guidelines advocate performing a DEXA bone densitometry scan in those patients with two or more of the following:

- persisting symptoms on a gluten-free diet for 1 year, or poor adherence to gluten-free diet
- weight loss >10%
- BMI <20
- age >70

Uncontrolled coeliac disease increases the risk of cancer, including enteropathy-associated T-cell lymphoma, as well as adenocarcinoma of the oropharynx, oesophagus, pancreas, small and large bowel, and hepatobiliary tract.

Approach to diagnosing the disease

Initial laboratory investigations in any patient with symptoms of malabsorption should always include coeliac serology. The most sensitive and specific antibodies are the tissue transglutaminase IgA, endomysial IgA, and reticulin IgA, and these antibodies have been shown to

correlate with the degree of mucosal damage. It is important to remember that a significant number of patients with coeliac disease have IgA deficiency and, as such, the IgA level should be checked in patients with negative serology results.

Supporting laboratory evidence of malabsorption includes iron, folate, and B₁₂ deficiencies, anaemia, hypoalbuminaemia, hypoproteinaemia, hypocalcaemia, hypomagnesaemia, hypokalaemia, and secondary hyperparathyroidism.

Other diagnoses that should be considered

Causes of malabsorption are listed in Table 202.1, which also serves as a list of differential diagnoses to consider.

'Gold-standard' diagnostic test

The gold-standard diagnostic test for malabsorption is an upper gastrointestinal endoscopy, with mucosal biopsies taken from the duodenum. This will provide a histological diagnosis of coeliac disease, which is staged using the Marsh classification:

- type I: normal mucosal architecture with an increased number of intra-epithelial lymphocytes
- type II: increase in crypt depth without villous flattening
- type III: villous atrophy; divided into:
 - type IIIa: partial villous atrophy
 - type IIIb: sub-total villous atrophy
 - type IIIc: total villous atrophy

Acceptable diagnostic alternatives to the gold standard

The only reason for employing alternative methods of diagnosis is when patients are unable to tolerate endoscopic investigations and it is impossible to obtain mucosal biopsies. In this instance, most centres would advocate implementing a strict gluten-free diet, and monitoring a serological and clinical response. Genetic testing can be useful to exclude coeliac disease, as >97% of patients are HLA DQ2 and/or HLA DQ8 positive, compared with ~40% of the general population.

Other relevant investigations

Further investigations would be used to diagnose alternative causes of malabsorption, and Table 202.2 provides diagnostic investigations for these differential diagnoses. Investigations to confirm carbohydrate malabsorption (e.g. an oral D-xylose tolerance test) are not generally performed nowadays.

Prognosis and how to estimate it

Apart from the slightly increased risk of malignancy, and the effect on quality of life of having to adhere to a strictly gluten-free diet, coeliac disease has a benign prognosis once the diagnosis has been established.

Treatment and its effectiveness

The only definitive treatment is lifelong adherence to a strictly gluten-free diet. Ancillary assistance that should be offered to patients is summarized in the mnemonic CELIAC:

- C: consultation with a skilled dietician
- E: education about the disease
- L: lifelong adherence to a gluten-free diet
- I: identification and treatment of nutritional deficiencies
- A: access to an advocacy group
- C: continuous long-term follow-up by a multidisciplinary team

The mainstay of treatment for coeliac disease is compliance with a strict gluten-free diet. This involves close interactions between the physician, the dietician, and the patient. Patients are able to receive gluten-free products on prescription and are encouraged to join Coeliac UK or other appropriate patient organizations. These can

Table 202.2 Treatment of causes of malabsorption		
Disease	Diagnostic investigation(s)	Treatment
Pancreatic insufficiency	Faecal elastase	Pancreatic supplements
Lactase deficiency	Hydrogen breath test Intestinal biopsy with measurement of lactase levels	Dairy-free diet Lactase supplements Calcium +/- vitamin D supplements
Alpha-glucosidase deficiency	Acid alpha-glucosidase activity in cultured skin fibroblasts or peripheral blood lymphocytes	Enzyme replacement
Bile salt deficiency	SeHCAT scan	Colestyramine
Eosinophilic gastroenteritis	Intestinal biopsy	Corticosteroids Elimination diet
IgA deficiency	Serum IgA level	Preventative measures to reduce, and early treatment of, infections
Radiation enteritis	Intestinal biopsy/histology	Antidiarrhoeals Bile-sequestering agents Corticosteroids Anti-emetics 5-Aminosalicylic acid Sucralfate Endoscopic therapy (e.g. argon plasma coagulation)
Autoimmune enteropathy	Antienterocyte autoantibodies	Exclusion diet Immunosuppressive therapy
Intestinal lymphangiectasia	Low protein, albumin, and immunoglobulin levels Small bowel endoscopy with jejunal biopsies	Dietary modifications Bulking agents Octreotide Antidiarrhoeals Investigate for secondary causes
Systemic mastocytosis	Total serum tryptase levels ≥ 20 ng/ml Bone marrow aspirate	Symptomatic treatment for anaphylaxis, malabsorption, peptic ulcer, diarrhoea, and pruritus Chemotherapy not seen to be effective
Abetalipoproteinaemia	Low serum cholesterol level No apolipoprotein B (confirmed by immunoelectrophoresis)	Vitamins A and E
Acrodermatitis enteropathica	Low serum zinc	Zinc supplementation
Enterokinase deficiency	Enterokinase activity in duodenal juice and intestinal mucosa	Pancreatic enzyme replacement
Small bowel lymphoma	Radiology Small bowel studies Histology	Surgical resection Chemotherapy
Short bowel syndrome	Previous medical history of bowel resections	Oral or IV replacement of nutrients Total parenteral nutrition
Circulatory defects	Mucosal biopsy/histology	Treat underlying disease
Small bowel overgrowth	Glucose hydrogen breath test	Antibiotics
Microbial agents	Stool culture Mucosal biopsy/histology	Antibiotics

provide support and information regarding the source of appropriate foods, and potential hazards. Patients are advised to avoid all wheat, rye, and barley, but oat is generally considered to be acceptable in the diet. Unfortunately, oat products are often contaminated with other gluten-containing grains. The majority of patients respond to gluten avoidance; should symptoms recur or persist, the first step is to assess compliance. Approximately 5% of patients develop refractory coeliac disease, despite a strict gluten-free diet. Corticosteroids can be effective, usually given as a tapering 6–8 week course.

Treatments for other, less common causes of malabsorption are listed in Table 202.2.

203 Inflammatory bowel disease

Satish Keshav and Alexandra Kent

Definition of the disease

Inflammatory bowel disease (IBD) encompasses ulcerative colitis (UC) and Crohn's disease (CD). Both conditions cause chronic relapsing inflammation in the gastrointestinal (GI) tract, but have different characteristics, as shown in Table 203.1.

UC causes diffuse mucosal inflammation limited to the colon, extending proximally from the anal verge, with the rectum involved in 95% of patients. UC is described in terms of the disease extent: proctitis (confined to the rectum), proctosigmoiditis (disease confined to the recto-sigmoid colon), distal disease (distal to the splenic flexure), and pan-colitis (the entire large intestine). The extent of disease can change, with proximal extension seen in approximately a third of patients with proctitis, although there is great variation between studies.

CD causes inflammation that can affect the entire thickness of the wall of the intestine, and is not confined to the mucosa. CD can affect any part of the GI tract. The terminal ileum is affected in approximately 80% of cases, the colon in approximately 60% of cases, and the rectum and perianal region in approximately 40% of cases. CD is classified by location (ileal, colonic, ileocolonic, upper GI tract), by the presence of stricturing or penetrating disease, and by the age of onset (before or after the age of 40). Penetrating disease refers to the development of fistulae, which can lead to complications such as abscesses or perforations. An earlier age at onset is associated with more complicated disease.

The diagnosis of UC or CD is established through a combination of clinical, endoscopic, radiological, and histological criteria rather than by any single modality. Occasionally, it is not possible to establish an unequivocal diagnosis of CD or UC in IBD, and a third category, accounting for nearly 10% of cases, is used, termed IBD unclassified.

Aetiology of the disease

The pathogenesis of IBD is considered to be due to an aberrant immune response to luminal bacteria in genetically susceptible individuals, although no specific pathogen has been identified. Inflammation is driven by immunological responses, including macrophage activation,

leucocyte trafficking, and the production of inflammatory cytokines such as tumour necrosis factor alpha, which seems to be a critically important mediator in IBD. Genome-wide scanning has confirmed multiple genetic loci that confer an increased risk of developing IBD, and many of these have roles in bacterial recognition within the intestinal lumen. The first gene, and the one for which the most results have been replicated, is the NOD2 gene, which is found on Chromosome 16, is associated with ileal disease, and has a role in the innate immune system. Further genes identified include the autophagy gene IRGM, the interleukin 23 receptor gene, the autophagy gene ATG16, and other loci in the region. Many more genes have been identified, but the results for these genes are less well replicated, although studies are ongoing. The importance of genetics in IBD development is confirmed by the greater incidence of IBD in first-degree relatives (5–20-fold increased risk), a 5%–10% concordance in dizygotic twins, and 50% concordance for disease in monozygotic twins.

Typical symptoms of the disease, and less common symptoms

UC is typically characterized by diarrhoea, often with the passage of blood and/or mucus. The extent of symptoms is related to the disease extent and depth of ulceration within the colon. Abdominal pain, or discomfort, is not uncommon. It is important to document the bowel frequency and the need to defaecate at night. More serious signs include tachycardia or fever ($>37.5^{\circ}\text{C}$); these indicate the need for hospital admission. Criteria developed by Truelove and Witts have been used to indicate the need for inpatient intensive treatment of acute severe colitis, which is a medical emergency.

Symptoms of CD are more varied, and related to the site of disease activity and nature of disease. Colonic inflammation (Crohn's colitis) may present with diarrhoea, with or without the presence of blood, in a fashion similar to that for UC. However, small bowel disease may be less evident, with abdominal pain prevailing. Stricturing disease may be due to active CD or to fibrosis from previous active inflammation. Stricturing can lead to progressive obstructive symptoms, with bloating, abdominal pain, and vomiting if the stricture is high in the GI tract. Penetrating disease most commonly affects the

Table 203.1 Comparison of ulcerative colitis and Crohn's disease

	Ulcerative colitis	Crohn's disease
Depth of inflammation	Mucosal/superficial inflammation	Transmural inflammation
Histology	Diffuse inflammatory infiltrate Goblet cell depletion Cryptitis Crypt abscesses No granulomas	Diffuse inflammatory infiltrate Goblet cell depletion Cryptitis Crypt abscesses Granulomas Fibrosis
Location	Colonic	Any part of the gastrointestinal tract
Pattern of inflammation	Continuous; starts at the rectum and progresses proximally	Patchy/segmental Cobblestoning Skip lesions
Response to immunosuppression	Yes	Yes
Response to 5-aminosalicylic acid medications	Yes	No
Strictures	No	Yes
Fistulae	No	Yes
Smoking history	Associated with non-smokers	Associated with smokers

perianal region, leading to fistulae and abscesses which are at risk of crossing the anal sphincters. Perianal fistulae lead to persistent discharge, and abscesses can be extremely painful. Perianal skin tags and anal fissures are also seen in Crohn's disease.

Fatigue is a common symptom, and IBD is commonly associated with anaemia. This is usually due to iron deficiency from chronic blood loss and the anaemia of chronic disease, which is a consequence of the effect of chronic inflammation on iron absorption and utilization. Small bowel disease can also disrupt absorptive capacity, reducing iron, folate, and B₁₂ absorption; this, in turn, can lead to anaemia.

IBD is associated with extra-intestinal manifestations, the commonest of which include oral ulceration, arthralgia, arthritis, erythema nodosum, pyoderma gangrenosum, iritis, uveitis, and mouth ulcers. Therefore, patients should be asked, as a matter of routine, about symptoms associated with these conditions: rashes, skin changes, painful or red eyes, and joint swelling or arthralgia.

Demographics of the disease

In the UK, UC has an annual incidence of 10–20 per 100 000 population, compared to the incidence of CD being 5–10 per 100 000 population. The prevalence rates for IBD are 100–200 per 100 000 population. Overall, IBD affects 1 in 400 people in the UK. The peak incidence is at 10–40 years old, with both genders equally affected. IBD is more common in the Western world, although immigrants have the same incidence as the indigenous population. Studies have also shown IBD to have a higher prevalence in colder climates and in urban areas.

Natural history and complications of the disease

Both UC and CD are relapsing–remitting conditions with an unpredictable course for any individual patient. The average UC patient has a 50% chance of a flare in 2 years, and up to 10% may have only one flare in their lifetime. Up to 80% of CD patients and 30% of UC patients require surgery at some point. However, the overall risk is dependent on the site and extent of the disease, and varies widely between studies. Patients with disease limited to the recto-sigmoid have a 12% risk of colectomy, while those with pan-colitis have a 60% risk. However, up to 50% of patients with proctitis may have some proximal extension during their lives. The prognosis and risk of colectomy in acute severe colitis can be calculated using the Truelove–Witts criteria, which are shown in Table 203.2. If, on Day 3 of admission, patients have a bowel frequency of >8 times per day or a C-reactive protein (CRP) level >45 mg/l combined with a bowel frequency of 3–8 times per day, they have an 85% risk of requiring colectomy on that admission.

There are multiple complications associated with IBD, beyond the nutritional deficiencies related to malabsorption. Extra-intestinal manifestations which physicians should pay close attention to include:

- dermatological manifestations such as erythema nodosum, pyoderma gangrenosum, Sweet's syndrome (neutrophilic dermatosis), and vasculitis
- ophthalmological manifestations such as iritis, uveitis, and episcleritis; these require urgent treatment in conjunction with an ophthalmological specialist, to prevent visual loss

Table 203.2 Truelove and Witts classification for activity of ulcerative colitis

	Mild	Moderate	Severe
Bowel frequency per day	<4	4–6	>6
Temperature	Afebrile	<37.8	≥37.8
Heart rate	Normal	Indeterminate	≥90
Haemoglobin (g/dl)	>11	10.5–11	<10.5
ESR (mm/hour)	<20	20–30	>30

Reproduced from *The BMJ*, S. C. Truelove, L. J. Witts, Cortisone in ulcerative colitis: final report on a therapeutic trial, volume 2, pp. 1041–8, copyright © 1955 with permission from BMJ Publishing Group Ltd.

- arthritis: axial arthritis, including ankylosing spondylitis and sacroiliitis, affects approximately 5% of IBD patients (usually those with CD) and is usually associated with HLA-B27; peripheral arthritis occurs in up to 10% of IBD patients
- hepatobiliary manifestations: primary sclerosing cholangitis (PSC) is associated with IBD, most commonly UC, and any patient with abnormal liver function should undergo investigations for this condition; there is a high incidence of cholangiocarcinoma in PSC, so establishing the diagnosis is vital
- renal associations: calcium oxalate renal stones are more common in CD
- osteoporosis: can occur due to malabsorption and recurrent steroid use
- thromboembolic phenomena: patients admitted to hospital with flares of IBD should be prescribed prophylactic heparin, as there is an increased risk of deep vein thrombosis and embolic phenomena

Approach to diagnosing the disease

The classic patient with IBD is a young adult (20–40 years) with a 4–8 week history of diarrhoea, often waking at night to defaecate. It is often difficult to differentiate them from patients with other conditions, although raised inflammatory markers and/or anaemia support the diagnosis. Most gastroenterologists would advocate performing a rigid sigmoidoscopy in the outpatient clinic, as the presence of proctitis would support the diagnosis and allow the doctor to initiate treatment in the absence of histological confirmation. Initiating topical (rectal) 5-aminosalicylic acid (5-ASA) therapy can often improve symptoms, and may well reduce the risk of progression prior to biopsy results. However, if infective colitis is a possible diagnosis, it may be necessary to withhold steroids until a histological diagnosis, or until negative stool cultures have excluded an infective cause. An endoscopy is required to accurately assess the extent of disease and obtain serial biopsies.

Other diagnoses that should be considered

The major diagnosis that needs to be excluded, prior to commencing steroid therapy in undiagnosed IBD, is infective colitis. In view of this, known IBD patients presenting with diarrhoea flares should always have stool samples sent to exclude concomitant infectious diarrhoea, particular dysentery caused by organisms such as shigella and campylobacter; amoebiasis; and diarrhoea associated with *Clostridium difficile* toxin. The exact presenting symptom influences differential diagnoses to be excluded, but the commonest include infectious diarrhoea, microscopic colitis, diverticulitis, coeliac disease, eosinophilic gastroenteritis, giardiasis, irritable bowel syndrome, lactose intolerance, bacterial overgrowth, radiation injury, and colorectal cancer.

'Gold-standard' diagnostic test

A colonoscopy, including intubation of the terminal ileum, will diagnose the vast majority of IBD cases. Many patients will have characteristic mucosal appearances, and typical histological changes confirm the diagnosis. Furthermore, in continuous or distal inflammation, histological results will differentiate between UC and CD.

Acceptable diagnostic alternatives to the gold standard

A true diagnosis of IBD requires histological confirmation, and treating patients for IBD without such confirmation requires the expertise of experienced physicians. A flexible sigmoidoscopy is the appropriate first-line investigation, especially in patients with severe inflammation, as these patients have a higher risk of perforation during a total colonoscopy. As UC is characterized by continuous inflammation, a sigmoidoscopy may pass beyond the extent of inflammation. As long as the full extent of inflammation is confirmed macroscopically and histologically, further investigations can be avoided. Patients unable to tolerate bowel purgation or an endoscopic examination may require CT colonography. Although it is not possible to obtain biopsies during a CT scan, characteristic inflammation with bowel wall thickening is easily identified, and can at least confirm the extent of disease. CT

scanning is also the first-line investigation for patients with an inflammatory mass, and/or possible luminal perforation.

Small bowel CD will require small bowel imaging, by MRI, CT, or barium radiography. CD of the upper GI tract may require an upper GI endoscopy or enteroscopy, with biopsies. In patients with stricturing CD or an inflammatory mass, a histological diagnosis is usually made after surgical resection of the affected bowel. Capsule endoscopy is rarely used for a diagnosis of small bowel CD, although it may be picked up in patients undergoing the procedure to investigate persistent anaemia.

Other relevant investigations

The following investigations should be performed:

- a full blood count: patients may be anaemic due to iron, folate or B₁₂ deficiency, or anaemia of chronic disease; a leucocytosis is unusual in IBD, unless the patient is taking steroids, and should direct the physician to exclude infections, especially infectious diarrhoea; thrombocytosis is common in active inflammation
- renal function: persistent diarrhoea can cause dehydration
- electrolytes: persistent diarrhoea causes hypokalaemia, and reduced oral intake and malnutrition or reduced absorptive capacity in IBD patients often leads to hypomagnesaemia and hypocalcaemia
- liver function: abnormal liver function tests can be due to associated PSC or medications (5-ASA, azathioprine, 6-mercaptopurine (6MP)); serum albumin drops in active disease
- inflammatory markers: the most commonly used markers of inflammation are CRP and the erythrocyte sedimentation rate (ESR), both of which correlate with disease activity, although CRP is probably more reliable and preferred
- haematinics: vitamin B₁₂, folate, and iron levels should be checked in all patients, as chronic blood loss, chronic disease, or malabsorption can lead to deficiencies
- coeliac serology: this should be checked to exclude coeliac disease as an alternative or concomitant diagnosis
- stool culture: all patients, on initial presentation and in the setting of a flare, should have stool samples sent for microscopy and culture and assessment for *Clostridium difficile* toxin
- plain abdominal X-ray: this should be performed on all patients presenting with a flare of their disease, as it can identify bowel wall thickening or thumbprinting, which are consistent with inflammation; proximal faecal loading (formed stool in the right colon) is not uncommonly seen in distal colitis, and helps delineate disease extent; it is also important to exclude toxic dilatation
- fistulogram: in patients with penetrating disease, a fistulogram can assess the depth, extent, and course of a fistula

Prognosis and how to estimate it

Studies have suggested there is a small, but significant mortality increase in IBD compared to non-IBD populations. However, the mortality rates have reduced dramatically in the last 40–50 years, due to the introduction of anti-inflammatory treatment, particularly hydrocortisone, for acute and severe disease. Earlier and more intensive management of chronically active IBD, and appropriate surgery, also contribute to the generally favourable prognosis in IBD. While the effects of the disease are mitigated by treatment, the major emerging cause of morbidity and mortality is also treatment, especially the use of powerful immunosuppressives such as thiopurines, anti-tumour necrosis factor (anti-TNF) antibodies, and corticosteroids.

Treatment and its effectiveness

Treatment for IBD should be tailored to the individual, and is influenced both by disease distribution, activity, and extent and by drug potency and side effects. There are a number of differences between treatment for UC and that for Crohn's.

5-ASA

5-ASA therapy is appropriate for treating active UC and maintaining remission. It is ineffective for CD. There are several 5-ASA products available, including sulfasalazine, mesalazine, balsalazide, and

olsalazine. 5-ASA can be given orally or topically as suppositories or rectal foam or liquid enemas (1 g per day). Proctitis should be initially treated with topical treatment, with suppositories more appropriate for rectal disease, and enemas reaching more proximally. Topical therapy is effective in a median of 67% of patients with active disease. In patients with disease extending beyond the rectum, topical treatment is combined with oral therapy (≥ 2 g per day). Remission rates vary between 20% and 60% amongst studies, although the response rates are higher. 5-ASA medications are the first-line treatment for maintaining remission, and studies have suggested 5-ASA therapy reduces the risk of colorectal cancer in the long term.

Steroids

If patients with mild-to-moderately active UC fail to respond after 2 weeks of combined oral and topical 5-ASA, or in Crohn's colitis, steroid therapy will be introduced. This is usually with prednisolone 40 mg daily, reducing over the course of 5–8 weeks, and can induce remission in 70%–80% of patients. Patients with severe colitis are usually commenced on steroids from the outset, and the majority, especially those with acute severe colitis, should be admitted to hospital for IV steroid therapy. Acute severe colitis is a potentially life-threatening condition, and treatment should not be delayed. Treatment with hydrocortisone 100 mg four times per day, combined with rectal steroid therapy is advocated, with a response seen in approximately 70%.

Small bowel CD is initially treated with budesonide. This achieves remission in 50%–60% over 8–10 weeks. It is preferred to prednisolone due to the reduced systemic bioavailability. However, if patients fail to respond, prednisolone can induce remission in up to 90%. In severely active disease, IV steroids should be commenced.

Nutrition

All patients with IBD should be carefully monitored for nutritional deficiencies. Enteral nutrition is important, but is less effective as a treatment option than steroids. The exception to this rule is in children, who are equally responsive to steroids or enteral nutrition, with the latter often used due to the reduced side effects.

Antibiotics

Many studies have been performed, assessing the efficacy of antibiotics in IBD. Overall, antibiotics are only suitable in the setting of infection such as, for example, perianal CD, abscess formation, or pouchitis. Treatment is usually instituted with metronidazole or ciprofloxacin.

Thiopurines: Azathioprine/6MP

IBD patients who become steroid dependent, or have early recurrence of disease, are commenced on azathioprine or 6MP. These drugs are associated with a higher rate of remission and mucosal healing than steroids or 5-ASA medications are, and avoid the complications of long-term steroids. These medications take up to 16 weeks to take effect, so patients often require steroid maintenance therapy until the drugs take full effect. The main side effects are bone marrow suppression, deranged liver function, pancreatitis, infections relating to immunosuppression, and GI symptoms. Bone marrow suppression and abnormal liver function may respond to reduced doses, but pancreatitis should prevent further use.

Ciclosporin

Ciclosporin is an effective therapy for IV-steroid-resistant, severe UC, with a response seen in 50%–80% of patients. However, Ciclosporin has a poorer long-term response, with many patients requiring a colectomy within the subsequent year.

Methotrexate

Studies have shown methotrexate to be an effective treatment for IBD, but there is less evidence than for azathioprine or 6MP. As such, it is reserved for patients who are resistant to, or intolerant of, these medications, with clear explanations of the teratogenic potential.

Therapeutic antibodies

Infliximab (a chimeric anti-TNF monoclonal antibody) is an effective therapy in moderate-to-severe UC and CD, where steroids and

immunomodulator therapy fail to induce remission. Adalimumab (humanized anti-TNF monoclonal antibody) and certolizumab (an anti-TNF Fab fragment conjugated to poly-ethylene glycol) are alternatives administered subcutaneously that induce remission in CD. The use of these and other therapeutic antibodies and other protein-based therapeutics should be closely supervised by those who are specialists in the field and have a good working knowledge of the risks and benefits of these agents, and of strategies to manage the patient's overall therapy.

Vedolizumab is a humanized antibody that blocks a surface protein found on lymphocytes and which mediates the movement of immune cells from the circulation into the intestine and liver exclusively. It is highly effective in treating UC, and is also effective in CD. Because it interrupts only the movement of immune cells to the intestine, this treatment should not cause global immunosuppression, and therefore may represent a new and more effective treatment strategy.

Subcutaneous heparin

Acute flares of IBD are associated with thromboembolic complications and, as such, all patients admitted to hospital for treatment of active disease should be commenced on heparin prophylaxis.

Surgery

In acute severe colitis, patients should be introduced to the surgical team and stoma nurses early on, as those in whom there is an inadequate response to treatment 3 days may well require colectomy. Even when secondary or 'rescue' treatment is introduced, the risk

of needing surgery remains high. Surgery for colitis usually has two stages, with a colectomy and ileostomy formation performed initially. At a later date, an anastomosis can be performed, with the formation of an ileo-anal pouch and pouch–anal anastomosis. The pouch acts as a reservoir, and the intact anus provides continence.

Surgery in CD is more varied, as the disease affects a greater extent of the GI tract. Surgery is kept to a minimum, and resections are planned to be as conservative as possible, to minimize the risk of short bowel syndrome and intestinal failure. Perianal CD requires integrated care from medical and surgical teams, often requiring a combination of surgical debridement, placement of seton sutures, and medical therapy.

204 Gastrointestinal tumours

Satish Keshav and Alexandra Kent

Approach to the patient with gastrointestinal cancer

Gastrointestinal (GI) tumours can affect any part of the GI tract, and colorectal cancer is the most common. Throughout the GI tract, chronic inflammation seems to promote the development of neoplasia: for example, chronic reflux oesophagitis is linked to oesophageal adenocarcinoma; chronic *Helicobacter pylori* infection is linked to gastric cancer; chronic pancreatitis is linked to pancreatic cancer; cirrhosis is linked to hepatocellular cancer; chronic biliary inflammation is linked to cholangiocarcinoma; untreated coeliac disease is linked to intestinal lymphoma; and chronic inflammatory bowel disease is linked to colorectal cancer. Symptoms depend on the location of the tumour, and occur as a result of local anatomical disruption, with consequent functional consequences and, less frequently, as a result of hormonal, metabolic, and immune effects. Weight loss is a common symptom seen in the gastroenterology outpatient clinic, given the high overall incidence of GI tumours. Often, the associated symptoms will direct the doctor to the site of a possible underlying cancer. Anaemia is another non-specific finding with a strong association with luminal cancers. Patients with anaemia with or without weight loss will normally undergo upper and lower GI investigations, usually via oesophagogastroduodenoscopy (OGD) and colonoscopy (either CT or endoscopic colonoscopy).

In tumours that are difficult to identify or for which assessing the malignant potential is difficult, PET scanning can provide a large amount of information. PET scanning is a nuclear medicine scanning technique that utilizes 18F-fluorodeoxyglucose (FDG), which is taken up by metabolically active tissue. When combined with CT scanning, it can provide information about both anatomical and metabolic activity. FDG is rapidly taken up by malignant tumours and, as a result, is often used for diagnosing, staging, and monitoring response in cancers.

Oesophageal cancer

Aetiology of oesophageal cancer

Oesophageal cancers are squamous cell carcinomas (SCCs) occurring in the mid- or upper oesophagus, or adenocarcinomas occurring at the gastro-oesophageal junction or associated with Barrett's oesophagus. Barrett's oesophagus is associated with gastro-oesophageal reflux disease (GORD). Etiological factors associated with SCC include tobacco smoking and alcohol (independently and synergistically), riboflavin deficiency (explaining the higher incidence in China), and tylosis.

Typical symptoms of oesophageal cancer, and less common symptoms

Progressive dysphagia is a worrying symptom, alongside odynophagia, oesophageal pain, weight loss, nausea, vomiting, and haematemesis. Aspiration pneumonia is more common due to poor clearance of food from the oesophagus. Invasion of the recurrent laryngeal nerve can lead to hoarseness and makes the cancer unresectable.

Demographics of oesophageal cancer

In 2005, 7823 people were diagnosed with oesophageal cancer, and it is the ninth most common cancer in the UK. It has a male-to-female ratio of 1.8:1, which rises to 4.8:1 for adenocarcinoma. Most patients are over 60 years old, and risk increases with age. It is more common, as the SCC form, in developing countries, with the highest reported area in the Asian 'oesophageal cancer belt': eastern Turkey,

north-eastern Iran, northern Afghanistan, and southern Russia to northern China.

Natural history of oesophageal cancer, and complications of the disease

Oesophageal cancer arises from the mucosa and spreads to the sub-mucosa, the muscle layers, and surrounding structures such as the lymph nodes (LN) and the bronchial tree. It eventually metastasizes to the lung and liver. The main complication is progressive dysphagia, which can lead to total obstruction of the oesophagus, with the associated nutritional deficiencies. Delayed clearance of food from the oesophagus can lead to aspiration pneumonia.

Other diagnoses that should be considered aside from oesophageal cancer

The symptoms associated with oesophageal cancer include dysphagia and dyspepsia. The differential diagnosis should include erosive and non-erosive GORD, peptic stricture, Schatzki ring, eosinophilic oesophagitis, oesophageal web, oesophageal dysmotility, and achalasia.

'Gold-standard' diagnostic test for oesophageal cancer

Gastroscopy is the gold-standard test for identifying upper GI cancers, allowing direct visualization and mucosal biopsy for a histological diagnosis.

Acceptable diagnostic alternatives to the gold-standard test for oesophageal cancer

In patients unsuitable for OGD, a barium (or alternative contrast agent) swallow can identify strictures and intra-luminal masses. In addition, intra-abdominal malignancies can often be identified on CT scanning, which also allows the detection of metastases, and may be used in patients with non-specific symptoms that do not aid the physician in identifying the likely site. CT scanning is also a safer investigation than interventional procedures, such as endoscopy, and may be used in patients seen to be unsuitable for endoscopic procedures. However, the physician must consider the benefit of diagnosing cancer in patients unable to undergo endoscopic procedures, as endoscopic procedures are far less risky than most cancer treatment strategies.

Other relevant investigations for oesophageal cancer

All patients should undergo the following routine blood tests: a full blood count, renal function tests, liver function tests, and a calcium profile. Haematinics should be done if anaemia is present, and the patient should be treated accordingly. All patients with GI cancers will need to undergo staging investigations, which usually involve a CT scan of the chest and abdomen, mainly to identify lung and liver metastases. If the patient describes bone pain, and/or X-rays or CT scans suggest bone metastases, a nuclear medicine bone scan can confirm this. Bone metastases are often associated with hypercalcaemia, which can worsen symptoms. In the case of upper GI cancers (oesophageal, gastric, duodenal, biliary, or pancreatic), endoscopic ultrasound can be used to assess for depth of invasion and lymphatic spread.

Prognosis of oesophageal cancer, and how to estimate it

Prognosis from oesophageal cancer is invariably poor, with an overall 5-year survival rate of <5%. Overall prognosis (expressed

as 5-year survival rate) can be related to the depth of invasion as follows:

- mucosa: 80%
- submucosa: 50%
- muscularis propria: 20%
- invasion into adjacent structures: 7%
- distant metastatic spread: 3%

Treatment of oesophageal cancer, and its effectiveness

Curative treatment is possible with surgery: an oesophagectomy. This is only possible if the cancer is localized (20%–30%) and the patient is able to undergo such a procedure. An oesophagectomy involves pulling up the stomach to replace the oesophagus and is a large, complicated operation with a significant associated mortality (5%–18%). The mortality is associated with cardiorespiratory and septic complications. Even curative surgery only has a 25% 5-year survival rate. Surgery is usually preceded by (neoadjuvant) chemoradiotherapy to shrink the cancer, and chemotherapy may be given after surgery to reduce metastases. Chemotherapy is usually cisplatin based. Photodynamic therapy can be used in small cancers. Only a small number of patients are suitable for surgical intervention; in the majority of these, treatment is aimed at reducing tumour growth and providing palliation of dysphagia. This can be done with laser therapy, radiotherapy, or insertion of expanding stents. Such treatment strategies are purely palliative, with no improvement in prognosis.

Gastric cancer

Aetiology of gastric cancer

The majority of gastric cancers are adenocarcinomas, with lymphomas, GI stromal tumours (GISTs), carcinoids, adenocarcinomas, and SCCs accounting for the rest. There are several factors which have been implicated in the development of gastric cancer. *H. pylori* is strongly associated with gastric cancer, although <5% of people with *H. pylori* infection develop cancer. However, patients with *H. pylori* infection can develop chronic atrophic gastritis, with a subsequent sixfold increase in the risk of gastric cancer. Previous gastric surgery, in particular partial gastrectomy, is also associated with gastric cancer, probably owing to an associated change in gastric pH. Smoking increases the risk, in proportion to number of cigarettes and length of smoking, with studies showing the risk is increased approximately 1.6-fold. Dietary factors, including salt and smoked meat, are associated with an increased incidence, as is obesity. Genetic factors may play a role, although these are poorly understood. Pernicious anaemia and some hereditary syndromes increase the risk of gastric cancer, including hereditary non-polyposis colorectal cancer, familial adenomatous polyposis, and Peutz-Jeghers syndrome.

Typical symptoms of gastric cancer, and less common symptoms

Indigestion and epigastric pain are common symptoms, alongside nausea, vomiting, early satiety, weight loss, haematemesis, and melena. Gastric cancers can present as ulcerated lesions; consequently, patients diagnosed with gastric ulcers must have biopsies taken in order to exclude an underlying malignancy, which is found in approximately 10% of cases. Bleeding from the cancer may lead to anaemia with the associated symptoms. Examination may reveal a palpable mass and/or Virchow's (left supraclavicular) node. Persistent vomiting of undigested food, with or without a succussion splash, suggests the patient is suffering from gastric outlet obstruction.

Demographics of gastric cancer

In 2005, 7980 people were diagnosed with gastric cancer in the UK, with 95% of patients over 50 years of age. It is the sixth most common cancer in men, and the eleventh in women and leads to 5250 deaths per annum in the UK. It has a slight predominance for men, and has the highest incidence in the eighth decade. There are far higher rates in Asian countries, particularly Japan, Taiwan, Korea, and China; this has led to the implementation of screening programmes.

Natural history of gastric cancer, and complications of the disease

Forty per cent of gastric cancers arise in the lower part of the stomach, 40% in the middle, and 10%–15% in the upper part. The remainder involve more than one part. At presentation, 25% of patients have localized disease; of the remainder, half have regional disease, and half have metastatic disease. Stomach cancer spreads into surrounding tissue directly, via lymphatics, or haematogenously. Cancers in the lower stomach can obstruct the pyloric sphincter, leading to gastric outlet obstruction.

Other diagnoses that should be considered aside from gastric cancer

Gastric cancer can present with dyspepsia. Gastric ulcers are related to *H. pylori* or drugs (NSAIDs), in the majority of cases.

'Gold-standard' diagnostic test for gastric cancer

As for oesophageal cancer, gastroscopy is the gold-standard test for gastric cancer, allowing direct visualization and mucosal biopsy for a histological diagnosis.

Acceptable diagnostic alternatives to the gold-standard test for gastric cancer

A barium meal will identify gastric mucosal lesions, although it removes the ability to obtain biopsies for a histological diagnosis.

Other relevant investigations for gastric cancer

All patients should undergo the following routine blood tests: a full blood count, renal function tests, liver function tests, and a calcium profile. Haematinics should be done if anaemia is present, and the patient should be treated accordingly. CT scanning will be necessary to stage the disease.

Prognosis of gastric cancer, and how to estimate it

Gastric cancer is staged using the TNM system, which further classifies staging into Stages I–IV, and correlates with prognosis as follows:

- Stage 0: >90% survival
- Stage I: 50%–80% survival
- Stage II: 30%–40% survival
- Stage III: 10%–20% survival
- Stage IV: <5% survival

The overall 5-year survival for gastric cancer has improved over the past 25 years, but is still low at 15%. Linitis plastica, where the stomach becomes rigid and thickened due to infiltration of the gastric wall, occurs in approximately 5% of cases and has an extremely poor prognosis.

Treatment of gastric cancer, and its effectiveness

Curative surgery usually involves LN dissection, with more extensive LN resection gaining popularity. Five-year survival rates following 'curative' surgery are related to tumour stage: 60%–90% in Stage I, 30%–50% in Stage II, and 10%–25% in Stage III. Neoadjuvant chemotherapy may be given to shrink the tumour. Chemoradiotherapy may shrink the tumour, but cannot cure the cancer. Newer biological treatments are currently used in clinical trial settings, but are not in widespread use as yet.

Pancreatic cancer

Aetiology of pancreatic cancer

Ninety-five per cent of pancreatic cancers are adenocarcinomas, of which the majority are ductal adenocarcinomas. Seventy-five per cent occur in the head of the pancreas, 15%–20% in the body of the pancreas, and 5%–10% in the tail of the pancreas. Specific genetic mutations have been associated with pancreatic cancer, although these are not yet applied to clinical practice. Patients known to carry the BRCA2 mutation, which is associated with breast cancer, have a higher incidence of pancreatic cancer. Smoking accounts for 25%–30% of cases of pancreatic cancer and double the risk of it

developing. Studies have also associated obesity, high-fat diets, and caffeine with an increased risk. Chronic inflammation (as with many other cancers) has been shown to increase the incidence of dysplastic change (e.g. chronic pancreatitis), but there is no screening programme for patients with chronic pancreatitis. Alcohol consumption has not been directly linked to the development of pancreatic cancer, except when it has led to the development of chronic pancreatitis.

Typical symptoms of pancreatic cancer, and less common symptoms

The classic symptom of pancreatic cancer is painless jaundice, although symptoms are often non-specific, such as weight loss, malaise, and anorexia. Pain is usually epigastric, radiating through to the back, and patients have been known to develop diabetes mellitus. Many patients are diagnosed at a late stage and, consequently, may present with symptoms related to local or distant metastases (e.g. ascites).

Demographics of pancreatic cancer

Pancreatic cancer is the tenth-commonest cancer in the UK, with an incidence of approximately 10 per 100 000 population per year. The incidence rises with age, being rare before the age of 40, with 75% of cases occurring in people aged 65 years or older.

Natural history of pancreatic cancer, and complications of the disease

Pancreatic cancer can spread locally and commonly presents with biliary obstruction, leading to jaundice and the associated complications of cholangitis and sepsis. Invasion into surrounding organs can cause gastric outlet, duodenal, and/or colonic obstruction. Metastatic disease spreads via the lymphatics to the regional LNs, the liver, and the lungs, with peritoneal spread leading to metastasis to any abdominal surface. It can also be associated with painful metastatic skin nodules.

Other diagnoses that should be considered aside from pancreatic cancer

The jaundice associated with pancreatic cancer, cholangiocarcinoma, or gall bladder cancer can also be associated with benign biliary disease (choledocholithiasis, biliary colic) or pancreatic cysts, which in themselves may cause nausea and/or weight loss. Chronic pancreatitis with exocrine insufficiency can imitate pancreatic cancer, presenting with abdominal pain, malabsorption, and weight loss.

'Gold-standard' diagnostic test for pancreatic cancer

CT has become the easiest and most reliable way of diagnosing pancreatic cancer and can also provide the means for percutaneous biopsy. Furthermore, it can identify tumour invasion and metastatic disease.

Acceptable diagnostic alternatives to the gold-standard test for pancreatic cancer

Endoscopic ultrasound is extremely accurate at diagnosis, even with small pancreatic lesions, and can also provide information regarding the staging of the tumour by assessing the depth of spread, and LN and portal vein involvement. Furthermore, fine-needle aspiration can be performed to obtain a histological diagnosis. MRI is also an excellent modality for diagnosing pancreatic cancer and may be more accurate for very small lesions, which are usually found incidentally on CT. Magnetic resonance cholangiopancreatography (MRCP) is usually used to identify the cause of obstructive jaundice when it is not clear from a transabdominal ultrasound scan.

Other relevant investigations for pancreatic cancer

All patients should undergo the following routine blood tests: a full blood count, renal function tests, liver function tests, and a calcium profile. Pancreatic and biliary cancers presenting with obstructive jaundice will reveal a raised conjugated bilirubin level, usually alongside raised alkaline phosphatase and gamma-glutamyltransferase levels. In pancreatic cancer, the amylase level will be raised in 30%–50%

of patients, whereas the level of the tumour marker CA-19-9 will be raised in 75%–85%. CA-19-9 levels are also raised in gall bladder cancer. Ultimately, normal amylase or CA-19-9 levels do not exclude pancreatic cancer, and these levels can also be raised in the setting of gallstones, cholecystitis, pancreatitis, and cirrhosis.

Prognosis of pancreatic cancer, and how to estimate it

Pancreatic cancer has a high mortality rate, as it is difficult to diagnose at an early stage; 52% of patients have distant metastases, and 26% have spread to the regional LNs at the time of diagnosis. The 1-year survival rate is 20%–25%, and the 5-year survival rate is <5%, with a median survival of 4–6 months. Staging also utilizes the TNM system.

Treatment of pancreatic cancer, and its effectiveness

Surgical treatments for resection of pancreatic cancer involve a large and complicated procedure, with patients being monitored on an intensive care unit following the procedure. The position of the cancer will dictate the surgical approach used, and the patient's pre-morbid status will influence their suitability for this approach. Chemotherapy is used in combination with surgery and for unresectable disease, and fluorouracil, gemcitabine, capecitabine, and erlotinib have been shown to be effective. Palliative treatment can involve surgery (in cases of luminal obstruction), chemotherapy, and endoscopically placed biliary stents to relieve jaundice. Relief of pain is paramount.

Cholangiocarcinoma

Aetiology of cholangiocarcinoma

Cholangiocarcinomas arise from the biliary epithelium, and 90% are adenocarcinomas, with SCC accounting for the remainder. There is a higher incidence of cholangiocarcinomas in Asian populations, due to chronic endemic infestations of parasites such as *Clonorchis sinensis* and *Opisthorchis viverrini*. There is an association with primary sclerosing cholangitis (PSC), with 5%–15% of PSC patients developing cholangiocarcinoma. Inflammatory bowel disease (both ulcerative colitis and Crohn's disease) incurs an increased risk, even in the absence of PSC. In addition, congenital diseases (Caroli disease and choledochal cysts), biliary adenomas, and biliary papillomatosis have been associated with cholangiocarcinoma.

Typical symptoms of cholangiocarcinoma, and less common symptoms

Cholangiocarcinoma classically presents with obstructive jaundice, with associated pale stools, bilirubinuria, and pruritus. Weight loss and abdominal pain are also commonly seen. A palpable mass and/or lymphadenopathy is an uncommon finding.

Demographics of cholangiocarcinoma

Cholangiocarcinoma has an incidence of 1–2 per 100 000 population, with a higher incidence in women. The incidence in South East Asia, Japan, and Israel is higher.

Natural history of cholangiocarcinoma, and complications of the disease

Cholangiocarcinomas grow slowly and insidiously, invading local structures, including the bile ducts, the porta hepatis, the liver, and the regional LNs. Fifty per cent of patients have LN involvement at presentation, and 10%–20% of patients have peritoneal or distant metastases. The main complication is obstruction of the biliary tree and the associated risk of cholangitis and sepsis. These should be treated aggressively with antibiotics and biliary drainage. Secondary biliary cirrhosis occurs in 10%–20% of patients.

Other diagnoses that should be considered aside from cholangiocarcinoma

The differential diagnosis for cholangiocarcinoma includes all conditions that can cause an obstructive jaundice.

'Gold-standard' diagnostic test for cholangiocarcinoma

Endoscopic retrograde cholangiopancreatography (ERCP) will enable the doctor to perform a cholangiography and image the site of obstruction and also obtain brushings or biopsies for a histological diagnosis. Furthermore, therapy can be performed at the same time, with placement of a biliary stent to relieve the obstruction.

Acceptable diagnostic alternatives to the gold-standard test for cholangiocarcinoma

Patients will undergo imaging to identify the probable cause of obstruction prior to therapeutic procedures. Often, a patient will initially undergo an ultrasound scan, which can confirm biliary dilatation and absence of gallstones as the cause. However, this modality has a poor sensitivity for cholangiocarcinomas, and patients will subsequently undergo a CT or MRI for further information. Currently, MRI should be considered the optimal investigation for diagnosing cholangiocarcinoma. Endoscopic ultrasounds can provide further information for diagnosis, provide the ability for obtaining samples of tissue, and stage the cancer.

Other relevant investigations for cholangiocarcinoma

All patients should undergo the following routine blood tests: a full blood count, renal function tests, liver function tests, and a calcium profile. CA-19-9 levels are also raised in 85% of patients with cholangiocarcinoma, and a level >100 U/ml, in the setting of PSC, has a sensitivity of 75% and specificity of 80% for cholangiocarcinoma. Carcinoembryonic antigen and CA-125 are raised in approximately 30% and 40%–50% of patients with cholangiocarcinoma, respectively.

Prognosis of cholangiocarcinoma, and how to estimate it

Cholangiocarcinoma has a poor prognosis. Distal tumours are associated with the greatest survival rate, which is related to these tumours being the most amenable to resection: 40% 5-year survival, with a median survival of 17–27 months. Intra-hepatic tumours carry the worst prognosis. Overall, cholangiocarcinoma has an average survival of 12–18 months and is considered to be an incurable and rapidly lethal disease in the majority of cases.

Treatment of cholangiocarcinoma, and its effectiveness

Relief of obstruction is achieved by placement of biliary stents, either endoscopically or percutaneously under radiographic control. Biliary stents can also become occluded, so it is not unusual for patients to require a repeat procedure. Chemotherapy is usually fluorouracil based, and can provide some survival benefit. Surgical resection offers the only chance of cure, but only 10% of patients present with disease with an early enough stage for this to be a reasonable treatment option. Resection requires a major operative procedure; thus, it is vital to know a patient's pre-morbid status when deciding on their suitability. The 5-year survival in patients undergoing surgery is 9%–18% in proximal lesions, and 20%–30% in distal lesions. The evidence for adjuvant therapy is yet to be established, and is mainly used in a trial setting. Unfortunately, there is a high rate of recurrence, closely correlated with TNM staging, and so patients require aggressive follow-up.

Gall bladder cancer

Aetiology of gall bladder cancer

Eighty to eighty-five per cent of gall bladder cancers are adenocarcinomas, with the remainder including SCCs, carcinoids, melanomas, sarcomas, and lymphomas. Chronic inflammation is known to be an aetiological factor for gall bladder cancer, most commonly associated with gallstones, which increase the risk of cancer four- to fivefold. Obesity is associated with an increased risk, but this may be due to the increased incidence of gallstones in obese people. Other, less common, sources of inflammation which are associated with inflammation include PSC, chronic infections (with *H. pylori*, *Salmonella*

typi, *S. paratyphi*, liver flukes, etc.), and ulcerative colitis. Gall bladder polyps and a calcified gall bladder increase the risk of cancer, and the latter has a 10%–25% risk of associated cancer. Therefore, gall bladder polyps bigger than 5 mm or so should be monitored with annual ultrasound to check there is no increase in size, and are generally removed if they are ≥ 1 cm.

Hereditary syndromes associated with gall bladder cancer include hereditary non-polyposis colorectal cancer, Gardner's syndrome, and neurofibromatosis type I. Congenital abnormalities, including choledochal cysts and anomalous pancreaticobiliary duct junctions, are also associated with an increased risk of gall bladder cancer. In addition, certain exposures increase the risk of gall bladder cancer, including drugs (methyl dopa, oral contraceptives), chemicals (vinyl chloride, pesticides, rubber), heavy metals (lead, chromium, cadmium), and occupational exposures (paper mill, petroleum, textile industries).

Typical symptoms of gall bladder cancer, and less common symptoms

Unfortunately, gall bladder cancer may remain asymptomatic until it has spread to adjacent structures. Symptoms include jaundice, nausea, anorexia, weight loss, weakness, abdominal pain (which can be due to biliary peritonitis in the setting of a perforated gall bladder), palpable right upper quadrant mass (Courvoisier sign), palpable Virchow nodes, and lymphadenopathy.

Demographics of gall bladder cancer

Gall bladder cancer is rare in the UK, with less than 600 cases per year; 70% of cases occur in women. There is considerable variation in incidence, associated with gender, age, and ethnicity. The UK, Norway, and Denmark have the lowest incidence rates, whereas the highest incidence rates are found in Peru, Chile, India, Korea, Japan, Bolivia, Spain, Columbia, Slovakia, the Czech Republic, and Ecuador. Females from India have the highest rate overall.

Natural history of gall bladder cancer, and complications of the disease

At presentation, only 10%–20% of patients have disease confined to the gall bladder wall; in 40%–60%, disease will have breached the gall bladder wall; 20% will have peritoneal spread; and 45%–50% will have disease that has spread to regional LNs. The disease can spread, via direct local invasion, to the liver, the duodenum, the pancreas, the stomach, the colon, and the peritoneum. The main complications are due to invasion of adjacent structures; perforation of the gall bladder, leading to biliary peritonitis; and biliary obstruction, with the associated risk of sepsis and kernicterus.

Other diagnoses that should be considered aside from gall bladder cancer

Gall bladder cancer often presents with non-specific symptoms, making it difficult to provide specific differential diagnoses, although you should consider alternative GI cancers and causes of dyspepsia, weight loss, and right upper quadrant pain.

'Gold-standard' diagnostic test for gall bladder cancer

CT is the most effective investigation and can identify tumour invasion into surrounding structures and metastatic disease.

Acceptable diagnostic alternatives to the gold-standard test for gall bladder cancer

Ultrasound scanning can identify a gall bladder mass in approximately 50%–70% of cases. MRI and/or MRCP may identify a lesion, whereas endoscopic ultrasound provides a means of obtaining bile samples for cytological analysis (sensitivity of 73%) and assessing tumour stage. Other methods of obtaining histology include ERCP and CT-guided biopsies.

Other relevant investigations for gall bladder cancer

All patients should undergo the following routine blood tests: a full blood count, renal function tests, liver function tests, and a calcium

profile. Haematinics should be done if anaemia is present, and the patient should be treated accordingly.

Prognosis of gall bladder cancer, and how to estimate it

Prognosis is correlated with the TNM staging; a large number of patients have LN and distant metastases at presentation, leading to an overall 5-year survival rate of 15%–20%. Localized cancer has a 5-year survival of approximately 40%, regional disease 15%, and metastatic disease <10%. Advanced disease has a median survival of 2–4 months.

Treatment of gall bladder cancer, and its effectiveness

Unfortunately, only approximately 25% of patients are suitable for surgical resection, which involves a complicated procedure with a significant associated morbidity and mortality, as with surgery for cholangiocarcinoma. If residual disease remains post-operatively, the survival is approximately 6 months, which can be extended to 12 months with adjuvant radiotherapy. Given the low numbers of patients presenting with potentially resectable disease, the evidence for adjuvant therapy is low, but chemotherapy regimens usually utilize fluorouracil or gemcitabine. There are no defined standards for chemotherapy treatment in gall bladder cancer. Patients with unresectable disease can be offered radiotherapy and/or chemotherapy on a palliative basis, as there is little evidence of any survival benefit. Endoscopic biliary stents may provide palliation by relieving biliary obstruction.

Colorectal cancer

Aetiology of colorectal cancer

Genetic mutations are well recognized to be associated with an increased risk of colorectal cancer. These mutations are not tested for in general practice but, in patients with a strong family history, genetic counselling should be sought in order to assess for inheritable mutations and the need for increased screening. Familial conditions associated with a significant increase in colorectal cancer include familial adenomatous polyposis, hereditary non-polyposis colorectal cancer, juvenile polyposis, and Peutz–Jeghers. These conditions are usually monitored by specialist centres. Other conditions associated with an increased risk of colorectal cancer include inflammatory bowel disease, PSC, acromegaly, and having undergone a ureterosigmoidostomy. The majority of cancers develop in adenomatous polyps. Consequently, patients who have adenomatous polyps should undergo regular screening, as this has been clearly seen to reduce the development of colorectal cancer. Smoking is associated with an increased risk of colorectal cancer. Dietary factors also have a role, including a diet high in red meat and low in fresh fruit, vegetables, fish, and poultry. Industrialized countries have a higher incidence of colorectal cancer, probably related to the differences in diet. Low physical activity and alcohol have also been associated with an increased risk.

Typical symptoms of colorectal cancer, and less common symptoms

Common symptoms of colorectal cancer include rectal bleeding, a change in bowel habit, anaemia (due to occult blood loss), and abdominal pain, but these symptoms can be associated with many other colonic diseases and, therefore, have a low predictive value. Tenesmus can also occur in rectal tumours. If the tumour grows large enough to fill the colonic lumen, obstruction can occur, with symptoms of distension, constipation, vomiting, and abdominal pain. This can lead to perforation and subsequent peritonitis. Deep vein thrombosis can occur as a paraneoplastic syndrome. Liver metastases can cause jaundice or abdominal pain.

Demographics of colorectal cancer

Colorectal cancer is the third most common cancer in the UK, with 100 new cases diagnosed daily. It accounts for 9% of new cancer cases worldwide. Eighty-three per cent of cases occur in people over

60. The male-to-female ratio is 1.2:1.0, with the lifetime risk being 1 in 18 for men, and 1 in 20 for women. Worldwide, the highest incidence rates are in Europe, North America, and Australasia, and the lowest are in Africa and Asia. There is a rapid increase in colorectal cancer risk in migrants moving from low- to high-risk countries. Incidence rates in the UK have slightly decreased, but colorectal cancer screening is likely to significantly increase the number of cases diagnosed in the next decade.

Natural history of colorectal cancer, and complications of the disease

Regardless of aetiology, most colorectal cancers arise from adenomatous polyps, and this information has led to colonoscopic surveillance in patients with adenomatous polyps (see Chapter 354). The size of polyps is proportional to the risk of cancer, with small polyps (<1 cm) posing less than 1% risk, and large polyps (>2 cm) with a cancer incidence of 50%. The worst complications are bowel obstruction and bowel perforation, both of which entail a worse prognosis. Ulcerative tumours are also associated with a worse prognosis. The cancer can spread locally, invading adjacent structures and the peritoneum, and usually metastasizes to the liver and lungs.

Other diagnoses that should be considered aside from colorectal cancer

Colonic symptoms independently have an overall poor predictive value for colorectal cancer. The strongest combination of symptoms to predict colorectal cancer is a change in bowel habit, with rectal bleeding and no anal symptoms in patients 60 or older. Many patients with classic colonic symptoms such as diarrhoea, constipation, and rectal bleeding have alternative diagnoses such as diverticular disease, irritable bowel syndrome, inflammatory bowel disease, haemorrhoids, microscopic colitis, or slow-transit constipation.

‘Gold-standard’ diagnostic test for colorectal cancer

Colonoscopy allows direct visualization of the tumour and the ability to obtain mucosal biopsies. Colorectal cancers require a total colonoscopy to exclude synchronous lesions.

Acceptable diagnostic alternatives to the gold-standard test for colorectal cancer

CT scanning is extremely good at identifying colorectal cancers. CT can be performed with oral contrast, which coats any faecal material, or with full bowel purgation and air insufflation (CT colonoscopy). CT colonoscopy has been considered to be safer than endoscopic investigations, due to a reduced risk of perforation. However, if lesions are seen at CT, an endoscopic examination is subsequently required for tissue diagnosis. Double-contrast barium enemas are used less often nowadays, as CT colonoscopy becomes more widely available.

Other relevant investigations for colorectal cancer

All patients should undergo the following routine blood tests: a full blood count, renal function tests, liver function tests, and a calcium profile. Haematinics should be done if anaemia is present, and the patient should be treated accordingly. Carcinoembryonic antigen is often raised in colorectal cancer, but cannot be used as a diagnostic tool, although it is often used to monitor response to treatment.

Prognosis of colorectal cancer, and how to estimate it

Colorectal cancer is the third most common cancer and the second leading cause of cancer-related death in the Western world. Prognosis is related to staging, and three systems can be used to classify tumour stage: the TNM staging system, the AJCC staging system, and the Dukes classification. The Dukes classification is older and simpler, with the following overall 5-year survival rates:

- Dukes A (confined to the intestinal wall): 90%
- Dukes B (invading through intestinal wall): 55%–85%
- Dukes C (LN involvement): 20%–55%
- Dukes D (distant metastases): <5%

Ulcerative cancers and those associated with bowel obstruction or perforation entail a worse prognosis.

Treatment of colorectal cancer, and its effectiveness

Surgery remains the only treatment for curing colorectal cancer and is usually combined with adjuvant chemotherapy to reduce cancer recurrence. Fluorouracil remains the backbone of chemotherapy, but oral fluoropyrimidines (e.g. capecitabine) are increasingly used. Newer chemotherapeutic agents and biological therapies (e.g. bevacizumab) are likely to increase survival, especially in patients with metastatic disease. Radiotherapy is standard therapy in rectal cancer but has limited use in colonic tumours. Palliative therapy includes endoscopically or radiologically placed stents, which can prevent obstruction by tumours which are encroaching the colonic lumen.

Anal cancer

Aetiology of anal cancer

Anal cancer is usually SCC. The human papilloma virus (HPV) is a strong risk factor for the development of anal cancer, with anal cancers being positive for the virus in 100% of homosexual men, 90% of women, and 58% of heterosexual men. The incidence of anal cancer is significantly higher in homosexual men, mainly related to anal intercourse increasing the exposure to HPV. In addition, having multiple sexual partners increases the risk of anal cancer. Smoking, immunosuppression, and benign anal lesions (inflammatory bowel disease, haemorrhoids, fistulae) have also been associated with anal cancer. Overall, the highest incidence is in homosexual HIV patients. Although there is no national screening programme, many HIV specialist centres advocate regular screening with anoscopy in homosexual HIV-positive patients. Anal smears are being studied to assess if they can be used to identify anal intra-epithelial neoplasia (AIN) in the same way that cervical screening is used to identify cervical neoplasia.

Typical symptoms of anal cancer, and less common symptoms

The commonest symptom of anal cancer is rectal bleeding. Other symptoms include lumps, discomfort, rectal mucus, or faecal incontinence. Twenty per cent of patients have no symptoms. Anal cancers may be identified during a rectal examination.

Demographics of anal cancer

Anal cancer is rare, with only 850 new cases annually in the UK. The incidence increases with age, with most patients 50 or older. The incidence is slightly higher in women, although the reason for this is not known.

Natural history of anal cancer, and complications of the disease

Anal cancer usually arises from a dysplastic area (AIN), which can progress to a carcinoma in situ and eventual frank cancer. Initially, it spreads locally, invading surrounding tissue, but can spread more distantly via the lymphatic system. Distant metastases usually occur in the liver and lungs. The main complication is faecal incontinence.

Other diagnoses that should be considered aside from anal cancer

Rectal symptoms are commonly associated with benign conditions such as anal fissures or haemorrhoids.

'Gold-standard' diagnostic test for anal cancer

Anal cancers can be diagnosed at anoscopy or proctoscopy.

Acceptable diagnostic alternatives to the gold-standard test for anal cancer

Pelvic CT or MRI scanning may identify anal cancers. Ideally, an MRI is performed in all patients with anorectal cancers to assess direct invasion into surrounding structures.

Other relevant investigations for anal cancer

Patients with anorectal carcinomas will require a pelvic MRI, to assess the overall local spread of disease.

Prognosis of anal cancer, and how to estimate it

The 5-year survival for patients with anal cancer is approximately 80%, dropping to 60% if it has spread locally and 20% in patients with distant metastases.

Treatment of anal cancer, and its effectiveness

Previously, surgical resection was the mainstay of treatment, involving removal of the anal sphincter; this meant that patients required permanent colostomies, to avoid faecal incontinence. However, combination chemoradiotherapy has been shown to be as effective as surgical resection, and preserves the anal sphincter. The commonest chemotherapy used is fluorouracil in combination with mitomycin or cisplatin.

Hormone-secreting tumours

Aetiology of hormone-secreting tumours

Hormone-secreting tumours found in the GI tract include pancreatic neuroendocrine tumours and carcinoids. These are rare, slow-growing tumours which are often found incidentally. Carcinoid tumours are derived from enterochromaffin cells, of which 55% occur in the GI tract (small intestine 45%, rectum 20%, appendix 16%, colon 11%, stomach 7%). Pancreatic neuroendocrine tumours arise from APUD (for amine precursor uptake decarboxylase) cells. Approximately 25% appear to be non-secreting; however, it is probably more likely that the secretion of hormones is so low that any effects are subclinical. The commonest tumours are gastrinomas, insulinomas, VIPomas, somatostatinomas, and glucagonomas.

Typical symptoms of hormone-secreting tumours, and less common symptoms

Carcinoid tumours can cause intestinal symptoms related to luminal obstruction or fibrosis. However, they are often more recognized for their hormone-secreting potential, with symptoms related to the specific hormone secreted. Typical symptoms of carcinoid syndrome are flushing, diarrhoea, bronchospasm, and valvular heart disease. Although these symptoms are usually associated with serotonin release, other hormones also play a role. For example, neuropeptide K, histamine, and bradykinin cause flushing, and glucagon, gastrin, prostaglandins, and vasoactive polypeptide cause diarrhoea. Seventy-five to eighty per cent of patients with carcinoid syndrome have small bowel carcinoid, and 90% have metastases.

Pancreatic neuroendocrine tumours are often diagnosed incidentally but can present with a palpable mass, biliary obstruction, or symptoms related to hormone production, as follows:

- gastrinoma: peptic ulcer disease, diarrhoea
- insulinoma: hypoglycaemia
- VIPoma: profuse diarrhoea, achlorhydria, hypokalaemia, hyperglycaemia
- somatostatinoma: gallstones, diarrhoea, steatorrhoea, diabetes mellitus
- glucagonoma: glucose intolerance, diarrhoea, anaemia, thromboembolic phenomena, dermatitis (necrolytic migratory erythema), stomatitis

Demographics of hormone-secreting tumours

Carcinoid tumours are rare, with only 1500–2000 cases per year in the UK. They have an incidence of 1.5 per 100 000 population, although the incidence rises to 650 at post-mortem, confirming the undiagnosed incidence in the majority. Patients are usually over 60 years of age and the tumours are slightly more common in men.

Neuroendocrine tumours are extremely rare, with an incidence of 3–10 per million in the UK. They are solitary and sporadic in those aged 30–50, and only occur in younger patients (aged 10–30) in the setting of multiple endocrine neoplasia type 1 (an autosomal

dominant condition associated with hyperparathyroidism and pituitary adenomas).

Natural history of hormone-secreting tumours, and complications of the disease

Carcinoid tumours are slow-growing and often multiple. They are often found incidentally and there are a significant number found at autopsy, with patients dying from other diagnoses. Only 10% of patients will develop carcinoid syndrome, and metastases usually spread to the liver.

Other diagnoses that should be considered aside from hormone-secreting tumours

As hormone-secreting tumours are usually diagnosed incidentally, the main differential includes neoplastic tumours. Consequently, patients with hormone-secreting tumours often undergo various imaging and/or endoscopic techniques prior to a final diagnosis being made, especially when there are pancreatic lesions causing biliary obstruction.

'Gold-standard' diagnostic test for hormone-secreting tumours

A 24-hour urine collection for 5-hydroxyindoleacetic acid, which is a breakdown product of serotonin and is usually raised in carcinoid tumours, is the gold-standard diagnostic test for hormone-secreting tumours, with a sensitivity of 75% and a specificity of 100%. Neuroendocrine tumours can also be diagnosed in the following ways, although usually in combination with an octreotide scan:

- gastrinoma: fasting serum gastrin level (normally <110 pg/ml); any proton-pump inhibitors and H2 antagonists should be stopped 7 days 2 days, respectively, prior to the test
- insulinoma: 72-hour fasting study with insulin, proinsulin, C-peptide, and glucose levels
- VIPoma: fasting VIP levels during symptoms should be 2–10 times the upper limit of normal
- somatostatinoma: fasting somatostatin >160 pg/ml
- glucagonoma: serum glucagon >500 pg/ml

Acceptable diagnostic alternatives to the gold-standard test for hormone-secreting tumours

Octreotide scans can be useful for carcinoid and most neuroendocrine tumours, based on the fact that they usually express somatostatin receptors. Octreotide scans are performed in the nuclear medicine department, utilizing radiolabelled octreotide, a somatostatin analogue. ¹²³I-MIBG scans work in a similar way. The vast majority of hormone-secreting tumours are identified on CT scans performed for unrelated reasons. MRI scans may be used to further image small lesions. Endoscopy may be used for lesions in the upper GI tract or colon, allowing visualization and biopsy. Endoscopic ultrasound

is often used for pancreatic neuroendocrine tumours, assessing size, invasion, and LN involvement. Provocation tests are currently rarely used.

Other relevant investigations for hormone-secreting tumours

Several investigations can confirm the diagnosis of a hormone-secreting tumour. Gastrinomas can be confirmed by secretin stimulation tests, with levels rising to >200 pg/ml. Furthermore, a gastric pH of <3 excludes secondary hypergastrinaemia. VIPomas cause hypochlorhydria, and this can also be confirmed by gastric pH. Furthermore, VIPomas cause >700 ml diarrhoea per day in all patients, and >3 l/day in 70%.

Prognosis of hormone-secreting tumours, and how to estimate it

The prognosis for carcinoid tumours, as with all cancers, depends on the degree of spread. The approximate 5-year survival is 78% in localized disease, 72% with regional disease, and 39% in patients with distant metastases. The overall 5-year survival for all stages is 68%. The prognosis for pancreatic neuroendocrine tumours is not dissimilar, dependent on the degree of spread, tumour grade, or age. Unfortunately, they may remain undetected for years, and only become symptomatic when metastases cause symptoms from tumour bulk or increased hormone secretion.

Treatment of hormone-secreting tumours, and its effectiveness

There are several forms of treatment for hormone-secreting tumours:

- surgery
- radiotherapy
- chemotherapy
- chemoembolization: this involves injecting a chemotherapeutic agent into the blood vessel supplying a liver metastasis, and then embolizing the artery and subsequently cutting off the blood supply
- percutaneous ethanol injection
- biological therapy: octreotide, lanreotide, interferon

205 Functional gastrointestinal diseases

Satish Keshav and Alexandra Kent

Definition of the disease

Irritable bowel syndrome (IBS) is a functional bowel disorder characterized by chronic abdominal pain associated with a change in bowel habit or stool consistency in the absence of any definite organic abnormality. It is the commonest functional gastrointestinal syndrome. Many others have been defined clinically, including functional dyspepsia, functional biliary pain, functional abdominal pain, and so on. Functional dyspepsia is dealt with in Chapter 25.

Aetiology of the disease

Mechanisms leading to the development of IBS are thought to include visceral hypersensitivity, altered intestinal motility, altered autonomic function, bacterial flora, and stress. Sixty per cent of patients with IBS show a disproportionate pain response to rectal balloon distension, and imaging has shown increased cerebral blood flow in response to pain. Intestinal mediators such as bradykinin and serotonin induce visceral hypersensitivity and may play a role. A large number of patients develop IBS following on from gastroenteritis, and this may be related to the raised concentration of serotonin-containing enteroendocrine cells which develop after gastrointestinal infections. Psychological factors are thought to play an integral role, with studies showing that up to 50% of IBS patients who seek medical care have concurrent depression or anxiety. Finally, the increased incidence in twins suggests there is a genetic link, although, to date, no specific genetic loci have been identified.

Typical symptoms of the disease, and less common symptoms

International consensus meetings have defined diagnostic criteria for IBS, and the latest is the Rome III criterion, which can be summarized as follows: recurrent abdominal pain or discomfort for 3 days per month for the past 3 months, with onset ≥ 6 months earlier and associated with two or more of:

- improvement with defaecation
- onset associated with change in appearance of the stool
- onset associated with change in frequency of the stool

IBS can be further subdivided into constipation-predominant IBS, diarrhoea-predominant IBS, or mixed IBS. Other symptoms associated with IBS include bloating, abdominal pain after eating, rapid gastrocolic reflex, passage of rectal mucus, urgency, incomplete evacuation, lethargy, nausea, and food intolerances. Most symptoms are intermittent, with 'flares' lasting an average of 1–4 days. Patients who have IBS-like symptoms but do not meet the Rome III criterion may still have a functional bowel disorder.

Demographics of the disease

IBS is very common, with a prevalence of 10%–20% of the general population and with the majority treated in primary care. The highest incidence is in the 20–30-year-old age group, with women being affected twice as often as men.

Natural history and complications of the disease

IBS symptoms are usually intermittent but protracted, lasting several years. IBS patients attend their general practitioner twice as much as non-IBS patients, incurring huge costs to the NHS. The diagnosis

does not need to be re-evaluated unless new symptoms develop. There are no long-term complications of IBS, although it can impact hugely on the patient's quality of life.

Approach to diagnosing the disease

The most important approach to diagnosing IBS is a good history. Many patients will not volunteer symptoms unless specifically asked, especially 'embarrassing' symptoms such as faecal incontinence. It is important to be sensitive to cultural and gender barriers in these patients, and assess how symptoms affect their quality of life, in particular time off work. Although investigations 'just to exclude ...' are to be avoided, because negative investigations may reinforce the patient's view that the underlying pathology has simply not yet been uncovered, it is pragmatic to perform some simple tests that make certain common diagnoses that can mimic IBS unlikely. These tests include a full blood count to check for anaemia, C-reactive protein levels as a sign of inflammation, a coeliac antibody test, and *Helicobacter* serology. If these tests are normal, then significant gastrointestinal disease such as peptic ulcer, coeliac disease, inflammatory bowel disease, and colorectal cancer are unlikely. In cases where there is an inadequate response to reassurance and symptomatic treatment, a case could be made for more specialized tests, such as an abdominal ultrasound scan and upper and lower endoscopy.

Other diagnoses that should be considered

Symptoms not compatible with IBS and so requiring further investigation include weight loss, rectal bleeding, abdominal masses, anaemia, and raised inflammatory markers. Furthermore, patients >50 years old with a persistent change in bowel habit should not be diagnosed with IBS until organic pathology, in particular colorectal cancer, is excluded. The main differential diagnoses to be excluded include microscopic colitis, inflammatory bowel disease, colorectal cancer, bacterial overgrowth, and lactose intolerance.

'Gold-standard' diagnostic test

Patients who meet the criteria for IBS, have no additional symptoms or signs, and are <50 years old need no additional investigations. Therefore, the majority of patients can be diagnosed from a history and examination, especially those with constipation-predominant IBS. For patients with diarrhoea-predominant IBS, most centres would advocate screening blood tests with a full blood count, erythrocyte sedimentation rate, C-reactive protein level, coeliac serology, and immunoglobulins. The role of these investigations is to ensure inflammatory and malabsorptive conditions are excluded.

Acceptable diagnostic alternatives to the gold standard

Since IBS is diagnosed on clinical presentation rather than results of investigation, there are no alternative diagnostic tests.

Other relevant investigations

Patient with persistent diarrhoea may require a more extensive workup, including stool microscopy and culture, haematinics, calcium, thyroid function, and a lower gastrointestinal endoscopy with mucosal biopsies. A more detailed description of investigations into chronic diarrhoea is in Chapter 29.

Prognosis and how to estimate it

The overall prognosis is unpredictable, and patients should be warned that there is a variable response to treatment. Some patients suffer intermittent, short-lived symptoms, while others suffer chronic, severe symptoms that seriously affect their quality of life.

Treatment and its effectiveness

Appropriate treatment can be highly effective, particularly when delivered professionally and with empathy and reassurance. Many patients are convinced there is something serious wrong with them; subsequently, reassurance is integral to patient care, as this may address accompanying anxiety and depression. The treatment of IBS aims at reducing symptoms, and includes changes in lifestyle as well as pharmacotherapy.

Dietary modification

Self-help booklets on IBS and the effect of diet on its symptoms can be very useful. In more complex cases, specialist help from a trained dietician may be needed. Those with constipation as a major symptom should be given advice regarding fibre levels, which should be optimized. Fibre intake should neither be inadequate nor excessive, and soluble fibre, such as ispaghula, is better than insoluble fibre, such as bran. Dietary advice can help avoid foods that can cause diarrhoea, such as caffeine, citrus fruits, and sorbitol. Wheat and dairy products are commonly identified as substances that can worsen symptoms.

Exercise and stress

Patients should be advised to take regular exercise and try to reduce stress levels, although the evidence behind these interventions is limited.

Pharmacological therapy

Peppermint oil has been shown to be an effective treatment for abdominal discomfort and bloating. Other antispasmodics that are effective in some patients include hyoscine butylbromide, mebeverine, and alverine.

Diarrhoea and urgency can be controlled with loperamide. Codeine should be avoided because it can cause sedation and other psychotropic effects, and may be addictive. Laxatives such as cracked linseed, syrup of figs, and sodium docusate are used to treat constipation. Lactulose is usually avoided because it aggravates wind and bloating.

Tricyclic antidepressants (TCAs) such as amitriptyline at low doses such as 20–50 mg daily reduce abdominal pain, and have been shown

to be most effective in diarrhoea-predominant IBS. Constipation is a recognized side effect, and may help diarrhoea. In patients unresponsive to TCA, selective serotonin reuptake inhibitors (SSRIs) can be tried. With both TCAs and SSRIs, patients should be warned of possible side effects, and doses should be titrated slowly.

Newer preparations that treat constipation and diarrhoea by targeting various serotonin-receptor subtypes are being developed and may radically improve the treatment of these two symptoms. Abdominal pain and bloating, however, remain a therapeutic challenge.

Complementary therapy

In patients with refractory IBS or in whom stress is a major factor, cognitive behavioural therapy, psychological therapy, or hypnotherapy may be effective, although their use is restricted by limited availability. In hypnotherapy, specific 'gut-related' hypnosis is applied, whereby the patient is taught to control gut function while in a hypnotic state.

Biofeedback

Biofeedback is a behavioural technique that teaches a patient to raise awareness and conscious control of their physiological responses.

Probiotics

There have been several controlled trials which have shown that probiotics can help abdominal distension and flatulence, with a reduction in IBS composite scores. However, it is difficult to draw definitive conclusions, as the studies use different bacterial species and doses.

Herbal medicines

Studies have suggested herbal or Chinese medicines can be effective at controlling symptoms. However, evidence for this is limited, so such treatment cannot be recommended at this time.

206 Psychiatry in gastrointestinal medicine

Satish Keshav and Alexandra Kent

Psychiatric conditions with gastrointestinal consequences

Eating disorders

Anorexia nervosa is characterized by extreme weight loss, which is maintained by dieting, excessive exercise, fear of weight gain, and a disturbed body image. Bulimia nervosa is characterized by binge eating following by purging, normally by self-induced vomiting. Patients classically develop these disorders in adolescence; the incidence is greater in women. Patients with bulimia may maintain their body weight due to the binge eating, while anorexics have a low BMI and typically appear emaciated.

The mainstay of treatment is provided by specialist psychiatry. However, gastroenterologists are commonly asked for advice for treating severe malnutrition. Electrolyte and nutritional deficiencies should be replaced, including trace elements such as selenium and zinc. As a healthy diet is introduced, the patient is at risk of refeeding syndrome. The increased oral intake causes a shift from metabolizing fat and ketones to carbohydrate metabolism. The result can be rapid and cause profound alterations in the concentration of critical ions, including K^+ , Na^+ , Mg^{2+} , and phosphate; K^+ and phosphate, particularly, may need to be replenished rapidly to prevent cardiac arrhythmias and seizures. Severe starvation and refeeding syndrome are both life-threatening emergencies, carrying a high risk of death.

Depression

One of the diagnostic criteria of depression is weight loss, related to a reduced appetite and disinterest in eating. Depression should be considered in any patient presenting with weight loss, and can be associated with stressful life events, such as bereavement. This usually responds to treatment of the underlying problem, and weight gain is a common sign of improvement in mood. Studies suggest that up to 70% of patients with irritable bowel syndrome (IBS) meeting the Rome III criteria (see Chapter 205) have underlying depressive disorders. Further studies have confirmed that antidepressants can improve IBS symptoms, a result that is almost certainly related to treating the symptoms of depression.

Psychiatric medications

Medications used to treat psychiatric conditions commonly have gastrointestinal (GI) side effects, and this emphasizes the importance of taking an accurate drug history. The GI side effects associated with each drug group are as follows:

- antidepressants: dry mouth, constipation, diarrhoea (selective serotonin reuptake inhibitors), nausea, weight gain, and abdominal pain
- neuroleptics: dry mouth, constipation
- lithium: at treatment doses, this can cause nausea and weight gain; toxic levels can cause diarrhoea, nausea, and vomiting

GI diseases with psychiatric symptoms

Hepatic encephalopathy

Hepatic encephalopathy is a neuropsychiatric condition that occurs acutely or chronically in the setting of liver failure. Portal hypertension leads to the development of a collateral circulation, with shunting of portal venous blood flow from the intestinal tract directly into the systemic circulation. This shunting, as well as reduced liver function, allows toxins in portal venous blood to enter the cerebral circulation and impair brain function. The severity of hepatic encephalopathy

varies from subclinical to frank coma, with decerebration and brain death. Early symptoms include reversal of the sleep–wake pattern, impaired cognition, impaired spatial perception, asterixis, lethargy, apathy, and subtle personality changes. Laxatives that accelerate intestinal transit, and reduce bacterial production of toxins such as ammonia, are the mainstay of treatment. Lactulose is particularly favoured because bacterial metabolism of lactulose acidifies intestinal contents and so inhibits the absorption of ammonia from the intestine.

Acute encephalopathy in patients with stable chronic liver cirrhosis can be precipitated by upper GI haemorrhage, infection, and electrolyte disturbances, which can be caused, for instance, by the use of diuretics to treat ascites. In these cases, an attempt is made to reverse or treat the precipitant. Coma and decerebration are more likely to occur in acute liver failure, such as that caused by paracetamol overdose, than in chronic liver disease.

Coeliac disease

Neuropsychiatric symptoms are well recognized in coeliac disease, and are especially prevalent in the untreated coeliac population. These may be the only presenting symptom, and include cerebellar ataxia, neuropathy, memory impairment, multifocal leucoencephalopathy, dementia, myoclonus, epilepsy, and internuclear ophthalmoplegia, amongst others. GI symptoms may be absent, and this fact accounts for the large undiagnosed population. The pathophysiology behind the neuropsychiatric disturbances is not completely understood, but improvement following a gluten-free diet suggests that nutrient deficiencies may contribute. Nutrients which could be implicated include folic acid, vitamin B_6 , and tryptophan. Treatment involves a gluten-free diet and replacement of nutritional deficiencies. Overall, it is important that coeliac testing should be part of the workup in patients presenting with neurological and psychiatric symptoms.

Wilson's disease

Wilson's disease is an autosomal recessive disorder, characterized by copper deposition in the brain, liver, kidney, and cornea. This leads to a widely variable presentation, but neurological and psychiatric symptoms are well described. Neurological symptoms and signs include dysarthria, dysdiadochokinesis, tremor, bradykinesia, ataxia, chorea, seizures, and dystonia. Many of these signs are extremely subtle, and not identified without careful examination. Psychiatric conditions are far less common than neurological ones, and are predominantly found in patients with neurological disease. Conversely, the majority of patients with neuropsychiatric symptoms already have established cirrhosis. Ten to twenty per cent of patients present with psychiatric symptoms, which can be divided into behavioural, affective, schizophrenic, and cognitive categories. Symptoms include emotional lability, belligerence, disinhibition, impaired social judgement, and temper outbursts. Case reports have also identified patients developing these abnormalities after years of treatment with penicillamine.

Acute intermittent porphyria

Acute intermittent porphyria is an autosomal dominant condition involved in defective haem processing. It is characterized by attacks consisting of abdominal pain, mild mental disturbance, and autonomic dysfunction. The autonomic neuropathy can cause neurovisceral symptoms, including constipation, abdominal pain, delirium, seizures, depression, and coma. Encephalopathy can develop, and psychosis has been reported. Most symptoms resolve with the attacks, which

are treated conservatively. Anxiety and depression are more common in patients with acute intermittent porphyria and are most likely related to the impact of chronic illness

Functional GI disease

It is well recognized that there is a strong association of functional disorder (functional dyspepsia, IBS) with psychiatric problems. The pathophysiology underlying functional disorders is not completely understood, but is thought to be due to visceral hypersensitivity, a disrupted hypothalamic–pituitary–adrenal axis and/or an altered brain–gut axis. Overall, it is thought there is a disrupted balance between the neural system, the neuroendocrine system, and the immune system. It is well recognized that stressful life events can exacerbate IBS symptoms. Studies have shown that approximately 25%–40% of patients with panic disorder, 35% of patients with obsessive–compulsive disorder, and 25%–30% of those with major depressive illnesses have IBS. It is important for a GI physician to identify underlying psychiatric disturbances, as treatment of the psychiatric disorder may provide relief of the GI symptoms. This may also explain the benefit seen in some patients for alternative therapies such as hypnotherapy or acupuncture. Given the limited

effective treatment strategies in functional disorders, psychiatric treatment may be a far more efficacious option.

Inflammatory bowel disease

Inflammatory bowel disease, as with many chronic illnesses, has a higher incidence of depressive illness, occurring in 16% in one large study. Children and adolescents have a higher risk of developing depressive illness. Depressive illnesses impact on quality of life, with symptoms increasing with progressive disease severity. There is no evidence that stress or psychiatric illness can initiate disease, but studies have suggested stress may play a role in exacerbating inflammation, although this is not a unanimous opinion.

PART 9

Disorders of the liver

207 Normal hepatic function

Satish Keshav and Palak Trivedi

Liver anatomy

Anatomy

The liver is the largest internal organ of the body, weighing about 1.5 kg in an adult. It is a wedge-shaped structure situated under the right hemidiaphragm and is covered by a connective tissue capsule (Glisson's capsule). Morphologically, the liver can be divided into four lobes: right, left, caudate, and quadrate. Three ligaments attach the liver to surrounding structures: the falciform ligament (anteriorly and superiorly) and two posterior triangular ligaments. The falciform ligament separates the larger right lobe from the smaller left lobe. It also attaches the liver to the anterior abdominal wall and diaphragm. A smaller structure called the ligamentum teres attaches the falciform ligament to the umbilicus. The two posterior triangular ligaments enclose the retrohepatic vena cava and the small bare area of the liver.

Inferiorly, Glisson's capsule is attached to the lesser curve of the stomach. At the hepatic hilum, it encases the hepatic pedicle, which consists of the hepatic artery, the portal vein, and the common hepatic bile duct.

Vasculature of the liver

The portal vein is formed by the union of the superior mesenteric vein and the splenic vein and divides into left and right branches to supply each lobe. The left gastric vein also enters the portal vein and is important in the development of varices.

The hepatic artery arises from the coeliac artery. Several anatomical variants of the liver arterial blood supply exist and become important when considering transplantation.

Venous drainage of the liver is through the right, middle, and left hepatic veins. The caudate lobe has a separate drainage system through the spigelian veins directly into the inferior vena cava. In hepatic vein obstruction, as occurs in, for instance, Budd–Chiari syndrome, more hepatic venous blood flows via the spigelian system, with hypertrophy of the caudate lobe.

The liver receives approximately one-quarter of the total cardiac output (one-third from the hepatic artery, and two-thirds from the portal vein). The flow rate at rest varies between 1.6 and 1.8 l/min. The rate depends on physiological states such as feeding (following which the flow rate will be increased), respiration (flow rate increases in the expiratory phase), and posture (hepatic flow is reduced on adoption of an upright position). The portal venous system is passive, without pressure-dependent autoregulation, and the major physiological factors controlling flow are those modulating supply to the intestines and spleen. There is an important relationship between portal venous flow and hepatic arterial flow: a reduction in portal venous input results in a compensatory decrease in hepatic arterial resistance and, hence, an increase in the arterial flow rate.

Biliary anatomy of the liver, and lymphatic drainage

Bile canaliculi drain from the right and left hepatic bile ducts before coalescing to form the common hepatic duct. The cystic duct then joins the common hepatic duct to form the common bile duct. The common bile duct passes behind the first part of the duodenum and joins the pancreatic duct before entering the duodenum through the ampulla of Vater.

The gall bladder lies on the underside of the liver and is connected to the cystic duct via a spiral valve. The gall bladder functions as a storage organ with a capacity of up to 50 ml of bile.

Lymphatic vessels drain via the portal tract, closely applied to the branches of the hepatic artery, up to the hepatic hilum and subsequently via the thoracic duct. In addition, a smaller proportion drain via the hepatic veins, and some interstitial fluid drains through Glisson's capsule directly into the peritoneum. The lymph flow of the liver is approximately 0.5 ml per kilogram of liver per minute.

Innervation of the liver

The liver receives sympathetic and parasympathetic autonomic innervation. Sympathetic stimulation leads to:

- glycogenolysis and subsequent glucose release
- reduced ammonia uptake
- reduced bile formation
- reduced oxygen consumption by the liver
- increased hepatic vascular resistance
- increased portal pressure
- the release of blood from the liver into the systemic circulation; sympathetic nerve stimulation may reduce hepatic blood volume by up to 50%

Functional anatomy of the liver

The central area where the common bile duct, the hepatic portal vein, and the main hepatic artery proper enter is termed the porta hepatis. There, they divide into left and right branches. The portions of the liver supplied by these branches constitute the functional left and right lobes, which are distinct from the anatomical right and left lobes. The right functional lobe is divided into anterior and posterior segments by the right hepatic vein. The left functional lobe is divided into medial and lateral segments by the left hepatic vein. The medial segment corresponds to the quadrate lobe.

In the Couinaud nomenclature system, each functional lobe is divided into eight subsegments, each of which is a complete functional unit with a single portal pedicle and hepatic venous drainage (see Figure 207.1 and Table 207.1). Within each functional segment of the liver, the structural unit is the hepatic lobule.

The hepatic lobule

Although the liver is the largest internal organ, it is only a few cells thick. This is because hepatocytes form hepatic plates that are one to two cells thick and are separated from each other by large capillary spaces called liver sinusoids. The plates are assembled in hexagonally shaped lobules (see Figure 207.2). In each lobule, there is a central vein, a peripheral portal triad (containing a bile duct and the respective branches of the portal vein and the hepatic artery), and the hepatic plates, which lie between the two. In venous congestion (as occurs in right heart failure), the zone around the central vein sustains injury while, in hepatitis/cirrhosis, damage begins at the portal triads and spreads outwards in ripples. The components of the hepatic lobule and their roles are discussed in Table 207.2.

Basic physiology of the liver

The liver is critical to the maintenance of homeostasis, and life cannot be supported in the anhepatic state.

Bile formation

Each day, the liver produces 600 ml of bile via osmotic filtration and active transport across the canalicular membrane. The principle bile salt conjugates are cholic acid and chenodeoxycholic acid. Once in bile ductules, the bile is modified as the duct cells absorb glucose

Figure 207.1 Functional segments of the liver.

Reprinted by permission from Macmillan Publishers Ltd: *Nature Reviews Clinical Oncology*, Siriwardena et al., volume 11, issue 8, pp. 446–459, copyright 2014.

from the bile and actively secrete amino acids and additional bile salts. Active secretion of bicarbonate and chloride also occur via the cystic fibrosis transmembrane regulator protein.

Bile salt conjugates secreted from hepatocytes into bile are deconjugated in the jejunum and ileum with reabsorption and reuptake by the liver. This is termed the enterohepatic circulation. This mechanism is responsible for conserving bile acids and hence maintains the high concentration of bile. Five per cent of bile acids will pass through the ileocecal valve and undergo deconjugation by colonic bacteria. They will then be reabsorbed as the secondary bile acids deoxycholic acid and lithocholic acid.

There are many digestive functions of bile, including the neutralization of duodenal pH, emulsifying fat (hence making fat and fat-soluble molecules absorbable), and activating lipase enzymes. In addition to their role in digestion, bile acids are the principal mechanism for the biliary secretion and clearance of cholesterol.

Bilirubin metabolism and transport

Bilirubin is transported within plasma, bound to albumin. A few substances can displace bilirubin from albumin (e.g. antibiotics from the sulfonamide group). Unbound bilirubin is insoluble in water. Fortunately, unbound bilirubin is only present in miniscule amounts in normal circumstances. Levels of insoluble bilirubin rise in the absence of the hepatic enzyme UDP-glucuronyl transferase. This is

an enzyme of the glucuronidation pathway and transforms bilirubin into a water-soluble metabolite. This enzyme is undetectable in the rare disorder Crigler–Najjar syndrome. Two main forms of this disorder exist:

- type I: absence of any recognizable forms of the enzyme
- type II: <10% of normal UDP-glucuronyl transferase; phenobarbital can be used as a therapeutic measure as it is an enzyme inducer and thus will increase levels of UDP-glucuronyl transferase

Coagulation

The liver produces Factors I (fibrinogen), II (prothrombin), V, VII, IX, X, and XI, as well as protein C, protein S, and antithrombin. The liver also produces the glycoprotein thrombopoietin, which regulates the production of platelets by the bone marrow.

Hepatic metabolic processes

Hepatic metabolic processes have a central role in protein, carbohydrate, and lipid metabolism. Adverse alteration to these processes results in the major metabolic consequences of acute and chronic liver disease.

Carbohydrates

During fasting, hepatic glucose release via glycogenolysis, and more so by gluconeogenesis (from lactate, pyruvate, glycerol, and glucogenic amino acids), takes place. This process is regulated by hormonal control through glucagon (accounting for fasting glucose output), cortisol, growth hormone, and catecholamines. After a carbohydrate load, insulin will suppress hepatic glucose release and promote the storage of glucose as glycogen.

Proteins and amino acids

Most circulating proteins are produced by hepatocytes (the exceptions being immunoglobulins produced by lymphocytes, and von Willebrand factor, which is produced by platelets). Acute-phase

Table 207.1 Correspondence between anatomical lobes and functional segments

Anatomical lobe/segment	Couinaud segments
Caudate	1
Lateral	2, 3
Medial	4a, 4b
Right	5, 6, 7, 8

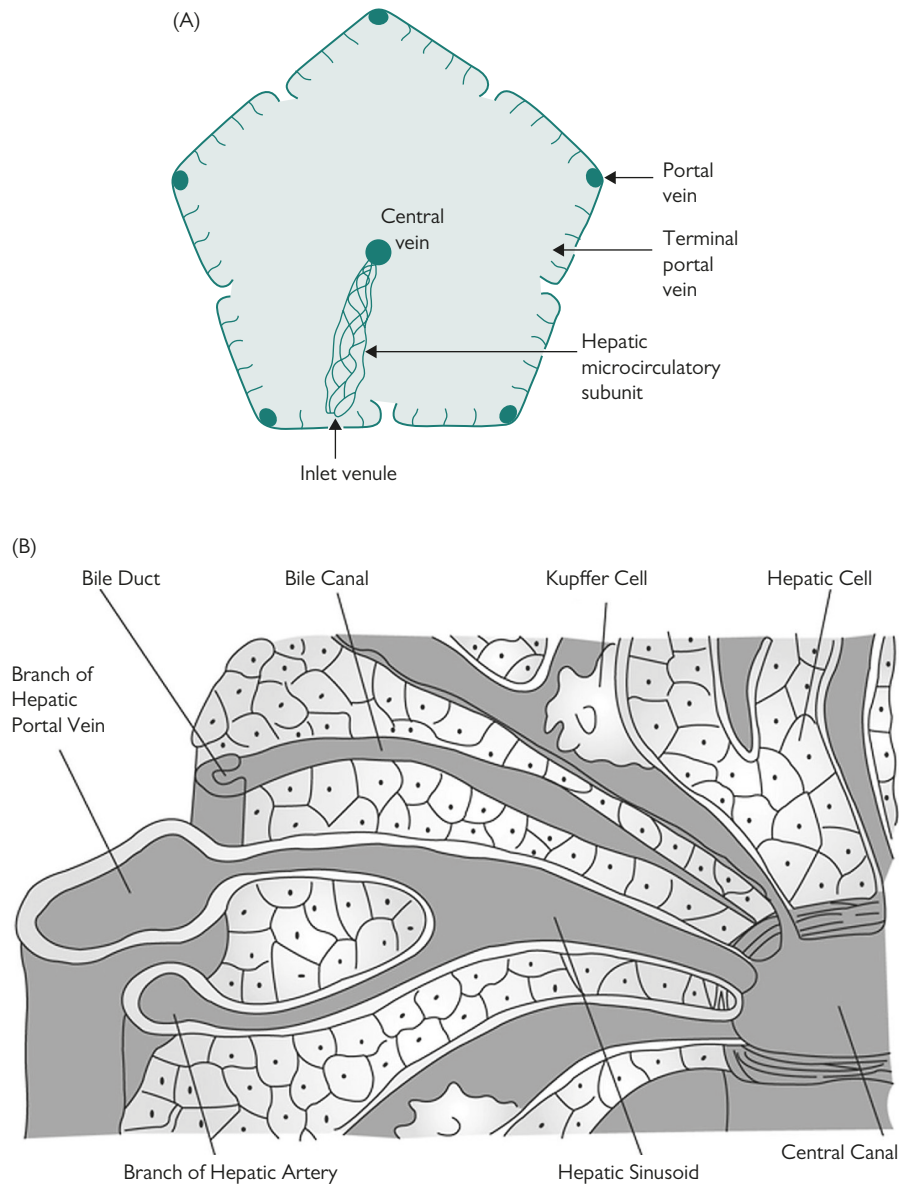

Figure 207.2 (A) Hexagonal lobule with portal venous branches and a hepatic microcirculatory subunit: the sinusoid. (B) Liver lobule and portal triad. proteins (e.g. C-reactive protein (CRP)) have a reciprocal relationship to albumin synthesis and other carrier proteins. This is demonstrated in acute inflammatory conditions when CRP rises and albumin levels fall.

The liver is also the most important organ in controlling plasma concentrations of amino acids. During prolonged starvation, glucagon stimulates hepatic proteolysis whereas, during the post-prandial absorptive state, amino acid uptake is increased. The liver has a critical role in clearing portal venous ammonia generated within the gut lumen.

Lipids

During carbohydrate intake, free fatty acids (FFAs) formed within the liver are exported as components of very-low-density lipoproteins (VLDLs) and taken up by muscle and adipose tissue, with extraction of FFAs via the degradation of VLDLs. This leaves intermediate-density lipoproteins (IDLs) and, subsequently, low-density lipoproteins (LDLs). Hepatocytes bear specific LDL receptors and remove LDL from the circulation so that the associated cholesterol may be utilized

for bile salt metabolism or excreted into bile (there are also peripheral LDL receptors, present in extra-hepatic tissues, that extract cholesterol). High-density lipoproteins (HDLs) transport cholesterol from peripheral tissues (including the blood vessel lumen) to the liver, where it can be used in bile synthesis.

Vitamin D

Whether it is made in the skin or ingested, vitamin D₃ (cholecalciferol) is hydroxylated by hepatocytes to 25-hydroxycholecalciferol (25(OH)D₃, or calcidiol) and stored until it is needed. 25-Hydroxycholecalciferol is further hydroxylated in the kidneys into the biologically active hormone 1,25-dihydroxycholecalciferol (1,25(OH)₂D₃, or calcitriol) and 24R,25(OH)₂D₃.

Other functions

Production of insulin-like growth factor 1

The liver produces insulin-like growth factor 1, which plays an important role in childhood growth and has anabolic effects in adults.

Table 207.2 The components of the hepatic lobule

Component	Main functions	Additional points
Sinusoids	Specialized capillaries Allow low-molecular-weight proteins to permeate into the space of Disse (the space between sinusoids and hepatocytes) Postulated to be a major site of portal venous resistance	Lack basement membrane Lined with endothelial lining cells The sinusoidal membranes of hepatocytes surrounding the sinusoids contain microvilli that increase the surface area sixfold
Bile canaliculi	Collect bile secreted by the hepatocytes and pass it into the bile ductile	The volume of bile passing into the duodenum is small and has a low flow rate Secretion is controlled by gall bladder tone and sphincter of Oddi tone
Hepatocytes	Protein synthesis and storage Carbohydrate synthesis and metabolism Synthesis of cholesterol, bile salts, and phospholipids Detoxification, modification, and excretion of exogenous and endogenous substances Synthesis and secretion of bile Vitamin D metabolism	Make up 70%–80% of liver parenchyma Possess specialized cell membranes: <ul style="list-style-type: none"> • sinusoidal membrane (70% of surface area); for exchange of material between the space of Disse and the intracellular compartments (via endo- and exocytosis) • canalicular membrane (15%); for exchange with the smallest of biliary canaliculi or hemicanals • lateral membrane (15%); connected to the canalicular membrane by tight junctions and involved in intercellular transport between hepatocytes
Endothelial lining cells	Control entry and exit of molecules from the sinusoidal flow into the space of Disse Express a range of surface adhesion molecules that enhance leucocyte adherence, activation, and migration towards sites of inflammation	Possess numerous specialized endocytotic mechanisms, some of which are linked to known receptors
Kupffer cells	Specialized macrophages; part of the mononuclear phagocyte system	Found in a periportal distribution, adherent to the sinusoidal surface
Hepatic stellate cells	Control sinusoidal perfusion Contain most of the body's vitamin A stores	Located within the space of Disse Morphologically very similar to fibroblasts but contain fat droplets Central to the process of hepatic fibrogenesis; mediators released by parenchymal and Kupffer cells cause hepatic stellate cells to transform into myofibroblasts
Pit cells	Act as natural killer cells	Located between endothelial cells

Erythrocyte production in the fetus

In the first-trimester fetus, the liver is the main site of erythrocyte production. By the thirty-second week of gestation, the bone marrow has almost completely taken over that task.

Nutrient storage

The liver is involved in the storage of vitamin A (which can be stored up to 4 years), vitamin B₁₂, iron, and copper.

Drug and toxin metabolism

The liver metabolizes virtually every drug or toxin introduced in the body. Many drugs are capable of inducing liver enzymes (e.g. cytochrome P450 enzymes) and so can decrease the effectiveness of other drugs by causing them to be more rapidly metabolized. The induction of microsomal enzymes (so called because they are found in microsomes) takes place over days because it requires transcription and translation of genetic material. The drugs that induce cytochrome P450 enzymes are as follows:

- phenobarbital
- phenytoin
- carbamazepine
- ethanol
- glucocorticoids
- rifampin
- griseofulvin
- quinine
- omeprazole

Similarly, many drugs are capable of inhibiting microsomal enzymes; this reduces the metabolism of many drugs, hence increasing their concentrations and the risks of side effects. Unlike induction, inhibition occurs immediately following drug ingestion. Agents that cause inhibition include:

- amiodarone
- cimetidine

- erythromycin
- grapefruit juice
- isoniazid
- metronidazole
- sulfonamides
- omeprazole

An introduction to liver dysfunction

Most insults to the liver bring the threat of necrosis and liver failure—a series of functional changes which can lead to the following features of hepatic decompensation:

- jaundice
- encephalopathy
- portal hypertension
- bleeding
- ascites

Jaundice

The yellowish discolouration of jaundice (also known as icterus) is caused by increased levels of bilirubin in the blood, as the bilirubin subsequently accumulates in extravascular spaces, particularly those high in protein (the skin, the conjunctiva, etc.). In order for jaundice to be picked up clinically, the bilirubin in plasma must exceed ~40 µmol/l.

Jaundice is discussed further in Chapter 31. A brief summary of the biochemical anomalies observed in the classes of jaundice is provided in Table 207.3.

Encephalopathy

Hepatic encephalopathy is a potentially reversible situation occurring in severe liver impairment. Toxic substances normally cleared by the liver accumulate in the blood and, due to portal hypertension and subsequent bypassing of the hepatic filtration system, travel directly to the brain without being purified or modified. This is discussed further in Chapter 209.

Table 207.3 Biochemical anomalies in jaundice

	Pre-hepatic jaundice	Hepatic jaundice	Post-hepatic jaundice
Total bilirubin	Normal/increased	Increased	Increased
Conjugated bilirubin	Increased	Normal/increased	Increased
Unconjugated bilirubin	Increased	Normal/increased	Normal
Urobilinogen*	Increased	Normal/increased	Decreased/negative
Urine colour	Dark	Light	Dark
Stool colour	Dark	Normal	Pale
Alkaline phosphatase levels	Normal	Increased	Increased
Alanine transferase and aspartate transferase levels	Normal	Increased	Increased
Conjugated bilirubin in urine	Not present	Present	Present

*In pre-hepatic jaundice, no bilirubin will be present in urine but urobilinogen may be increased more than twofold. However, in neonates who have yet to develop gut flora, this trend will be absent.

Portal hypertension

The portal vein enters the liver at the porta hepatitis and sends a branch to each lobe. When portal flow is obstructed (from outwith or within the liver), a collateral circulation develops to carry blood into the systemic veins. This causes two main problems:

- the liver's metabolic function is bypassed
- increasing pressure in collaterals (known as varices) causes bleeding

Varices are commonly oesophageal, derived from the left gastric vein (usually from deep intrinsic layer of oesophagus). Other sites include the stomach, the colon, and the rectum.

A hyperdynamic circulation accompanies portal hypertension and may, in part, develop to maintain portal flow (collaterals will lower portal pressure). Causes of portal hypertension may be:

- presinusoidal (e.g. from splenic or portal vein thrombosis, schistosomiasis, or extrinsic compression)
- intra-hepatic (sinusoidal; e.g. from cirrhosis, acute hepatitis, or congenital hepatic fibrosis)
- post sinusoidal (e.g. from hepatic venous obstruction or constrictive pericarditis)

The clinical consequences of portal hypertension are:

- gastrointestinal haemorrhage; this can often be the first indication of varices; in addition, there may be mucosal congestion and bleeding from the stomach, the small bowel, or the colon; this is termed port-systemic enteropathy
- development of caput medusae
- an audible venous hum
- splenomegaly
- secondary hypersplenism (causing peripheral blood cytopenias)
- ascites

The diagnosis of portal hypertension can be made through imaging. Doppler-duplex ultrasound demonstrates portal flow, portal vein cavernous transformation, and portal vein or splenic vein thrombosis. The finding of splenomegaly and a collateral circulation may be seen. The disadvantages of this technique include a lack of data reproducibility, and inter-observer variability.

Spiral CT and CT angiography may allow more accurate demonstration of liver vasculature and collateral circulations. Dilatation of the inferior vena cava is also suggestive of portal hypertension and may be seen. Magnetic resonance angiography has the additional advantage of providing quantitative data regarding portal vein and azygous vein flow. Direct portal pressure measurements (assessing the hepatic venous pressure gradient) are not routinely performed due to the invasive nature and risk of complications.

Treatment is directed at the cause of portal hypertension. Gastroesophageal variceal haemorrhage is the most dangerous complication of portal hypertension. Most of the treatment focuses on the prevention and treatment of variceal haemorrhage. This is discussed in Chapters 22 and 210.

Bleeding

Bleeding is consequent upon a number of problems:

- prolonged prothrombin time (consequent upon depletion of coagulation factors) due to impaired synthetic hepatic function
- thrombocytopenia: splenomegaly and hypersplenism; alcohol as an etiological factor is directly marrow toxic and will further affect platelet count; liver dysfunction also impairs the release of thrombopoietin
- portal hypertension leading to the development of variceal shunt vessels (very friable; bleeding can be profuse)
- gastritis and peptic ulceration associated with alcohol-induced liver disease

Ascites

Ascites is caused by the accumulation of fluid in the peritoneal cavity. In general, ascites may occur because of three main mechanisms:

- raised portal pressure
- reduced oncotic pressure
- direct peritoneal irritation

It is not unusual for more than one mechanism to be in play at any one time.

In liver cirrhosis, ascites can occur in up to 50% of patients during the 10 years following the diagnosis (Cardenas and Gines, 2005). The median 2-year survival is reduced from 90% (compensated cirrhosis) to 50% in those who develop ascites. Ascites usually develops gradually and continuously, with onset over weeks to months, and is relatively painless. When ascites becomes massive, there may be vague discomfort caused by stretching of the abdominal wall and parietal peritoneum. If ascites is painful, one should always consider the presence of infected peritoneal fluid or the presence of a hepatoma. In gross ascites, there may be respiratory embarrassment or the development of a leak of fluid through diaphragmatic lymphatics causing pleural effusions.

The mechanisms thought to be in play in cirrhotic ascites are as follows. First, there is peripheral vasodilatation due to an impaired metabolism of vasodilator substances; increased endothelial nitric oxide and prostacyclin may play a role. As a consequence, renal blood flow is reduced, stimulating the renin-angiotensin-aldosterone system. Salt and water retention occurs.

Portal venous (sinusoidal) hypertension then encourages fluid transudation into the peritoneal cavity. Ascites is rare in those with a hepatic-wedge pressure gradient of <12 mm Hg. Interestingly, those individuals with presinusoidal portal hypertension without cirrhosis rarely develop ascites.

The salt retention is followed by worsening water retention through the action of vasopressin. This will cause hyponatraemia (but increased total body sodium) and reduced renal blood flow predisposing to hepatorenal failure. Reduced oncotic pressure (due to hypoalbuminaemia) also contributes to the process.

The examination of ascitic fluid content, and other causes of ascites, are explained in Chapter 208. The management of ascites is discussed in Chapter 210.

208 Investigation in liver disease

Satish Keshav and Palak Trivedi

Blood tests

Liver chemistry

Liver chemistry tests are frequently abbreviated as LFTs, for liver function tests. In reality, they comprise mainly markers of liver injury rather than true measures of liver function, although a number of other blood tests, such as the prothrombin time and albumin level, offer a reliable measure of liver function. Routine liver chemistry includes tests to determine the levels of serum bilirubin, transaminases, alkaline phosphatase, gamma-glutamyl transpeptidase, and lactate dehydrogenase.

Bilirubin

Bilirubin (normal reference range: 3–17 $\mu\text{mol/l}$) is a breakdown product of haem, which is metabolized in the liver. Bilirubin is taken up by hepatocytes, conjugated, and secreted into bile before being released into the intestine. Bilirubin metabolism is discussed further in Chapters 31 and 207. Jaundice does not necessarily reflect hepatic dysfunction, as bilirubin levels reflect production, hepatic uptake, conjugation, and secretion. Conjugated bilirubin is highest in cholestatic disease whereas unconjugated bilirubin may reflect a pre-hepatic cause such as haemolysis (total bilirubin levels rarely >50–90 $\mu\text{mol/l}$) or genetic causes such as Gilbert's syndrome (a relatively benign condition where there is deficient glucuronyl transferase activity and hence reduced conjugation of bilirubin; individuals with Gilbert's syndrome become jaundiced at times of physical stress or fasting. In addition, certain drugs metabolized by the liver are more likely to cause side effects, given the reduced activity of the glucuronyl transferase enzyme). Rising levels of (conjugated) bilirubin reflect approaching end-stage disease in many chronic liver conditions, and in secondary malignancy often signal a preterminal event.

Transaminases

Transaminase levels do not reflect the functional capacity of the liver as such, but are more so tests of liver injury. They are produced following cytosol burgeoning, which leads to plasma membrane leak and hepatocyte lysis. Marked elevations (>1000 IU/l) are unusual in alcoholic liver disease, wherein levels rarely exceed 350 IU/l. Massive elevations are usually seen in paracetamol overdose, untreated autoimmune hepatitis, and acute viral hepatitis. Persistent elevation should arouse suspicion of significant chronic liver disease (e.g. chronic viral hepatitis, autoimmune disease, or haemochromatosis). Transferases include:

- aspartate aminotransferase (AST; normal reference range: 5–45 IU/l); this is also known as serum glutamic oxaloacetic transaminase and occurs in two isoforms:
 - glutamic oxaloacetic transaminase 1, which is located in the cytoplasm and is found mainly in cardiac muscle and erythrocytes
 - glutamic oxaloacetic transaminase 2, which is located in the mitochondria and is expressed mainly in the liver
- alanine aminotransferase (ALT; normal reference range: 5–45 IU/l); this is also known as serum glutamic pyruvate transaminase and is a more liver specific transaminase enzyme

AST is also found in skeletal muscle, the pancreas, and the kidneys. AST is usually more markedly raised than ALT (alanine transaminases) in alcoholic liver disease, whereas the ratio is reversed in non-alcoholic fatty liver disease unless advanced fibrosis is present.

Alkaline phosphatase

Alkaline phosphatase (the normal reference range is centre specific) is located in the biliary membrane of hepatocytes lining the bile ducts.

This enzyme is associated with cholestasis (where it can reach three or more times the upper limit of normal). Milder elevations can also be seen in hepatocellular injury. Other sources of this enzyme include bone, the small bowel, placental tissue, and the kidneys. In cases where elevated alkaline phosphatase level is observed in isolation, consider an extra-hepatic cause.

Gamma-glutamyl transferase

Gamma-glutamyl transferase (normal reference range: 5–40 IU/l) is a membrane-bound enzyme found in all cells but with particularly high concentrations in the liver, the bile ducts, and the kidney. It is elevated in even minor, subclinical levels of hepatic dysfunction. It is particularly useful when attempting to attribute the origin of a raised alkaline phosphatase level. Elevated levels may also be associated with pancreatitis, obesity, hyperlipidaemia, anorexia nervosa, hyperthyroidism, diabetes mellitus, and certain enzyme inducers such as anticonvulsants.

Lactate dehydrogenase

Lactate dehydrogenase (normal reference range: 105–330 IU/l) is another enzyme present in all cells, with a variety of isoenzymes. The test for lactate dehydrogenase becomes particularly useful when the enzyme level is raised out of proportion to other LFTs, whereby its presence points toward ischaemic liver injury (see Chapter 217). It is also raised in the presence of secondary malignancy.

Tests of liver synthetic function

Serum albumin

Serum albumin (normal reference range: 39–50 g/l) is the most abundant plasma protein and is produced by the liver. Its concentration is dependent upon nutrition, hepatic synthesis, and losses. In chronic liver disease, low albumin is a major prognostic indicator representing diminishing hepatocyte function. Albumin has a half-life of 17–26 days. Reduced levels of albumin may also occur with malnutrition and increased losses (e.g. nephrotic syndrome).

Prothrombin time and internationalized normalized ratio

Vitamin K-dependent clotting factors are synthesized by the liver. The prothrombin time (PT; normal reference range: 11–14 seconds) assesses the activity of these clotting factors and is a surrogate marker for the extrinsic clotting pathway. The internationalized normalized ratio (INR; 0.9–1.2) is the ratio of a patient's plasma PT divided by that of a laboratory control. By logic, one can deduce that, in significant liver disease, vitamin K-dependent clotting factors will fail to be synthesized; hence, the PT (the time it takes for blood to clot) will increase. A raised INR or PT may also reflect poor intake of vitamin K or malabsorption; parenteral administration of vitamin K may correct the abnormality in these circumstances, provided the intrinsic hepatocellular function is intact. (NB: in cases of large-volume transfusion, one should recall that stored blood contains anticoagulant but no clotting factors, which may also need replacing.)

Alpha-fetoprotein

Alpha-fetoprotein is normally produced by the yolk sac of the embryo during pregnancy, and by the liver. Pathologically raised levels are observed in two-thirds of patients with hepatocellular carcinoma, but levels may be mildly elevated in acute and chronic liver disease without malignancy. For this reason, alpha-fetoprotein is no longer recommended as part of hepatocellular carcinoma surveillance

Table 208.1 Viral hepatitis: Serology testing		
Test positive	Interpretation	Additional points
HAV		
Anti-HAV IgM	Recently infected with HAV	Confirms acute HAV illness
Anti-HAV IgG	Previous infection with HAV or immunity to HAV through vaccination	
HBV		
Anti-HBc IgM	Recent infection of HBV	Confirms acute HBV illness
HBsAg	Present or chronic HBV infection	
HBeAg (e antigen)	Active viral replication present	Highly infectious
HBV DNA*	Presence of complete virus†	Highly infectious
Anti-HBe	No active viral replication	No longer infectious
Anti-HBs	Previous infection or vaccination	
HCV		
Anti-HCV	Exposure to HCV	
HCV RNA	Confirms the presence of the virus	Useful in monitoring response to treatment
HCV genotype		Helps identify serotype which is important in treatment
Other viral hepatitis		
EBV IgM	Recent EBV infection	Cross reactivity with CMV IgM
Glandular fever test	Recent EBV infection	
EBV IgG	Previous EBV infection	
CMV IgM	Recent CMV infection	Cross reactivity with EBV IgM
CMV IgG	Previous CMV exposure	

Abbreviations: anti-HBe, antibody to the hepatitis B e antigen; anti-HBs, antibody to the hepatitis B surface antigen; EBV, Epstein–Barr virus; HAV, hepatitis A virus; HBc, hepatitis B core protein; HBsAg, hepatitis B surface antigen; HBeAg, hepatitis B e antigen; HBV, hepatitis B virus; HCV, hepatitis C virus.

Note: Acute hepatitis D and E virus infection can be diagnosed with positive IgM serology to the respective viruses.

* This is a quantitative marker.

† This may be used as a surrogate marker for those with active disease in presence of ‘precore mutant disease’ and who do not produce HBeAg but are still highly infectious.

programmes, although it may be of prognostic significance in monitoring treatment response in those with confirmed liver cancer.

Viral serology

Viral hepatitis has been covered in more detail in Chapter 212. Testing for viral serology is important when investigating the cause of deranged LFTs. A summary of the common tests for viral hepatitis is provided in Table 208.1.

Autoantibodies and immunoglobulins

Autoantibodies and autoimmune liver disease have been covered in more detail in Chapter 213. Despite obtaining positive autoantibody serology in the workup of someone with chronic liver disease, confirmation often requires liver biopsy. Moreover, up to 19% of patients with autoimmune hepatitis, and 5% of patients with primary biliary cholangitis, may lack identifiable autoantibodies (i.e. they are ‘seronegative’). A summary of the common tests in autoimmune liver disease is given in Table 208.2.

Other laboratory tests

Other laboratory tests include iron studies for haemochromatosis; copper studies for Wilson’s disease; alpha-1-antitrypsin levels for alpha-1-antitrypsin deficiency (see Chapter 214); thyroid function tests; and lipid and glucose tests, for hepatic steatosis (see Chapter 216).

Ascitic fluid analysis

The mechanisms in ascites development are explained in Chapter 207. Examination of ascitic fluid is essential, particularly when ascites is first diagnosed or when the patient’s clinical picture changes. Consider non-hepatic causes if LFTs and coagulation studies are normal. Remember, serum albumin levels may be low in protein-losing nephropathies and enteropathies. Ascitic fluid should always be sent for red and white blood cell counts, blood culture, albumin, total protein, glucose, amylase, triglyceride, and cytology. The peritoneal fluid characteristics for common causes of ascites are outlined in Tables 208.3 and 208.4.

Table 208.2 Autoimmune liver disease serology

Test	Association
Antinuclear antibody	Autoimmune hepatitis type I (classical variety; good response to immunosuppression)
Anti-smooth muscle antibody	Autoimmune hepatitis type I
Raised IgG	Autoimmune hepatitis (any type but more so with type I)
Anti-liver kidney microsomal antibody	Autoimmune hepatitis type II (females/teenagers; frequently steroid dependent)
Anti-soluble liver antigen	Autoimmune hepatitis type III (behaves like type I)
Anti-mitochondrial antibodies	Primary biliary cholangitis (95% sensitivity)
Raised IgM (subclass 2)	Primary biliary cholangitis
Raised IgA	Alcoholic liver disease
Anti-endomysial antibody (an IgA antibody)	Coeliac disease: can predispose to liver steatosis (5% of the coeliac population will be total IgA deficient)
Antineutrophil cytoplasmic antibody (p type)	Non-specific; found in up to 92% of patients with autoimmune hepatitis, and 94% of individuals with primary sclerosing cholangitis; may also be detectable in ~>70% of patients with ulcerative colitis alone

Imaging

Hepatobiliary ultrasound

Hepatobiliary ultrasound is usually the first-line approach in terms of imaging when deranged liver biochemistry, jaundice, hepatomegaly, or ascites is present. It is used for assessing gross hepatic architecture, ductal dilatation, stone disease, and tumours. Doppler studies of venous flow can be performed in both hepatic venous and portal venous systems to aid in the diagnosis of certain conditions.

Table 208.3 Causes of ascites

High SAAG	Low SAAG	Other rarer causes
Liver cirrhosis*	Malignancy with peritoneal spread [†]	Vasculitis
Cardiac failure	Tuberculosis	Myxoedema
Hepatic venous occlusion/ Budd–Chiari	Pancreatitis	Peritoneal mesothelioma
Constrictive pericarditis	Serositis	
Portal vein thrombosis	Protein-losing states	
Fatty liver of pregnancy		
Internal malignancy with liver metastasis		

Abbreviations: SAAG, serum–ascites albumin gradient.

Note: A high SAAG (≥ 11 g/l) indicates that the ascites is due to portal hypertension; a low SAAG (< 11 g/l) indicates that the ascites is not due to portal hypertension

* Occurs in 80% of cases of ascites.

[†] Common malignancies which spread to the peritoneum are ovarian cancer, bladder cancer, colon cancer, stomach cancer, breast cancer, pancreatic cancer, lung cancer, and lymphoma (with nodal obstruction).

Ultrasound is also useful in differentiating solid from fluid-filled lesions; this is not always possible on CT scans. Ultrasound is widely accessible and relatively inexpensive. Individuals undergoing hepatobiliary ultrasound should abstain from oral intake for 4 hours prior to the test if the biliary tree and gall bladder are to be looked at in the study. The disadvantages are an inability to depict smaller lesions, and the possibility of inaccuracy when dealing with individuals with a larger body habitus.

CT

CT provides excellent detail of anatomy and has the advantage of picking up smaller lesions that are often missed on ultrasound. It has the advantage in cases where doubt regarding diagnosis persists on ultrasound and in cases where ultrasound is not technically feasible (e.g. when there is a large quantity of intra-abdominal fat). CT is also better at looking at other retroperitoneal structures. The main disadvantage of CT is that it is not as portable as ultrasound and is relatively more expensive. Frequent CT scans also entail the risk of radiation exposure.

MRI

MRI may be needed if it is the only modality that can pick up the lesion in question. For example, MRI is usually indicated for the evaluation of isolated hepatic lesions to distinguish adenomas from focal nodular hyperplasia or tumours. Magnetic resonance cholangiography is indicated for detailed evaluation of the hepatobiliary tree before endoscopic biliary intervention (i.e. endoscopic retrograde

cholangiopancreatography), as it can detect smaller ductal stones that are missed on ultrasound.

Endoscopic ultrasound

Endoscopic ultrasound is a procedure in which upper gastrointestinal endoscopy is combined with internal ultrasound in order to obtain images of the internal organs. It is particularly useful in the identification of small (< 1 cm) lesions in the distal hepatobiliary tree and the pancreas, as well as the identification of gallstones which have migrated into the distal common bile duct.

Liver biopsy

Liver biopsy has been practised for over a century and is still used in establishing the underlying aetiology of many liver diseases. The broad indications for proceeding with a liver biopsy are:

- liver disease in general; to determine the severity and extent of the disease
- persistently elevated LFTs without an underlying cause being identified through laboratory or radiological testing
- serological diagnosis (e.g. of autoimmune liver disease), for confirmation of the diagnosis, and prognostication
- indeterminate hepatic lesions (see Chapter 218) on radiological scanning

Contraindications to percutaneous liver biopsy are:

- elevated PT (> 1.5 seconds)
- thrombocytopenia (platelet count $< 50 \times 10^9$)
- large body habitus, or ascites (although a transjugular liver biopsy can be performed in experienced hands)
- echinococcal infection (due to the risk of severe anaphylaxis)
- suspected haemangioma
- hepatic peliosis (i.e. randomly distributed multiple blood-filled cavities throughout the liver; associated with AIDS, the use of synthetic oestrogens, and the use of anabolic steroids)

Complications of a liver biopsy are rare, but can be serious when they occur; 95% of complications occur in the first 24 hours. Possible complications are as follows:

- pain:
 - normally localized in the right upper quadrant or may radiate to the shoulder
 - usually not more than a dull ache
 - relatively short-lived
 - responds to simple analgesia
 - more severe and longer-lasting pain may indicate a biliary leak or intra-peritoneal haemorrhage
- haematoma:
 - occurs either as a parenchymal haematoma or as a subcapsular haematoma

Table 208.4 Characteristics of ascitic fluid

Aetiology	Colour	SAAG (g/l)	RBCs (10^6 cells/l)	WBCs (10^6 cells/l)	Cytology	Other comments
Cirrhosis	Straw	≥ 11	Few	≤ 250		
Infected	Straw Turbid	≥ 11	Few	≥ 250 PMN ≥ 400 total		Culture is essential: any growth is abnormal
Tuberculosis	Turbid Haemorrhagic	< 11	Abundant	≥ 1000 (lymphocytes)	Ziehl/Nielsen stain	Send for AAFB and culture
Neoplasia	Haemorrhagic mucinous	< 11 (unless directly due to liver mets)	Variable	Variable	Large volume (50 ml) needed	Malignant cells diagnostic
Cardiac failure	Straw	≥ 11	Few/nil	< 250		Echo should be performed
Pancreatitis	Turbid Haemorrhagic	< 11	Variable	Variable		Amylase may be increased
Chylous	Milky	< 11	Nil	Nil		Fat globules Triglyceride > 5 mmol/l is abnormal
Biliary leak	Yellow	< 11	Few	Variable		Ratio of ascitic fluid to serum bilirubin is > 1.0

Abbreviations: AAFB, acid- and alcohol-fast bacteria; Echo, echocardiography; PMN, polymorphonuclear; RBC, red blood cell; SAAG, serum–ascites albumin gradient; WBC, white blood cell.

- the majority are asymptomatic
- the few that are painful will respond to simple analgesia (avoid aspirin and NSAIDs)
- haemobilia:
 - although rare, this is one of the most serious complications
 - may present as rapid exsanguination through a gastrointestinal bleed or give rise to a chronic anaemia
 - biliary colic and jaundice are common in cases of gastrointestinal blood loss
 - the interval between onset and presentation of symptoms may be as long as 5 days
 - although conservative treatment usually suffices, consider biliary angiography in severe cases
- intra-peritoneal haemorrhage:
 - the most serious complication

- occurs in the first few hours post procedure (late-onset haemorrhage >24 hours post procedure is associated with a poorer outcome)
- suspect if severe abdominal pain and haemodynamic instability are present
- angiography with embolization is the treatment of choice
- rarer complications include pneumothorax, bacteraemia, surgical emphysema, and biopsy of other organ tissue

209 Acute liver failure

Satish Keshav and Palak Trivedi

Definition of the disease

Acute liver failure (ALF) is the term given to a potentially reversible condition characterized by rapid deterioration in hepatocyte function, coagulopathy, and encephalopathy in the absence of preexisting liver disease.

Aetiology of the disease

Ingestion of drugs or toxins, and viral hepatitis, are the most common causes of ALF (Table 209.1), with a large number of other causes accounting for the remaining cases.

Typical symptoms of the disease and less common symptoms

The key features are a rapid deterioration in liver function with nausea, anorexia, malaise, fatigue, altered consciousness, jaundice, and disordered clotting parameters progressing to hepatic encephalopathy (Table 209.2), coma, and death, if uncorrected. Most patients with ALF demonstrate 'warm shock' with profound vasodilatation, intravascular depletion, and low mean arterial pressures. Severe alterations in nearly all clotting parameters are seen in ALF in part due to failure of synthesis as well as factor consumption. The classic interpretation has been that severe bleeding is a likely outcome. Overall, however, there are abnormalities in both the coagulation and fibrinolytic pathways, and recent data suggest that the defects are balanced.

Patients with ALF have an overwhelming susceptibility to the development of infection. Proposed mechanisms include severe complement deficiency and impaired polymorphonuclear cell and Kupffer cell function. The quoted incidence of bacteraemia varies between 22% and 80%, and fungaemia 32%.

The varying etiologies of ALF may harbour phenotypic differences although, in practice, diagnostic tests including liver biopsy may be requested early in order not to miss dual pathology, and also to ensure that a diagnosis is reached quickly.

Table 209.1 Causes of acute liver failure

Type	Cause
Common	Paracetamol/acetaminophen overdose Viral hepatitis: HBV, HEV, HSV, CMV, EBV Drugs: e.g. isoniazid, halothane, tetracycline, thioflitazones, amphetamines, cocaine, herbal remedies
Uncommon	Autoimmune hepatitis Cryptogenic (no cause found) Alcoholic hepatitis
Rare	HELLP syndrome and fatty liver of pregnancy Budd–Chiari syndrome Acute hypotension or vascular catastrophe: e.g. catastrophic antiphospholipid syndrome <i>Amanita phalloides</i> mushroom poisoning Wilson's disease

Abbreviations: CMV, cytomegalovirus; EBV, Epstein–Barr virus; HBV, hepatitis B virus; HEV, hepatitis E virus; HSV, herpes simplex virus.

Table 209.2 West Haven grading of hepatic encephalopathy

Grade	Features
I	Altered mood or behaviour, shortened attention span, dyspraxia, altered sleep
II	Drowsy, lethargy, or apathy disorientation for time or place
III	Somnolence responsive to verbal stimuli, confusion, asterixis
IV	Coma unresponsive to verbal or noxious stimuli, abnormal plantar reflex
V	Coma unresponsive to painful stimuli, abnormal plantar reflex

This article was published in *Gastroenterology*, Volume 72, issue 4 (pt 1), Conn HO, Leevy CM, Vlahcevic ZR, et al., Comparison of lactulose and neomycin in the treatment of chronic portal-systemic encephalopathy. A double blind controlled trial, pp. 573–583, Copyright Elsevier 1977.

Symptoms of ALF due to acetaminophen/paracetamol overdose

Symptoms of acetaminophen/paracetamol overdose present 1–3 days after the overdose, which may be deliberate or accidental. Clinical features include anorexia, malaise, abdominal discomfort, and altered consciousness. Jaundice occurs early. Therapeutic doses of paracetamol are converted to non-toxic metabolites by conjugation with sulphate and glucuronide. Approximately 5% of paracetamol is oxidized by cytochrome p450 (Cyp450) to a highly reactive intermediary, N-acetyl-p-benzoquinone imine (NAPQI). NAPQI is then detoxified by conjugation with glutathione. In cases of overdose, the sulphate and glucuronide pathways are saturated, resulting in the generation of excessive levels of NAPQI that cause hepatocellular necrosis.

Symptoms of ALF due to acute viral hepatitis

Acute viral hepatitis typically presents acutely or subacutely, with typical viraemic prodromal symptoms, followed by jaundice that progresses rather than resolves. The prognosis after transplantation appears to be better if the presentation is acute, particularly for hepatitis B.

Symptoms of ALF due to drugs or herbal remedies

There may be no clues to the diagnosis of ALF due to drugs or herbal remedies, apart from a history of exposure to potential hepatotoxins.

Symptoms of ALF due to autoimmune hepatitis

Autoimmune hepatitis (AIH) affects females more frequently than males and tends to occur in middle age or later. Classical immunoserological and histological features of AIH may be absent or altered in fulminant disease and, in a recent retrospective review of the US Acute Liver Failure Registry, >50% of patients with acute liver failure of previously indeterminate origin were considered to have probable AIH. The commonest histological finding in fulminant AIH is central perivenulitis or centrilobular (Zone 3) necrosis. In such situations, the severity of necroinflammatory activity can be variable, ranging from mildly active hepatitis to massive hepatic necrosis. It is important not to mistake such changes for cirrhosis.

Symptoms of ALF due to alcoholic hepatitis

Alcoholic hepatitis typically occurs on a background of chronic excessive alcohol use followed by a brief period of abstinence (~4 weeks). The patient may be feverish and have signs of chronic liver disease,

although splenomegaly, ascites, and portal hypertension can occur acutely and do not necessarily indicate cirrhosis.

Symptoms of ALF due to pregnancy-associated liver failure

Acute fatty liver in pregnancy typically occurs in the third trimester and is more often associated with pre-eclampsia and twin pregnancy. HELLP (haemolysis, elevated liver enzymes, and low platelets) is a severe complication of pre-eclampsia (10%–15% of cases), with mortality approaching 25% (usually due to cerebral haemorrhage and disseminated intravascular coagulation). Elevations in liver enzymes can be dramatic, and there is a risk of hepatic rupture. True failure of hepatic synthetic function is rare.

Symptoms of ALF due to Wilson's disease

Wilson's disease can present with acute hepatitis and liver failure in young patients and, for unknown reasons, haemolysis is a typical feature. Although liver enzymes may be elevated, serum alkaline phosphatase level is usually normal or disproportionately closer to normal.

Symptoms of ALF due to Budd–Chiari syndrome

Budd–Chiari syndrome presents with ascites and jaundice, and typically occurs in the context of a myeloproliferative syndrome, other malignancy, or prothrombotic diathesis, all of which may be subclinical at the time of liver failure.

Demographics of the disease

ALF is uncommon, affecting ~2000 patients annually in the US; approximately 7% of all US liver transplants are performed for ALF. Paracetamol overdose accounts for over 70% of cases of acute hepatic failure in the UK. Where viral hepatitis is endemic, it accounts for more cases; for instance, in the Indian subcontinent, it accounts for 30% of cases.

Natural history, and complications of the disease

ALF can be divided into three categories according to the time from the onset of jaundice to the onset of hepatic encephalopathy: hyperacute (<7 days), acute (7–28 days), or subacute (>28 days). The outcome after hyperacute failure is often better than that for subacute failure.

Different aetiologies typically have different time frames. For example, paracetamol cases are virtually always hyperacute, while viral hepatitis, idiosyncratic drug reactions, or cases of indeterminate cause demonstrate slower onset and evolution (acute or subacute). The etiologic diagnosis per se appears to be the strongest driver of outcome. Untreated liver failure may progress to death, which may occur from cerebral oedema and coma, metabolic failure including hypoglycaemia, coagulopathy and haemorrhage, autonomic and haemodynamic instability, and/or infection.

Elevated liver enzymes alone give little information about hepatic function. The key tests demonstrating progressive liver failure are elevated bilirubin, prolonged prothrombin time (PT) or international normalized ratio (INR), and reduced serum albumin. The PT can worsen precipitously over a few hours and so it is essential to take repeated measurements. The albumin level falls over a period of days. Elevated bilirubin may persist or even continue to rise even when the liver is recovering. The development of ascites, particularly in cases of subacute failure, indicates worsening disease.

Oliguria and renal dysfunction occur in approximately 50% of cases. Frequently, these are poor prognostic signs and can be associated with worsening liver failure or even hepatorenal syndrome. In other cases, however, they may be independent of the precipitating cause, for instance high doses of paracetamol causing renal damage; alternatively, they may result simply from dehydration, which can be readily corrected.

Potential outcomes from ALF include full recovery; progressive deterioration and death; death from complications such as renal failure and sepsis; and recovery after liver transplantation. Patients with

ALF due to autoimmune liver disease or, in some cases, viral hepatitis, may recover but then progress to chronic liver disease.

Differential diagnosis

The full constellation of signs and symptoms of ALF are rarely seen together in any other context. ALF is distinct from decompensation in a patient with chronic liver disease and cirrhosis triggered by intestinal haemorrhage from varices, infection, alcoholic binge drinking, hepatotoxic drugs, hepatocellular carcinoma, and so on.

The differential diagnosis for acute jaundice includes biliary obstruction, haemolysis, and infection such as Weil's disease. The differential diagnosis for an elevated PT includes warfarin poisoning, disseminated intravascular coagulation, and sepsis. The differential diagnosis for coma and encephalopathy includes extremely rare inherited defects of the urea cycle, hyperammonemia, uraemia, and overdose with psychoactive drugs.

Approach to diagnosing the disease

The diagnosis of ALF must be considered in anyone presenting with a quick onset of hepatic illness with prolonged PT/INR and encephalopathy, provided they have had an illness of short duration and do not have cirrhosis. Patients often appear hypotensive and vasodilated with low systemic vascular resistance.

The following laboratory studies should be checked where there is suspicion of ALF:

- coagulation, including PT
- glucose
- electrolytes
- creatinine
- bilirubin
- albumin
- liver enzymes
- amylase
- full blood count
- group and save
- serum lactate

In addition, blood cultures and a chest X-ray should be obtained, as sepsis is a frequent complication.

Causes of acute liver injury that can be readily tested for should be tested. These include viral hepatitis, paracetamol, serum copper and caeruloplasmin, IgG levels, and autoantibodies (although these are often negative in acute fulminant presentations of AIH). An urgent liver ultrasound with Doppler measurement of hepatic venous and portal venous flow should be obtained. If there is ascites, an ascitic tap should be performed to quantify the number of leukocytes, and measure albumin and protein.

'Gold-standard' diagnostic test

The constellation of clinical signs of liver decompensation, with elevated PT, elevated bilirubin, and low serum albumin make the diagnosis of ALF when they occur in the appropriate timescale. However, no single feature distinguishes between acute and acute-on-chronic liver failure.

Other relevant investigations

Transjugular liver biopsy can be performed safely even in the presence of ascites and coagulopathy. Findings may be non-specific, although they may provide clues to the underlying aetiology. In particular, AIH, acute alcoholic hepatitis, and drug-induced liver damage may require biopsy to support the diagnosis. The presence of microvesicular steatosis suggests certain medications (e.g. sodium valproate, salicylates) and is also found in acute fatty liver of pregnancy. Central perivenulitis is the commonest feature in acute, fulminant AIH, which may progress to Zone 3 necrosis, making distinction from drug-induced disease difficult. In such situations, the severity of necroinflammatory activity can be variable, ranging from mildly active hepatitis to massive hepatic necrosis. It is important not to mistake

such changes for cirrhosis. Less specific findings include ballooning degeneration, spotty hepatocyte necrosis, apoptotic bodies, and syncytial multinucleated hepatocyte giant cells. Giant cell hepatitis is seen more frequently in children but also in atypical viral infections and idiosyncratic drug injury.

Prognosis and how to estimate it

If the patient survives an episode of ALF and its immediate complications, they usually have an excellent long-term prognosis. Overall survival is approximately 70%. Where recovery with supportive care seems unlikely, orthotopic liver transplantation offers a good chance of recovery, albeit with the long-term implications of living with an allograft and lifelong immunosuppression. Transplantation is performed in ~25%–30% of patients.

Paracetamol-related ALF carries a better prognosis than drug-induced ALF, cryptogenic ALF, and ALF of most other etiologies, largely through the advent of acetylcysteine (NAC) therapy.

Treatment and its effectiveness

ALF is a medical emergency, of which good coma care is the hallmark of management. By establishing timely diagnosis and determining the aetiology and severity, appropriate triage to an intensive care unit or transfer to a transplant centre can be rapidly accomplished. Determining eligibility and listing for transplantation must be an early consideration.

Should the individual progress beyond Grade II encephalopathy, the airway should be protected. Cerebral oedema is a frequent cause of mortality, and occurs secondary to osmotic changes and loss of capillary integrity within the brain. Sedation should be avoided, as this can worsen encephalopathy. Invasive monitoring of intracranial pressure is to be considered in the intensive care setting (preferably in a dedicated liver unit) in cases of higher-grade encephalopathy. Phenytoin can reduce subclinical seizure activity, and mannitol can be given in cases of raised intracranial pressure, provided there is adequate renal output.

Cardiovascular support with fluid resuscitation is essential, and consideration given to central venous pressure monitoring. This will assist in accurate fluid balance and avoid exacerbating encephalopathy. Low systemic vascular resistance and renal artery vasoconstriction is potentially reversible with improvement in liver function.

Patients should have the serum glucose monitored and, if hypoglycaemic, treated as appropriate. In addition, blood tests should be checked regularly, particularly electrolytes, renal function coagulation, full blood count, and albumin. This is essential in the first 48–72 hours. Fresh frozen plasma, cryoprecipitate, or platelets are reserved for active bleeding or if an invasive procedure is planned. Moreover, withholding fresh frozen plasma allows for the use of INR as a continuously available surrogate and reliable measure of hepatic synthetic function and outcome.

Patients with paracetamol poisoning may demonstrate acute kidney injury due to the direct toxic effects of acetaminophen, with oliguria requiring continuous venovenous haemofiltration. The initial aim should be volume resuscitation and, if the mean arterial pressure falls to <80 mm Hg, consideration should be given to inotropic support. Renal failure is also a well-recognized manifestation of fulminant hepatic failure secondary to acute Wilson's disease.

As up to 80% of ALF cases are complicated by sepsis, and meticulous care of lines, catheters, and procedures should be taken. It is essential to take all relevant material for culture prior to the institution of antibiotics. Patients will often be critically ill and, as a result,

Table 209.3 Guidelines for referral for liver transplantation

Guidelines for referral for liver transplantation		
Hyperacute	Acute	Subacute
Encephalopathy	Encephalopathy	Encephalopathy
Renal failure	Renal failure	Renal failure
PT > 30 sec	PT > 30 sec	PT > 20 sec
		Sodium <130 mmol/l
		Shrinking liver volume
Guidelines for referral to a liver unit following paracetamol overdose		
Day 1	Day 2	Day 3
Acidosis: arterial pH <7.3	Acidosis: arterial pH <7.3	Progressive rise in PT
Oliguria	Oliguria	Oliguria
Creatinine >200 µmol/l	Creatinine >200 µmol/l	Creatinine >300 µmol/l
PT > 50 sec	PT > 60 sec	PT > 75 sec
Hypoglycaemia	Encephalopathy	Encephalopathy

Abbreviations: PT, prothrombin time.

recognized signs of sepsis may not manifest. There should be a low threshold for administering IV antibiotics and antifungals, pending further sensitivities.

Osmotic laxatives such as lactulose reduce intestinal bacterial production of ammonia and psychoactive amines, and therefore reduce encephalopathy. Intestinal decontamination such as neomycin may also be used.

Rapid evaluation should be performed, with initiation of specific antidotes where feasible. NAC infusion is an effective antidote to the depletion of hepatic glutathione caused by paracetamol overdose. Historically, clinical practice was to institute therapy based on the serum paracetamol level (in the case of 'single-point' overdose); however, recent guidelines advocate NAC to be commenced immediately for suspected overdose (before serum levels become available) and only discontinued in cases where the time of overdose is certain and serum levels fall below the nomogram treatment line (<http://www.mhra.gov.uk/Safetyinformation/DrugSafetyUpdate/CON185624>). NAC is to be continued until the PT returns to normal. Paracetamol toxicity is dose dependent but its effects are enhanced by induction of Cyp450 by chronic use of alcohol or drugs such as antiepileptics. Patients receiving NAC within 24 hours of overdose have the best prognosis; however, benefit can be demonstrated even when treatment is provided after 36 hours ingestion. In addition, early consideration should be made to use NAC in non-paracetamol settings, as this may improve transplant-free survival.

In cases of pregnancy-induced ALF, the fetus should be delivered. In idiosyncratic reactions, withdrawal of the causative agent can potentially reverse hepatic injury. Early discussion with a transplant centre is vital. Indications for transfer are highlighted in Table 209.3. Wilson's disease is an indication for early transplantation, as these individuals deteriorate rapidly.

210 Chronic liver failure

Satish Keshav and Palak Trivedi

Definition of the disease

Chronic liver failure is the functional syndrome resulting from cirrhosis. Clinical features of chronic hepatic decompensation include encephalopathy, coagulopathy, and hepatocellular jaundice (also see Chapters 207 and 209). Cirrhosis is the final common pathway for a variety of chronic liver diseases and is characterized by fibrosis and the conversion of normal liver architecture into structurally abnormal nodules.

There often exists a poor correlation between biopsy findings and the clinical presentation. Some individuals with cirrhosis are asymptomatic and have a reasonably good life expectancy, while others have severe symptoms of chronic liver failure and limited life expectancy.

Aetiology of the disease

There are many causes of cirrhosis, the most prevalent being alcohol, viral hepatitis (usually hepatitis C), and, as is increasingly recognized, non-alcoholic fatty liver disease. A list of causes is given in Table 210.1.

Typical symptoms of the disease and less common symptoms

Patients with cirrhosis are often asymptomatic. In fact, up to 80%–90% of liver parenchyma must be destroyed before liver failure can be manifest clinically. Early, well-compensated disease may manifest as weight loss, fatigue, and anorexia. Osteoporotic fracture may result from defective vitamin D and calcium metabolism. In addition, the patient may show heightened sensitivity to a range of drugs normally metabolized by the liver.

Decompensated disease (see also Chapter 207) may manifest as

- jaundice
- pruritus
- ascites, with or without spontaneous bacterial peritonitis
- hepatic encephalopathy (see Chapter 209)
- portal hypertension
- variceal bleeding
- hepatopulmonary syndrome (15% of cirrhotics) due to the overproduction of nitric oxide and overexpression of the endothelin

B receptor, resulting in pulmonary vessel vasodilatation, shunting, and hypoxaemia

- portopulmonary hypertension; this is less common and is probably caused by excess of pulmonary artery vasoconstrictors and profibrogenic factors

Physical signs of decompensated chronic liver disease include:

- signs in the hands, such as:
 - Dupuytren's contracture
 - clubbing
 - palmar erythema
 - asterixis
 - half-and-half nails (chronic disease of any cause)
 - leukonychia
- conjunctival icterus
- gynaecomastia
- spider naevi (also occur in severe malnutrition and pregnancy)
- hepatomegaly
- splenomegaly
- ascites
- caput medusae
- testicular atrophy

Demographics of the disease

The exact prevalence of cirrhosis worldwide is unknown. There are an estimated 30 000 people living with cirrhosis in the UK, and at least 7000 new cases being diagnosed each year. The numbers of people living with both alcoholic cirrhosis and non-alcohol-related cirrhosis seems to be rising. The number in developing countries is higher due to the prevalence of viral hepatitis. Since the disease often goes undetected for extended periods, a reasonable estimate is that up to 1% of the population may have histological evidence of cirrhosis.

Natural history, and complications of the disease

The natural course of cirrhotic liver disease depends on the cause of underlying disease and treatment provided. Decompensation rates with chronic viral hepatitis B and C are 10% and 4%, respectively, per year. Decompensation in alcoholics is even higher with continued alcohol consumption and may be associated with an acute hepatitis on a background of cirrhosis. The complications of cirrhosis are essentially those of hepatic decompensation. This defines chronic liver failure.

Approach to diagnosing the disease

Imaging

Ultrasound, MRI, and CT are not usually sensitive enough to detect the presence of cirrhosis, but may give evidence of hepatic decompensation (e.g. ascites and other features of portal hypertension). They can also be used in the investigation of hepatocellular carcinoma.

Ultrasound is an inexpensive way of providing clues about hepatic architecture and may show increased echogenicity, irregularity, atrophy, and a nodular appearance (some of these feature may also be present in steatosis). The diagnosis of portal hypertension can be made through Doppler/duplex ultrasound by demonstration of portal flow. This can also diagnose portal vein cavernous transformation and portal vein or splenic vein thrombosis. The finding of

Common	Less common	Less prevalent causes
Alcohol	Autoimmune hepatitis	Carbohydrate disorders: <ul style="list-style-type: none"> • galactosaemia
Chronic viral (C or B) hepatitis	Drug induced	<ul style="list-style-type: none"> • glycogen storage disease
Haemochromatosis	Alpha-1-antitrypsin deficiency	Lipid disorders: <ul style="list-style-type: none"> • abetalipoproteinaemia
Non-alcoholic fatty liver disease	Porphyria	Sarcoidosis
Primary biliary cirrhosis	Wilson's disease	Vascular: <ul style="list-style-type: none"> • right-sided heart failure • hereditary haemorrhagic telangiectasia

Non-alcoholic fatty liver disease	ALT:AST >1 Lipids Fasting glucose Thyroid function Coeliac serology
Primary biliary cirrhosis	AMA (IgM)
Wilson's disease	Serum caeruloplasmin and urinary

Abbreviations: ALT, alanine aminotransferase; AMA, anti-mitochondrial antibody; ANA, antinuclear antibody; AST, aspartate aminotransferase; γ GT, gamma-glutamyl transferase.

splenomegaly and a collateral circulation may be seen. The disadvantages include the lack of reproducibility of data due to inter-observer variability.

Spiral CT and CT angiography may allow more accurate demonstrations of liver vasculature and collateral circulations. Dilatation of the inferior vena cava is also suggestive of portal hypertension. Magnetic resonance angiography has the additional advantage of providing quantitative data regarding portal vein and azygous vein flow. MRI can sometimes differentiate between regenerating or dysplastic nodules and hepatocellular carcinoma; it is best used as a follow-up study to determine whether lesions have changed in appearance and size.

Direct portal pressure measurements are not routinely performed due to their invasive nature and the risk of complications.

Blood tests

Although liver function test results may not correlate exactly with degree hepatic dysfunction, interpreting certain patterns from the liver panel in conjunction with the clinical picture may give clues toward certain etiologies (see Table 210.2).

Other diagnoses that should be considered

See Table 210.2 for other diagnoses that should be considered.

'Gold-standard' diagnostic test

Liver biopsy is often considered the 'gold standard' not only for diagnosing cirrhosis but also for sequential histological grading of inflammation and staging of fibrosis. It also becomes important in determining aetiology in about a fifth of patients. Ascites and coagulopathy need correcting prior to percutaneous biopsy but, if correction is needed urgently, a transjugular approach may be attempted. Liver biopsy is subject to a degree of sampling variability regardless of underlying aetiology. Biopsy confirmation of cirrhosis is not needed if clear signs of cirrhosis, such as ascites, coagulopathy, or a nodular, shrunken appearance of the liver, are present.

Acceptable diagnostic alternatives to the gold standard

Non-invasive biomarkers to stage liver fibrosis have been researched extensively (e.g. TIMP1, fibrotest). A problem is the heterogeneity of liver disease, with different stages being present at different parts of the liver during any one time.

A newer imaging technique to determine the 'stiffness' of the liver is based on the velocity of an elastic wave via intercostally located

wave transmitters. Shear wave velocity correlates with liver stiffness. The disadvantage is that the test is less accurate in those who are obese or those with ascites.

Other relevant investigations

Other relevant investigations include liver chemistry, immunoglobulins, and a full blood count (also see Table 210.2).

Liver chemistry

Liver chemistry may be normal in the compensated phase. Marked elevation of levels of alanine aminotransferase or alkaline phosphatase can occur in primary biliary cirrhosis or alcoholic hepatitis (alanine aminotransferase and aspartate aminotransferase levels rarely exceed 350 IU/l if the sole aetiology is alcohol). In terminal disease, these levels may fall. This is due to loss of hepatocyte function, in which case no enzymes can be produced.

Immunoglobulins

Raised IgA is common in alcoholics. IgM is common in primary biliary cirrhosis. IgG is common in other autoimmune conditions.

Full blood count

When performing the full blood count, look for features of hypersplenism (e.g. leucopenia, thrombocytopenia).

Prognosis and how to estimate it

Once decompensation occurs in any type of cirrhosis, mortality can be as high as 85% in 5 years, without transplantation. The Child–Turcotte–Pugh classification is used to gauge disease severity in patients with liver disease (Table 210.3). However, at the turn of the century, the Model for End-Stage Liver Disease (MELD) was developed to provide a more accurate prediction of short-term mortality:

$$\text{MELD} = (3.78)(\ln [\text{bilirubin}]) + (11.2)(\ln \text{INR}) + (9.57)(\ln [\text{creatinine}]) + 6.43,$$

where '[bilirubin]' is the serum concentration of bilirubin (in milligrams per decilitre), 'INR' is the international normalized ratio, and '[creatinine]' is the serum concentration of creatinine (in milligrams per decilitre). This equation is used to identify patients who are most likely to die without liver transplantation.

Treatment and its effectiveness

Cirrhosis need not be progressive. Once complications have developed, appropriate patients should be referred to a specialist liver

Table 210.3 Child–Turcotte–Pugh scoring system to assess liver disease severity

Measure	1 point	2 points	3 points
Bilirubin (total) in $\mu\text{mol/l}$	<34 (<2)	34–50 (2–3)	>50 (>3)
Serum albumin in g/l	>35	28–35	<28
INR	<1.7	1.71–2.20	>2.20
Ascites	None	Suppressed with medication	Refractory
Hepatic encephalopathy	None	Grade I–II (or suppressed with medication)	Grade III–IV (or refractory)

Score 5–6 \equiv Class A: 100% survival from liver cirrhosis at 1 year; 85% survival at 2 years. Score 7–9 \equiv Class B: 81% survival from liver cirrhosis at 1 year; 57% survival at 2 years. Score 10– ∞ \equiv Class C: 45% survival from liver cirrhosis at 1 year; 35% survival at 2 years. Abbreviations: INR, international normalized ratio.

unit for management of end-stage liver disease, and consideration for transplantation. This section deals with the features of hepatic decompensation, but treatment of the underlying aetiology (e.g. venesection for haemochromatosis) is also important.

Conservative measures for the treatment of chronic liver failure

Conservative measures for the treatment of chronic liver failure are as follows:

- abstinence from alcohol: this is essential if alcohol is thought to be an aetiological factor; for other causes, restriction to <10 units a week should be advised
- salt restriction, in those with ascites
- good nutritional intake, in those with compensated disease

Treatment for ascites

Managing ascites can be difficult, but the aim is a gradual, controlled reduction of ascitic fluid volume, with weight loss of 0.5–1.0 kg per day. Fluid losses at a rate greater than this exceed the capacity of the peritoneum to absorb ascites and can result in hypovolaemia. Medications which can cause fluid retention (e.g. NSAIDs, calcium channel blockers) should be stopped. The mainstays of treatment are:

- dietary sodium restriction (intake not to exceed 2000 mg/day)
- water restriction (1.5 l/day), if the sodium level is below 125 mmol/l
- diuretic therapy

Note that most patients cannot be managed without diuretic therapy. If ascites is present in moderate quantities, then outpatient management is adequate, starting with spironolactone 100 mg daily. Amiloride (up to 15 mg daily) is an alternative if patients cannot tolerate spironolactone. Eplerenone is a newer drug akin to spironolactone; it is licensed for use in cardiac failure but not yet widely used in the management of ascites. It has the advantage of not causing gynaecomastia. Loop diuretics (bumetanide 1–3 mg daily or furosemide 40–120 mg daily) augment the response to spironolactone. Renal function must be monitored closely and should be normal for these medications to work. A weight loss of 2–4 kg per week till the disappearance of clinical ascites is the aim. Spironolactone can be increased by 100 mg every few days to achieve response (maximum 400 mg daily).

Refractory ascites (5%–10% of cases) is defined as an inadequate response to sodium restriction and maximal diuretic treatment (400 mg of spironolactone and 160 mg of furosemide daily). In these cases, one should ensure all appropriate samples have been sent for analysis to exclude treatable causes. If the ascites is tense, and particularly if it is causing respiratory distress or discomfort despite the measures previously mentioned, then therapeutic paracentesis should be instituted. The aim is to drain to dryness; however, one should not leave the drain in situ for greater than 6 hours, in order to prevent the development of iatrogenic bacterial peritonitis. IV colloid replacement should be provided (5–8 g 20% albumin for every 1–2 l of fluid drained). This latter measure is essential to avoid hypotension and hepatorenal syndrome. Diuretics are continued to prevent reaccumulation of ascites. Other measures for refractory ascites include peritoneovenous shunting, use of a transjugular intra-hepatic portosystemic shunt (TIPS), and transplantation.

Peritoneovenous shunting

Peritoneovenous (LeVeen) shunting was introduced in the early 1970s for the treatment of refractory ascites (in patients with cirrhosis). Unfortunately, this procedure has many reported complications, particularly in those with significant hepatocellular insufficiency. Shunt obstruction (particularly at the venous end) is the main problem, necessitating replacement of the shunt. This remains an option in those who are not candidates for TIPS or transplantation.

TIPS

TIPS creates an artificial fistula between the hepatic vein and portal vein via the placement of an expandable metal stent. It can also be used to treat those with persistent variceal haemorrhage, by reducing portal pressure. However, shunt dysfunction is still quite common.

Recent trial data comparing the use of TIPS and medical therapy to large-volume paracentesis and medical therapy demonstrate that the former approach is superior for ascites control but does not improve survival, hospital stay, or subjective quality of life. Hepatic encephalopathy is more common in those who receive TIPS but variceal bleeding and renal impairment have similar rates of occurrence. The recent development of PTFE-coated shunts improves patency and reduces the incidence of TIPS dysfunction and possibly even encephalopathy.

Transplantation

Individuals who develop diuretic resistant ascites have an increasingly worse prognosis. Any individual who develops diuretic resistance should be considered for transplantation, as the 1-year survival rate can be increased to greater than 75%.

Treatment for bacterial peritonitis

Recognition of spontaneous bacterial peritonitis and differentiation of it from bacterial peritonitis due to a secondary cause is important. The latter often warrants surgical intervention, whereas the former is treated medically. Secondary peritonitis should be considered in the following circumstances:

- ascitic total protein >1 g/dl
- ascitic lactate dehydrogenase >225 mU/ml (or higher than the upper limit of normal for sodium)
- ascitic glucose >2.75 mmol
- polymicrobial ascitic fluid

Patients with secondary peritonitis must be evaluated by urgent imaging to exclude viscus perforation.

Cirrhotic patients are at risk of developing spontaneous bacterial peritonitis. This can have a mortality of 40%–70%. Increased risk is present in the following conditions:

- gastrointestinal haemorrhage
- ascitic fluid total protein <10 g/l; this is particularly important if bilirubin is very high and the patient is thrombocytopenic
- a history of previous episodes of spontaneous bacterial peritonitis
- fulminant hepatic failure

Spontaneous bacterial peritonitis is usually caused by *E. coli*, and enteric organisms have been isolated from ascitic fluid in >90% of cases of spontaneous bacterial peritonitis, suggesting that the gastrointestinal tract is the source of bacterial contamination. Because of the predominance of enteric organisms in spontaneous bacterial peritonitis, it was once thought that spontaneous bacterial peritonitis was caused by the direct transmural migration of bacteria from the intestinal lumen, or 'bacterial translocation', although experimental evidence suggests that bacterial translocation might not be only factor responsible. Nonetheless, a key predisposing factor may be intestinal bacterial overgrowth (attributed to decreased intestinal transit time), combined with impaired phagocytic function, low serum and ascites complement levels, and decreased activity of the reticuloendothelial system; an increased number of microorganisms, combined with a decreased capacity to clear them from the bloodstream, may result in their migration to and proliferation within ascitic fluid.

A diagnosis of spontaneous bacterial peritonitis is made when the ascitic fluid total white-cell count exceeds 400 cells/mm³, or the total polymorph count exceeds 250 cells/mm³. This is the case even if no organisms are identified in the ascitic fluid. In patients with haemorrhagic ascites, when the ascitic fluid red-cell count is >10 000 cells/mm³, 1 neutrophil should be subtracted for every 250 red blood cells, to adjust for the presence of blood.

Following a diagnosis of spontaneous bacterial peritonitis (by diagnostic paracentesis), the following treatment should be started promptly:

- all diuretic treatment should be stopped, and large-volume paracentesis should be avoided (except for diagnostic purposes); this will reduce risk of progression to hepatorenal syndrome
- cefotaxime should be provided at 2 g twice daily for 5 days
- if the patient is systemically unwell but with normal renal function, then a single dose of gentamicin 5 mg/kg should also be given, for rapid bactericidal kill

- 20% human albumin solution should be provided: 1.5 g/kg on Days 1 and 2 of treatment, followed by 1.0 g/kg on Day 3; this may improve mortality and reduce the incidence of developing renal failure
- following treatment, a fluoroquinolone should be prescribed in the long term, to prevent future recurrence

Portal hypertension

Regardless of the aetiology of liver cirrhosis, the development of portal hypertension is usually inevitable and occurs due to an increased resistance to portal flow secondary to scarring, narrowing, and compression of the hepatic sinusoids (see also Chapter 207). Raised portal pressure leads to the development of varices. The British Society of Gastroenterology guidelines recommend that endoscopic surveillance for varices should take place every 3 years in those who have not had an episode of variceal bleeding in the past.

Primary prophylaxis (of varices) is aimed at reducing portal pressure with propranolol 40 mg two or three times per day. This is also the treatment of choice in portosystemic gastropathy. Variceal banding is not usually indicated as a prophylactic measure unless bleeding has occurred, and has to be done repeatedly to be of any value. Isosorbide mononitrate (20 mg twice daily) can be used if propranolol is contraindicated. Acute variceal bleeding is covered in Chapter 22; band ligation is the first treatment of choice in an acute oesophageal, variceal bleed. Injection of Histoacryl glue has been used successfully in managing gastric varices. Vasoconstrictors terlipressin (2 mg bolus followed by 2 mg every 4 hours) and octreotide can be used as a bridge to endoscopy. Varices recur after obliteration in about 40% of cases. In recurrent cases of variceal bleeding, TIPS should be considered. Surgery is another option in refractory cases in the absence of deranged liver function and encephalopathy. Options available include surgical shunting, oesophageal stapling, and transection.

Hepatic encephalopathy

See Chapter 209 for a discussion of hepatic encephalopathy.

Hepatorenal syndrome

The term 'hepatorenal syndrome' (HRS) refers to acute renal failure that occurs in the setting of cirrhosis or fulminant hepatic failure and is sometimes associated with portal hypertension in the absence of intrinsic diseases of the kidney. Type I HRS is characterized by rapidly

progressive renal failure with a doubling of serum creatinine to a level greater than 221 $\mu\text{mol/l}$. This carries a very poor prognosis, usually with less than 50% survival at 1 month. Patients with type I HRS are usually ill, may have low blood pressure, and may require therapy with inotropes or IV drugs to maintain blood pressure. In contrast, type II HRS is characterized by a slowly progressive increase in serum creatinine level to greater than 133 $\mu\text{mol/l}$. It is typically associated with ascites unresponsive to diuretics and also carries a poor outlook, unless the patient undergoes transplantation.

It can be challenging to distinguish HRS from other entities that cause renal failure in the setting of advanced liver disease. The key to effective treatment is early recognition; once HRS has been recognized, the following steps should be taken:

- diuretics and all nephrotoxic drugs should be stopped
- intravascular albumin (colloidal solution) should be provided, to correct hypovolaemia
- terlipressin should be provided (to vasoconstrict the splanchnic circulation; 0.5 mg twice daily); this is not a definitive treatment, but may lead to short-term improvements in cases of reversible liver disease
- haemodialysis or continuous venovenous haemofiltration may be needed to correct uraemia and electrolyte imbalances, although these procedures have no impact on survival
- it may be too late for liver transplantation once HRS has developed, but it is the only treatment that can affect survival

Other therapies for HRS

Some studies have demonstrated improvements in renal blood flow and glomerular filtration rate in type 1 HRS after 20 days treatment with oral midodrine and parenteral octreotide, compared with treatment with dopamine. These therapies may improve survival rates and act as a bridge to liver transplantation.

211 Alcoholic liver disease

Satish Keshav and Alexandra Kent

Definition of the disease

Alcoholic liver disease (ALD) develops in excessive drinkers and can manifest in three forms:

- alcoholic fatty liver (steatosis): >80%
- alcoholic hepatitis: 10%–35%
- cirrhosis: 10%

Aetiology of the disease

The more alcohol consumed, the greater the risk of ALD (the recommended daily intake of alcohol is ≤ 14 units for women, and ≤ 21 units for men). However, other important etiological factors are as follows:

- 10%–20% of patients have a genetically inherited susceptibility to the harmful effects of alcohol
- women are more sensitive to the harmful effects of alcohol than men are
- daily drinking is more harmful than binge drinking
- poor nutrition and alcohol work synergistically to cause hepatotoxicity

Typical symptoms of the disease and less common symptoms

Alcohol can cause significant damage without producing any symptoms, and many patients will only have liver dysfunction detected on routine blood tests. Many patients report non-specific symptoms, such as anorexia, morning nausea, diarrhoea, and vague right upper quadrant abdominal pain.

Alcohol withdrawal produces additional symptoms of tremulousness, headache, anxiety, tachycardia, and hypertension. Severe withdrawal ('delirium tremens') can produce profound confusion, disorientation, hallucinations, hyperactivity, and extreme cardiovascular disturbances.

Patients with ALD may present with complications related to alcohol misuse, such as rib fractures, head injuries, pancreatitis, and so on. Alcoholic hepatitis can present with a constellation of symptoms, including rapidly developing jaundice, ascites, and liver failure. ALD symptoms may also reflect complications of liver disease, for example haematemesis from bleeding varices, a distended abdomen from ascites, and/or confusion from encephalopathy.

Demographics of the disease

Since 1950, alcohol consumption in the UK has risen from 3.9 l of pure alcohol per capita per year to a peak of 9.4 l in 2004. In the UK, there are 150 000 hospital admissions per year due to alcohol, with >39 000 due to ALD, and 22 000 alcohol-related deaths. Alcohol misuse costs the NHS £1.7 billion per year.

Of adults in England, aged 16–64, 38% of men and 16% of women have an alcohol use disorder, 21% of men and 9% of women are binge drinkers, 23% (7.1 million) consume alcohol at hazardous or harmful levels (32% of men, 15% of women), and 3.6% (1.1 million) are alcohol dependent (6% of men, 2% of women). In addition, there is an increasing incidence of women drinking in excess of the recommended daily alcohol intake. However, there is wide variation in alcohol consumption between racial groups: 91% of Caucasian British drink alcohol, but only 52% of British of African descent and 10% of those of Pakistani and Bangladeshi descent. Nonetheless,

UK teenagers report more alcohol consumption, more episodes of intoxication, and more adverse effects from drinking than do teenagers in any other European country.

Natural history, and complications of the disease

The underlying pathogenesis of alcohol-induced injury is not fully understood but is thought to involve various mechanisms, including reactive acetaldehyde derivatives; oxygen-derived free radicals; the pro-inflammatory cytokines interleukin 1 beta, interleukin 6, and tumour necrosis factor alpha (TNF α); elevation of hepatocyte and Kupffer cell iron; mitochondrial damage; reduced levels of cellular antioxidants; and alterations in intracellular signalling and hormones.

Minimal change/steatosis

In alcoholic fatty liver, the cytoplasm of affected hepatocytes is occupied by a single large triglyceride occlusion, thought to be due to increased free fatty acid synthesis, diminished triglyceride utilization, decreased fatty acid oxidation, a block in lipoprotein excretion, and enhanced lipolysis, thus increasing delivery and uptake of free fatty acid. Fatty change in the liver is universal 3–7 days after a large amount of alcohol is consumed, and lasts for 2–4 weeks.

Alcoholic hepatitis

In alcoholic hepatitis, hepatocyte ballooning due to water, fat, and protein accumulation occurs, along with inflammation. Mallory's hyaline bodies are seen histologically.

Cirrhosis

Continuing alcohol exposure leads to the development of cirrhosis, which is characterized microscopically by regeneration nodules (containing regenerating hepatocytes) surrounded by fibrous septa. Portal tracts, central veins, and the radial pattern of hepatocytes are absent. Biliary ducts may become damaged, proliferate, or distend, leading to biliary stasis.

Patients who drink excessive volumes of alcohol are at risk of the complications of alcohol toxicity and all complications of chronic liver disease. Box 211.1 lists complications of excessive alcohol consumption. Specific hepatic complications include:

- varices
- ascites
- spontaneous bacterial peritonitis
- encephalopathy
- hepatorenal syndrome

The presence of one or more of these complications significantly worsens prognosis (see Chapter 210 for more information regarding the complications of chronic liver disease).

Approach to diagnosing the disease

Patients may self-present for detoxification or requesting help. Ultimately, a good clinical history and suspicious mind is all that is required to diagnose ALD, and friends and relatives are often useful in providing a collateral history. Questionnaires, such as the Alcohol Use Disorders Identification Test (AUDIT) or CAGE may aid diagnosis. The CAGE questionnaire consists of four questions:

- Have you ever felt you should cut down on your drinking?
- Have people annoyed you by criticizing your drinking?

Box 211.1 Complications of excess alcohol consumption

- peptic ulcers
 - dyspepsia/acid reflux
 - throat and mouth cancer
 - enteropathy and diarrhoea
 - pancreatitis
 - malnutrition
 - vitamin deficiency
 - cardiomyopathy
 - peripheral neuropathy
 - cerebellar atrophy/syndrome
 - Korsakoff's syndrome
 - Wernicke's encephalopathy
 - depression
 - immunosuppression
 - coagulopathy
 - bone marrow suppression
 - reduced libido
 - erectile dysfunction
 - congenital disorders in babies born to alcoholic mother (fetal alcohol syndrome)
- Have you ever felt **guilty** about your drinking?
 - Have you ever had a drink first thing in the morning (an eye opener) to steady your nerves or get rid of a hangover?

Other diagnoses that should be considered

It is important to ensure the patient has no other underlying liver disease, as alcohol will increase susceptibility to liver damage. Most gastroenterologists would advocate a full liver screen to ensure there is no concomitant diagnosis. In patients presenting with bleeding oesophageal varices, an ultrasound of the liver should be performed to ensure there is no portal vein thrombosis related to turbulence from portal hypertension.

'Gold-standard' diagnostic test

The only investigation which can truly gauge the degree of liver damage is a liver biopsy. This is normally performed under ultrasound guidance but, in patients with coagulopathy or thrombocytopenia, a transjugular approach may be a safer alternative. Histological analysis will help identify features of steatosis, hepatitis, and/or cirrhosis and can exclude pathognomonic features of other liver diseases. The presence of a typical pattern of fine pericellular reticulin fibrosis and Mallory's hyaline are highly suggestive of alcohol-related liver damage.

Acceptable diagnostic alternatives to the gold standard

Various tests are performed to help clarify a diagnosis of ALD, although each test individually has a low sensitivity. The gamma-glutamyltransferase (γ GT) test and mean corpuscular volume test each have a sensitivity of 30%–40% in ALD but, in when the tests are taken in combination, the sensitivity increases. However, the γ GT level also increases proportionally with BMI. Serum carbohydrate-deficient transferrin is a sensitive and specific test of alcohol excess, but is not widely available. Serum transaminases are often only mildly raised in ALD, and hyperbilirubinaemia is more suggestive of acute alcoholic hepatitis. Hepatic synthetic function is assessed by the albumin level and prothrombin time.

Ultrasound examination can provide information about the liver; fatty infiltration produces a hyperechogenic, bright image, whereas an irregular shrunken liver is in keeping with cirrhosis. An ultrasound can also identify other features of chronic liver disease, such as splenomegaly, ascites, varices (splenic, abdominal wall), and portal vein patency.

Newer investigations assessing the degree of hepatic fibrosis are not in widespread use but include serum fibrosis markers (e.g. procollagen III propeptide, laminin, type IV collagen) and Fibroscan®.

Other relevant investigations

Patients with cirrhosis or evidence of portal hypertension should undergo endoscopic variceal surveillance, at least once every 3 years. Cirrhosis predisposes to hepatocellular carcinoma (HCC); therefore, patients should undergo 6-monthly alpha-fetoprotein measurements and liver ultrasound scans. These guidelines should be adapted for each patient, as patients with severe chronic liver disease will not be eligible for treatment of an underlying HCC, so screening investigations will not be of benefit.

Prognosis and how to estimate it

Prognosis is dependent on patients remaining abstinent from alcohol, as steatosis is reversible. Cirrhosis causes irreversible damage, but abstinence prevents further hepatic damage. Survival for cirrhotic patients is dependent on the degree of liver damage, but overall is 60%–70% at 1 year, and 35%–50% at 5 years. Alcoholic hepatitis has a high mortality rate: 50% in 30 days. Each additional complication (e.g. spontaneous bacterial peritonitis, variceal bleeding) worsens prognosis. The Maddrey discriminant function (DF) was originally used in studies investigating the use of corticosteroids in acute alcoholic hepatitis. The formula used to calculate this index is

$$DF = 4.6 (\text{prothrombin time} - \text{control prothrombin time}) + [\text{bilirubin}],$$

where the prothrombin time and the control prothrombin time are in seconds, and '[bilirubin]' is the concentration of bilirubin in milligrams per decilitre (NB: if bilirubin is measured in micromoles per litre, then divide the measurement by 17.1). A $DF \geq 32$, with or without encephalopathy, is associated with a 65% 28-day survival, and a $DF < 32$ with a 93% 28-day survival.

Treatment and its effectiveness

Abstinence is integral to prognosis and should be encouraged with help from family, friends, social services, and support groups such as Alcoholics Anonymous. Naltrexone and acamprosate have been shown to reduce alcohol cravings, although their effect on abstinence is not known. Vitamin deficiency is common, particularly for thiamine, folate, pyridoxine, and riboflavin. Patients admitted to hospital usually receive IV vitamins (Pabrinex® I + II ampoules, twice daily for 3 days) and then oral supplements. Patients suffering with withdrawal should receive chlorthalidone or clomethiazole in reducing doses, to reduce agitation and withdrawal phenomena.

Nutrition is extremely important; patients should be reviewed by the dietician, and enteral supplements provided. In severely malnourished patients, nasogastric feeding can be given as a supplement.

The use of corticosteroids in ALD has been the subject of much debate. However, a pooled analysis of three large, well-designed studies showed that steroids improved survival (85%), compared to placebo (65%), when used in patients with a $DF \geq 32$ and/or encephalopathy, although the survival benefit only lasted for 1 year post treatment. Furthermore, it suggested that a reduction in bilirubin by Day 7 might be a prognostic factor.

Pentoxifylline is a phosphodiesterase inhibitor with anti-TNF α activity and has been shown to reduce mortality by 40%, mainly due to a reduction in hepatorenal syndrome. Antioxidant therapy has not yet been shown to have a beneficial effect, and the use of anti-TNF α biological therapies is still being investigated.

Liver transplantation is considered in patients who meet the following criteria:

- abstinence from alcohol for 6 months, to allow for spontaneous liver recovery, allow time for other alcohol-related morbidities to recover, and on the theory that preoperative abstinence can

predict a reduced risk of post-operative relapse, although this theory is not substantiated

- advanced liver disease with complications
- no other organ damage
- good social or family support

Propranolol should be given to all patients with Grade 2–4 varices, with doses escalated as tolerated.

212 Viral hepatitis

Satish Keshav and Palak Trivedi

Definition of the disease

Hepatitis means 'inflammation of the liver' and is manifest with symptoms that include malaise, anorexia, fever, flu-like symptoms, and pain in the right upper quadrant of the abdomen, with the pain being caused by swelling of the liver and its capsule. Elevations in circulating hepatic enzymes, particularly aspartate transaminase (AST) and alanine transaminase (ALT), are common, with jaundice occurring some time after the onset of other symptoms and signs.

There are five viruses that primarily cause viral hepatitis (see Table 212.1): hepatitis A, B, C, D, and E viruses, abbreviated HAV, HBV, HCV, HDV, and HEV, respectively. These viruses are all hepatotropic, in that the liver is the primary site of infection. HAV, HBV, and HEV are most often acute, self-limiting infections that may nonetheless cause morbidity and, in the case of HEV, fatality in selected groups of patients. However, HBV and, more so, HCV can cause chronic carriage of the virus over many years, as well as the development of chronic hepatitis. HDV is only pathogenic in conjunction with HBV. There is also emerging evidence of chronic hepatitis E virus infection in patients who are immunosuppressed.

After recovery from acute infection with HAV, individuals have long-lasting immunity against further infection. The same holds true for the majority of individuals with acute HBV infection. There seems to be little natural immunity to HCV infection, and a significant proportion of cases result in chronic hepatitis. Immunity to HEV is not long-lasting, and repeated infections are possible.

Many other viruses can cause hepatitis; of these, cytomegalovirus (CMV), herpes simplex virus (HSV), Epstein-Barr virus (EBV), and flaviviruses such as dengue and yellow fever are the most important. The liver, however, is not their primary site of replication or cellular damage.

Aetiology of the disease

Replication of hepatotropic viruses in hepatocytes causes cellular damage, resulting in elevations in circulating liver enzymes and compromise of liver function. Activation of the immune system by the infection, and immune-mediated damage to hepatocytes, are also important in causing liver damage. This is demonstrated by the potential for asymptomatic carriage of HBV infection, with overt hepatitis becoming apparent only when the immune system is activated, whereupon the infection may be cleared entirely (seroconversion).

Hepatitis A is transmitted via the faecal-oral route and, hence, has a higher prevalence in areas with poor hygiene and sanitation. Increased incidences are recognized after natural disasters that disrupt sanitation systems that were already marginal at best. Deep-water crustaceans can concentrate the virus and can be a risk if consumed when undercooked or raw.

Hepatitis B is transmitted by infected blood and bodily fluids, percutaneously or through sexual contact. Hepatitis B can also be transmitted vertically from mother to child, and this is one of the most common modes of transmission worldwide. A major mechanism of acquired infection in the UK is IV drug use. Prior to the use of effective methods of blood testing (pre-1990s), blood products also carried a risk of transmission. The majority of observed new cases in the UK arise through immigration from those who resided in endemic countries.

Hepatitis C infection is primarily acquired following contact with infected blood; this can occur through IV drug use, nasal drug use, tattooing, and, less so, skin piercings. Hepatitis C transmission through blood products was particularly an issue in the haemophilic population prior to the use of heat-treated Factor VIII concentrates, which started in 1985. Fortunately, the proportion of cases due to this route of transmission has fallen greatly. Sexual transmission of hepatitis C through heterosexual relationships is low, but up to 20% of those with hepatitis C infection have no known percutaneous risk factor, and report exposure to sexual contact with a known carrier. However, promiscuous homosexual behaviour amongst men is a risk factor. Vertical transmission of hepatitis C is between 1% and 6%, and does not appear to be affected by the mode of delivery chosen during labour.

Hepatitis D virus infection only occurs with co-transmission of hepatitis B. Its presence should be suspected when an individual with known, stable hepatitis B has an acute deterioration in their clinical condition.

Hepatitis E virus is transmitted through the faecal-oral route and is endemic in countries with poor sanitation, particularly Mexico, Central America, Asia, and Africa. Increasing frequencies have been identified in the Indian subcontinent, with epidemic outbreaks being attributed to contamination of drinking water. Sporadic outbreaks are also recognized in developed countries, usually attributed to travellers returning from endemic countries. Some authorities report a zoonotic source, and pigs are a recognized reservoir. Direct person-to-person transmission is uncommon.

Typical symptoms of the disease, and less common symptoms

Acute infection with HCV is asymptomatic in 50%–90% of cases, although failure to eradicate infection and subsequent progression to chronic disease is the rule rather than the exception (discussed later). HDV superinfection should be suspected when an individual with previously stable chronic HBV suddenly develops features of an acute hepatitis flare or decompensated liver disease. Acute infection with HAV, HBV, or HEV often presents with the classical symptoms of acute viral hepatitis.

Table 212.1 Hepatitis viruses

	Hepatitis A virus	Hepatitis B virus	Hepatitis C virus	Hepatitis D virus	Hepatitis E virus
Transmission	Enteric	Parenteral	Parenteral	Parenteral	Enteric
Classification	Picornavirus	Hepadnavirus	Hepacivirus	Deltavirus	Hepevirus
Genome	ssRNA	dsDNA	ssRNA	ssRNA	ssRNA
Incubation period	15–45 days	45–60 days	15–160 days	30–60 days	15–60 days
Icteric period	Variable	Begins 10 days after the incubation period, lasting up to 4 weeks	Usually occurs in decompensated, chronic infection	N/A	Variable

Abbreviations: dsDNA, double-stranded DNA; ssRNA, single-stranded RNA.

Common symptoms

Infection begins with an incubation period as the virus multiplies and spreads without symptoms. Following the incubation period, a viral prodrome of up to 2 weeks is recognized, including anorexia, malaise, nausea, severe fatigue, myalgia, and fever. Some patients may have a serum-sickness-type presentation including arthralgia, arthritis, and urticarial skin lesions. This is seen more with HBV (up to 20% of infected patients) than with the other hepatitis viruses. It is associated with the formation of immune complexes between antibodies and viral antigens.

When one starts to notice the onset of jaundice, prodromal symptoms will start to resolve and the patient begins to feel much better. Palpable, smooth hepatomegaly may be felt. Jaundice develops within 1–2 weeks and peaks around 4 weeks.

Examination findings often reveal the presence of jaundice and tender hepatomegaly. Other signs of chronic liver disease are rare in acute infection; however, splenomegaly is common in EBV infections.

Resolution of the acute illness is usually spontaneous over the next 4–8 weeks in the majority of patients.

Less common symptoms

Pruritus is unusual with jaundice due to viral hepatitis, although obstructive symptoms (dark urine, pallor to stools) may be noticed.

HBV infection may become chronic in a minority of affected patients, and can lead to features of chronic liver disease as a consequence (discussed later).

Demographics of the disease

Hepatitis A occurs worldwide, with an estimated 1.5 million cases occurring per year. The regions where hepatitis A is endemic include the Indian subcontinent, sub-Saharan and North Africa, the Far East, Middle and Central America, and the Middle East. Interestingly, clinical cases of hepatitis A in adults are uncommon in endemic countries, as most people in those countries are exposed to the virus at a very young age and hence acquire lifelong immunity.

There are over 350 million carriers of hepatitis B worldwide, most of them being concentrated in developing countries. Sub-Saharan Africa, most of Asia, and the Pacific are hit hardest, with 10% of those infected becoming chronic carriers. Five per cent of all people in India and the Middle East are affected. The estimate chronic HBV carrier rate in South East Europe and Central Europe is between 2% and 7%. Australia, New Zealand, Northern Europe, Western Europe, and North America have a prevalence of chronic hepatitis B viral infection of approximately 2%. In the UK, 0.5% of the population is hepatitis B surface antigen (HBsAg) positive, which is representative of chronic infection. Furthermore, up to 2% have prior evidence of hepatitis B virus infection.

Hepatitis C virus is also prevalent worldwide, but epidemiological data is difficult to interpret accurately, as many infections are asymptomatic. It is estimated that 3% (130–210 million) of the world's population are chronically infected with HCV. The highest prevalence rates are found in the African continent, particularly Egypt (up to 50% in some areas), the Eastern Mediterranean, South East Asia, and the Western Pacific. The United Kingdom and Western Europe are considered to be low-prevalence regions; in 2003, the estimated number of individuals with positive hepatitis C antibodies in England and Wales was just over 230 000 (aged 15–59).

Large outbreaks of hepatitis E have been seen in Central and South America, the Indian subcontinent, and bordering nations.

Natural history and complications of the disease

Rarely, acute liver failure may occur with the initial infection. One per cent of symptomatic, acute HBV infections can lead to fulminant liver failure. This complication is more common in the elderly, in whom mortality approaches 15%. Acute liver failure is typical of HEV in pregnancy and elderly men. However, this complication is uncommon outside these settings. Acute liver failure does not usually occur with hepatitis A or C. Complete recovery from the acute

episode can take many weeks to months, with lethargy and anorexia persisting. However, acute HCV inevitably leads to the development of chronic hepatitis. In addition, type III mesangiocapillary glomerulonephritis (immune deposits in sub-endothelial space and mesangium) is associated with HBV or HCV infection.

Viral hepatitis infection typically resolves completely, except in 5% of cases of HBV infection, and in the majority of patients with HCV infection, where disease may persist and become chronic. These viruses represent some of the commonest etiological risk factors worldwide for the development of chronic liver disease and its associated complications.

Chronic HBV infection

Chronic HBV infection has six distinct, dynamic phases of infection: the immune tolerance phase, the immune active phase, the inactive-HBV carrier phase, the HBeAg-negative phase, the HBsAg-negative phase, and HBeAg-negative chronic hepatitis. These do not necessarily occur in a sequential manner.

Immune tolerance phase

The immune tolerance phase of chronic HBV infection is characterized by persistent positivity for the hepatitis B e antigen (HBeAg) following the acute infection (see “Gold-standard” diagnostic test for hepatitis B”), high levels of viral replication, and mild or no hepatic necroinflammation with little progression to fibrosis.

Immune active phase

The immune active phase of chronic HBV infection usually occurs after many years of immune tolerance and is characterized by HBeAg positivity, lower levels of HBV DNA and viral replication, increased/fluctuating levels of transaminases, and moderate-to-severe hepatic necroinflammation with rapid progression to fibrosis. The rate of spontaneous HBeAg loss is enhanced. This phase ends with seroconversion to antibodies against HBeAg (anti-HBe).

Inactive carrier phase

The inactive carrier phase (5%–10% of all patients infected) may follow seroconversion to anti-HBe and is characterized by very low/undetectable serum HBV DNA levels and normal serum aminotransferases. ALT levels (usually <40 IU/ml) and serum HBV DNA levels (<2000 IU/ml) should be tested every 3–4 months. HBV DNA levels <2000 IU/ml with elevated ALT values necessitate liver biopsy. The inactive carrier state confers a favourable long-term outcome with a very low risk of cirrhosis or hepatocellular carcinoma (HCC) in the majority of patients. HBsAg loss and seroconversion to antibodies against HBsAg (anti-HBs) may occur spontaneously (in a minority) but, conversely, some individuals progress to develop chronic hepatitis (HBeAg negative). Therefore, inactive carriers should be followed up for life with regular ALT determinations and measurements of HBV DNA levels.

HBeAg-negative chronic hepatitis

HBeAg-negative chronic hepatitis may follow seroconversion from the immune active phase, or develop after years of the inactive carrier state. It is characterized by periodic reactivation with a pattern of fluctuating levels of HBV DNA and aminotransferases, and an active hepatitis. These patients harbour HBV viruses which have developed mutations that render the viruses unable to express HBeAg, and so undergo low rates of prolonged spontaneous disease remission. It is important yet difficult to distinguish true inactive carriers from patients with active HBeAg-negative chronic HBV but who are undergoing spontaneous remission, as the latter have active liver disease with a high risk of progression to advanced hepatic fibrosis, cirrhosis, and subsequent complications such as decompensated cirrhosis and HCC.

HBsAg-negative phase (‘occult’ HBV disease)

In some patients who achieve loss of HBsAg following HBV infection, low-level viral replication persists, with detectable HBV DNA in the liver. Generally, HBV DNA is not detectable in the serum, while antibodies against the HBV core protein HBeAg (anti-HBc), with or without anti-HBs, are. Immunosuppression for other diseases may lead to HBV reactivation in individuals in this phase, emphasizing the importance of HBV serology testing in all patients for whom

immunosuppression is being proposed. Should such an individual show evidence of past infection (e.g. anti-HBc), antiviral therapy is advised prior to starting immunosuppressive therapy.

Long-term impact of chronic HBV infection

The long-term impact of chronic HBV infection on hepatic disease varies greatly, and all grades and stages of hepatitis, including minor changes, chronic hepatitis, fibrosis, and cirrhosis with or without HCC may be observed. Hepatitis B also has a rare association with polyarteritis nodosa, membranous glomerulonephritis, and nephrotic syndrome.

Chronic HCV infection

In most cases, chronic HCV infection usually leads to the development of histologically identifiable hepatitis which may progress to cirrhosis. Cryoglobulinaemia is also a recognized association with hepatitis C leading to type I mesangiocapillary glomerulonephritis.

Approach to diagnosing the disease

History and examination will provide evidence that viral hepatitis is a diagnostic possibility. In acute infection, elevated serum ALT and AST levels signify acute liver damage; levels are typically $>10\times$ normal levels. In 10%–15% of those infected with hepatitis A, a characteristic cholestasis with a rise in alkaline phosphatase levels occurs following the acute phase, and an apparent relapse may occur after initial recovery. However, the condition does not become chronic.

As the illness progresses, transaminase levels decline over weeks, and the serum bilirubin level rises. The peak bilirubin level typically occurs weeks after the peak transaminase levels.

With chronic infection, apart from mild-to-moderate elevation in the levels of transaminases, clinical hepatitis may be inapparent. The key to making the diagnosis is to proceed to serological and virological testing for viral hepatitis.

Hepatitis C may not necessarily present as a notable acute, symptomatic hepatitis, and transaminases may not reach the high levels seen in other acute virus infections.

Ultrasound scanning of the liver and the gall bladder is usually indicated to exclude biliary disease, liver abscesses, or mass as a cause of symptoms.

Other diagnoses that should be considered

Other diagnoses that should be considered aside from viral hepatitis include:

- glandular fever (acute EBV infection): a glandular fever test or equivalent (monospot, Paul–Bunnell test) should be performed if hepatitis A and hepatitis B serology are negative, in order to exclude infectious mononucleosis
- acute CMV infection: serology (CMV IgM) may be useful in diagnosing acute CMV infection (does not usually present with posterior cervical lymphadenopathy as seen in acute EBV infection)
- HSV infection
- malaria
- toxoplasmosis infection
- flavivirus/leptospirosis (**always** ask travel history and occupation)
- other causes of hepatitis:
 - alcohol (AST and ALT very rarely rise above 350 IU when solely due to alcohol)
 - mycoplasma pneumonia is an important differential not to miss (often treatable with antibiotics of the macrolide class)
 - drug-induced liver injury
 - autoimmune hepatitis
 - ischaemic hepatitis

'Gold-standard' diagnostic tests

Most viral hepatitis can be readily diagnosed on serological testing.

'Gold-standard' diagnostic test for hepatitis A

Acute infections can be diagnosed on testing hepatitis A IgM. This antibody appears within 8 weeks of the acute illness, may persist for

3–6 months, and clears with the end of jaundice. Hepatitis A IgG indicates immunity either from past infection or through vaccination.

'Gold-standard' diagnostic test for hepatitis B

Hepatitis B testing is complex. To understand the test, it is worth reviewing the structure of the virus and immune response of the host.

HBV is part of the hepadnavirus family, and the complete virus is called the 'Dane particle.' The virus particle consists of an outer lipid envelope and a nucleocapsid core. The nucleocapsid encloses the viral DNA and a viral DNA polymerase bearing reverse transcriptase activity.

There are four known HBV genes: C, X, P, and S. The core protein, HBcAg, is encoded by C. HBcAg cannot be detected in the serum. Upstream to the start codon for the core protein is the coding region for what is known as the 'pre-core' protein. HBeAg is produced by proteolytic processing of the pre-core protein. The DNA polymerase is encoded by P. S is responsible for encoding HBsAg.

About 5–6 weeks following acute hepatitis B infection, the HBsAg titre begins to rise (see Figure 212.1). A level of the HBsAg titre persisting for >6 months indicates chronic infection (see 'Chronic HBV infection'). Once an individual has been identified as HBsAg positive, the HBeAg status should be checked. This begins to rise about 5–6 weeks following infection. HBeAg positivity is a marker of infectivity.

A certain percentage of individuals will not produce HBeAg, due to what is known as pre-core mutant disease. These individuals should have HBV DNA levels assessed as an alternate marker of infectivity. This phenomenon is more common in those who have received prior antiviral therapy (e.g. for coexisting retroviral disease).

IgM antibodies to HBcAg (HBc IgM) generally start to appear 7 weeks after the initial/acute infection. Anti-HBe should appear 15 weeks following infection. Anti-HBs begins to manifest 22 weeks after infection.

During the incubation period of acute infection, the patient will be positive for HBsAg and HBeAg. The acute viral hepatitis is evidenced by derangement of liver function in the presence of HBsAg, HBeAg, anti-HBc IgM, and, later, IgG. Anti-HBe may also be present.

Chronic carriers will bear HBsAg (>6 months after acute infection) and may or may not be HBeAg positive. Anti-HBc IgG should be present, but anti-HBe status is variable.

Recovery is evidenced by anti-HBs, anti-HBe, and anti-HBc (anti-HBc IgM will only remain positive in the acute recovery phase; anti-HBc IgG will remain positive for life). A previously vaccinated individual should only be anti-HBs positive, with anti-HBc and anti-HBe being negative.

A summary of hepatitis B serology is outlined in Table 212.2.

The gold standard for identifying HBV infection (acute or chronic) is an HBsAg test. Following a diagnosis of chronic HBV infection, infectivity should be assessed by determining HBeAg and HBV DNA titres.

'Gold-standard' diagnostic test for hepatitis C

The diagnosis of hepatitis C is rarely made during the acute phase of the disease because the majority of people infected experience no symptoms during this period. The diagnosis of chronic phase hepatitis C is also challenging due to the absence or lack of specificity of symptoms until advanced liver disease develops. This may not occur for many years.

Chronic hepatitis C is usually suspected based on previous medical history and usually begins with serological testing (via an ELISA) to detect antibodies to hepatitis C (anti-HCV). These antibodies usually appear 3–5 months following acute infection in up to 80% of individuals. The pick-up rate approaches 100% at 6 months into the disease. Although anti-HCV antibodies have a strong positive predictive value for exposure to hepatitis C, they cannot determine the presence of ongoing infectivity and tests for these antibodies may fail to identify a significant number of individuals who have not yet undergone, or in the process of undergoing, seroconversion. In addition, the ELISA, although highly sensitive, is not terribly specific and yields many false-positive results. Moreover, the antibody that is detected by the ELISA is non-neutralizing and so does not signal immunity.

HBsAg: hepatitis B surface antigen
 HBeAg: hepatitis B e antigen
 Anti-HBc IgM: IgM antibody to hepatitis B core antigen
 Anti-HBs: antibody to hepatitis B surface antigen
 Anti-HBe: antibody to hepatitis e antigen.

Figure 212.1 Hepatitis B antigens and serology in acute infection and recovery; Anti-HBc IgM, IgM antibody to hepatitis B core antigen; Anti-HBe: antibody to hepatitis e antigen; Anti-HBs, antibody to hepatitis B surface antigen; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen.

The diagnosis of hepatitis C should be confirmed in cases with positive serology by PCR testing for circulating viral RNA. In acute HCV infection, or in those patients who are profoundly immunosuppressed, anti-HCV antibodies may not be detected; if clinical suspicion remains high, then confirmation should be sought with HCV RNA testing.

Gold-standard’ diagnostic test for hepatitis D

As HDV can only be present with the aid of HBV, initial testing in the workup of liver disease is not needed. Hepatitis D should be suspected in any individual who has had long-standing, stable hepatitis B but suddenly deteriorates. Antibodies to hepatitis D can be detected (via an ELISA) in serum or plasma samples; the presence of these antibodies correlates with ongoing viral replication. PCR can also be performed to detect the presence of viral RNA.

Gold-standard’ diagnostic test for hepatitis E

There should be a high index of suspicion of hepatitis E for anyone who has travelled to an endemic area and presents with a hepatitis A-like illness that is HAV-IgM negative. Commercial ELISAs are also available in specialist centres for detecting antibodies against HEV.

Table 212.2 Hepatitis B serology

	Acute infection	Chronic carrier	Recovered	Vaccination
Anti-HBc	+	+	+	-
HBsAg	+	+	-	-
Anti-HBs	-	-	+	+
HBeAg	+	+/-	-	-
Anti-HBe	+/-	+/-	+	-

Abbreviations: anti-HBc, antibody to the hepatitis B core antigen; anti-HBe, antibody to the hepatitis e antigen; anti-HBs, antibody to the hepatitis B surface antigen; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen.

Acceptable diagnostic alternatives to the gold-standard tests

As most assays for hepatitis A, B, and C are widely available throughout the UK, alternatives to the investigations already mentioned are rarely necessary.

Acceptable diagnostic alternatives to the gold-standard test for hepatitis B

The issue of pre-core mutant disease and HBeAg negativity in the presence of active disease has already been touched upon. In this situation, testing for HBV DNA serves as an alternative for signalling infectivity.

Histological analysis serves as a useful tool to guide treatment and assess the severity of liver damage; however, liver biopsy with staining for HBV is seldom needed to make a diagnosis.

Acceptable diagnostic alternatives to the gold-standard test for hepatitis C

Second-generation serological tests for HCV are more reliable than earlier tests. All individuals who are anti-HCV positive should be referred for specialist hepatology intervention, staging of disease, and suitability for genotype testing and treatment. Treatment must be guided by initial and subsequent estimation of circulating viral RNA levels, and by the specific genotype or subtype of virus causing the infection.

Other relevant investigations

All individuals who test positive for hepatitis B or hepatitis C should have a full assessment detailing travel history, sexual practices, IV drug use, social habits involving needles (e.g. body art, tattoos, piercings), previous transfusions, and any significant family history. Social circumstances should also be discussed (e.g. sharing of razors, cutlery, crockery, and toothbrushes). Once a diagnosis of hepatitis B is made, testing for hepatitis C co-infection is mandatory (and vice versa).

Liver biopsy

Liver biopsy in hepatitis B

Although a liver biopsy is not needed to establish the diagnosis of hepatitis B, it is important for assessing the severity of inflammation, particularly as some treatment modalities can exacerbate hepatic inflammation.

Liver biopsy in hepatitis C

In hepatitis C, assessment of liver disease severity is recommended prior to starting therapy. Identifying patients with cirrhosis is of particular importance, as their likelihood of responding to therapy, and post-treatment prognosis, are altered. Significant fibrosis may be present in patients with repeatedly normal ALT; thus, evaluation of disease severity should be performed, regardless of liver biochemistry. Based on the available evidence, current guidelines advocate using alternative, non-invasive methods (such as transient elastography (Fibroscan®)) of assessing the severity of fibrosis in patients with chronic HCV infection, reserving liver biopsy for difficult or indeterminate cases.

Liver biopsy and cirrhosis

The presence of cirrhosis identifies the subgroup of patients with chronic viral hepatitis most likely to develop complications of chronic liver disease and HCC.

Additional investigations

Additional investigations worth noting once a diagnosis of hepatitis B or C are made include:

- HIV testing (document any reasons why this has not been done)
- sexual health screening, and screening for other sexually transmitted disease, where appropriate
 - investigations to exclude other etiologies of chronic liver disease; perform a liver ultrasound and appropriate follow-up, depending on the results

Prognosis and how to estimate it

Prognosis for hepatitis A

Hepatitis A usually has a self-limiting course with no long-lasting sequelae. As a result, most patients have an excellent prognosis with long-lasting immunity. Acute liver failure is rare, with cases confined to those having underlying chronic liver disease of another aetiology.

Prognosis for hepatitis B

Most adults with acute HBV infection have a self-limiting illness, developing full immunity. Chronicity is commoner in those who acquire infection as newborns (>90% chronicity) as a result of vertical transmission. These individuals do not tend to develop immunity.

Sixty per cent of chronic carriers may not have active inflammation with normal levels of transaminases. Markers of infectivity may be negative. In contrast, those with marked inflammation have a mortality approaching 50% in 5 years and may progress to cirrhosis. Furthermore, 20%–30% of inactive carriers may develop reactivation of HBV.

Morbidity and mortality in chronic HBV are linked to persistence of viral replication and evolution to cirrhosis. Cirrhosis is a cardinal factor leading to the development of HCC, which has an annual incidence of 2.5%–8.0%. Non-cirrhotic patients with chronic HBV infection may also be at risk (0.2% annual incidence of HCC), as HBV is able to integrate into the human genome and is believed to be pro-oncogenic. The incidence rises in the presence of coexisting HCV.

The 5-year cumulative incidence of developing cirrhosis ranges from 8% to 20%. The 5-year cumulative incidence of hepatic decompensation is approximately 20% for untreated patients with compensated cirrhosis. Untreated patients with decompensated cirrhosis have a poor prognosis, with a 14%–35% probability of survival at 5 years.

Prognosis for hepatitis C

Acute hepatitis C is usually an asymptomatic illness; however, progression to chronic infection is frequent. Cirrhosis occurs over

20 years in up to 20% of those with chronic infection; this figure is higher in those with coexisting liver disease of other etiologies (e.g. alcohol). Many factors will enhance this process:

- excessive alcohol
- coexisting fatty liver disease
- HIV co-infection
- hepatitis B co-infection
- coexisting liver disease of any aetiology

HCC develops in 2%–8% of those with cirrhosis each year after an average of 30 years. The worldwide incidence of HCC has increased, mostly due to persistent HBV and/ or HCV infections; presently, it constitutes the fifth-most-common cancer, representing around 5% of all cancers.

Prognosis for hepatitis E

Hepatitis E usually causes an acute, self-limiting illness which does not progress to chronic carrier status. There is, however, a high case fatality rate in pregnant women (mostly those in their second and third trimesters), with death usually resulting from fulminant hepatic failure resulting in encephalopathy and disseminated intravascular coagulation. The overall mortality rate is in the order of 1%–4%.

Treatment and its effectiveness

In discussing the various treatment options of viral hepatitis, one should differentiate between treatment of the acute infection, treatment of the chronic infection (if appropriate), and vaccination. All types of viral hepatitis in the acute setting are notifiable diseases.

Treatment of hepatitis A

Acute HAV infection

No specific treatment of acute HAV infection is necessary, as most individuals settle on their own. Hospital admission is rarely needed unless there are complications of significant hepatic failure (evidenced by encephalopathy, coagulopathy, etc.). Prevention against transmission of contacts is essential (good sanitation and cleanliness is key; avoid contact with bodily fluids). Contact tracing should include all household contacts, sexual partners, and those who share washroom facilities with the patient. Patients should be advised to abstain from alcohol (until liver function returns to a normal level) and other known hepatotoxic substances.

Vaccination for HAV

There are two forms of vaccination for HAV. The first is active immunization with live-attenuated and killed vaccines. This form is offered to those travelling to endemic areas, those in the military, childcare workers, and other high-risk individuals. The second form is passive immunization with human immunoglobulin. With this form, immunity lasts for 3–4 months. This form can be offered to those with acute hepatitis A and those travelling to endemic areas but who not able to complete the full immunization schedule for active vaccination.

Immunoglobulin therapy has not been shown to be of any additional benefit in changing the outcome in immunocompetent patients.

It is thought to be good practice that all individuals with retroviral disease and chronic liver disease should be screened and offered vaccination if they are non-immune, although the evidence and cost-effectiveness of this approach is a topic for academic debate.

Treatment of hepatitis B

Acute HBV infection

Most cases of acute HBV are self-limiting, and individuals should adopt the same measures as for acute HAV infection. Fewer than 1% of patients may develop a severe acute hepatitis (usually those with coexisting liver disease or immunosuppression). These individuals may require antiviral therapy to suppress active viral replication. Interferon (see 'To treat or not to treat') should be avoided in this situation, due to the risk of the patient developing fulminant liver failure.

Chronic HBV infection

Indications for treatment in chronic HBV infection depend on the serum HBV DNA titre, serum transaminase levels, fibrosis stage, presence of coexisting disease (e.g. HIV or HCV), and patient choice. The specific regimen is determined by evolving protocols developed in specialist hepatitis clinics.

To treat or not to treat?

Patients who are chronic carriers (HBeAg positive or not) bearing a high viral load ($> 10^5$ ml⁻¹) and evidence of hepatic damage (elevated transaminases for 6 months, or liver biopsy showing active inflammation) should be considered for therapy. All patients with evidence of chronic HBV infection and cirrhosis mandate treatment. All patients with co-infection (HCV/HIV) also require treatment. All those with HBV/HCV or HBV/HIV co-infection should be considered for anti-HBV treatment.

Carriers with normal liver biochemistry, negative HBeAg, positive anti-HBe, and non-detectable/low-level DNA titres need not receive antiviral therapy, as low levels of hepatitis B DNA are not associated with progressive liver disease. These patients should, however, be followed up in the long term with regular (3–4 monthly) assessment of liver biochemistry and HBV DNA levels.

Patients who are HBeAg negative and have evidence of active disease at lower HBV DNA levels may, under specialist supervision, require therapy if they have elevated liver enzymes or there is histological proof of active disease.

Regular-interval ultrasound screening, together with alpha-feto-protein tests, is recommended for patients who are cirrhotic and at risk of HCC, although a false-positive raised alpha-fetoprotein level is not uncommon in cirrhotic patients. Regular surveillance for the development of HCC is also recommended for the following categories of non-cirrhotic individuals who have chronic hepatitis B:

- Asian male HBV carriers above the age of 40, and Asian female HBV carriers above the age of 50
- hepatitis B carriers with a family history of HCC
- African or North American blacks with chronic hepatitis B and who are above the age of 20

Effective antiviral therapy must ensure a degree of virological suppression, biochemical remission, histological improvement, and prevention of complications. Although HBsAg seroconversion is extremely rare (<15% of cases), long-lasting immunity and remission are likely if this end point is achieved. Additional target end points of therapy include:

- durable anti-HBe seroconversion in those who are HBeAg positive (serological remission)
- sustained biochemical remission (normal ALT levels)
- maintained virological response, as defined by HBV DNA <2000 IU/ml.

Durable HBV DNA suppression also increases the likelihood of HBe seroconversion in HBeAg-positive patients, and the possibility of HBsAg loss in HBeAg-positive and HBeAg-negative patients.

Drugs for treating chronic HBV infection

At present, there are three main drug classes for the treatment of chronic HBV infection: interferon (IFN), nucleoside analogue reverse transcriptase inhibitors (e.g. lamivudine, entecavir), and nucleotide analogue reverse transcriptase inhibitors (e.g. adefovir, tenofovir). Treatment practice varies and combination regimens of two agents may be given by some.

IFN Interferon alpha is usually indicated in cases of HBeAg positivity with evidence of significant necroinflammatory activity. IFN enhances clearance of HBV while improving the immune response. Controlled studies of conventional IFN have shown that a 4–6-month course achieves HBeAg loss in 29%–32% of HBeAg-positive patients compared with 12% of controls. Seroconversion is sustained in 80% of cases. The standard IFN formulation used (IFN- α_{2b}) has largely been replaced by pegylated IFN- α_{2b} in routine practice. A recognized side effect of interferon is the emergence of flares of acute disease. This can be seen in 25%–40% of patients with IFN treatment and is due to the stimulatory effect of IFN, which is capable of increasing T-cell cytolytic activity and natural killer cell function. Predictors of flares during IFN treatment include preexisting cirrhosis and initial low levels of ALT.

Nucleoside/nucleotide analogues Lamivudine directly inhibits viral replication (via reverse transcriptase) without stimulating the immune response. Lamivudine significantly reduces viral DNA and normalizes liver function tests. It has few side effects and rarely leads to flares of hepatitis. For this reason, it is particularly useful for those with cirrhotic liver disease but for whom IFN is contraindicated. Lamivudine is effective for a combination virologic and biochemical response, and demonstrates histological improvement in both HBeAg-positive and HBeAg-negative patients. The incidence of lamivudine resistance, however, increases with a greater duration of time spent on therapy, and peaks at 80% after 5 years of treatment. Lamivudine is not recommended as a first-line therapy for this reason.

Adefovir inhibits both reverse transcriptase and DNA polymerase activity. Like lamivudine, adefovir has few side effects, but the resistance rates are relatively low (<2% per year). Adefovir also has the advantage of suppressing lamivudine-resistant disease. The major disadvantage is that the drug is nephrotoxic (this is a dose-dependent effect).

Entecavir is a potent selective inhibitor of HBV polymerase and has shown superiority to lamivudine in pivotal Phase III randomized controlled trials. Resistance rates in treatment-naïve patients over 2 years are low. Entecavir is effective in lamivudine-refractory patients, but exhibits higher rates of resistance.

Tenofovir exerts strong and early suppression of infection of HBV with or without lamivudine-associated mutations. It is more potent than adefovir, without the associated renal toxicity: results from multicentre, randomized, adefovir-controlled trials in HBeAg-positive patients showed that tenofovir has better efficacy with respect to histological improvement, viral suppression, ALT normalization, and HBeAg seroconversion, and it achieved a virologic and histological response in a higher proportion of HBeAg-negative patients.

The efficacy of each of the drugs mentioned is variable (see Tables 212.3a–c), and it is not uncommon to use a combination of agents in order to achieve treatment end points. Treatment rationale is largely based on the presence of HBeAg status, viral load, and the severity of liver injury (inflammatory activity and fibrosis). Predictors of anti-HBe seroconversion include:

- the pretreatment viral load (HBV DNA $< 2 \times 10^8$ IU/ml)
- a decrease of HBV DNA levels to $< 20\,000$ IU/ml at 12 weeks of treatment with pegylated IFN alpha (PEG-IFN α) regimens, or an undetectable viral load at 24 weeks of treatment with regimens based on nucleoside/nucleotide analogues
- high pretreatment ALT levels (2–5 \times the upper limit of normal) and/or high inflammatory activity on liver histology
- a decline of HBsAg levels below 1500 IU/ml at 12 weeks of treatment (in contrast, an HBsAg level $> 20\,000$ IU/ml or no decline of HBsAg levels at 12 weeks is associated with a very low probability of subsequent anti-HBe seroconversion)

Treatment duration with peg-interferon alpha is finite, usually for 48 weeks, and restricted to well-compensated, non-cirrhotic individuals. Notably, IFN therapy is contraindicated in pregnancy. By contrast, monotherapy with nucleoside/nucleotide analogues (usually entecavir or tenofovir) is often continued indefinitely, with the aim of suppressing viral replication to undetectable levels. Peg-interferon alpha is also the only medication of proven efficacy in treating HDV, although the optimal duration of treatment in this setting is unclear.

Transplantation is an option for HBV-induced cirrhosis and end-stage liver disease, but antiviral cover will be needed to prevent recurrence in the graft. The use of anti-HBV immunoglobulin during and after the transplant period dramatically reduces the recurrence rate of HBV infection.

Vaccination for HBV

Active immunization against HBV has been available since the 1980s and the vaccine has evolved to consist of modified surface antigen proteins. It is a three-course vaccine, given at 0, 1, and 6 months. The efficacy of the vaccine has been quoted to reach up to 90% following the full course. About one-fifth to one-third of those vaccinated will have a drop in antibody titre below critical protective levels within 5 years, necessitating booster therapy at 5–10 yearly intervals.

Active immunization is recommended for:

- contacts of those with acute hepatitis B
- patients undergoing dialysis

Table 212.3a Treatment efficacy in HBeAg-positive patients

	PEG-IFN α	Nucleoside analogues		Nucleotide analogues	
		Lamivudine	Entecavir	Adefovir	Tenofovir
Anti-HBe seroconversion (%)	29–32	16–18	21	12–18	21
HBsAg loss (%)	3–7	0–1	2	0	3
Biochemical remission (%)	32–41	41–72	68	48–54	68
HBV DNA <60–80 IU/ml (%)	7–14	36–44	67	13–21	76

Abbreviations: HBV, hepatitis B virus; PEG-IFN α , pegylated interferon alpha.

Note: Values provided are in per cent of patients.

Data from EASL practice guidelines (see 'Further reading').

Table 212.3b Treatment efficacy in HBeAg-negative patients

	PEG-IFN α	Nucleoside analogues		Nucleotide analogues	
		Lamivudine	Entecavir	Adefovir	Tenofovir
HBsAg loss (%)	4	0	0	0	0
Biochemical remission (%)	59	71–9	78	72–7	76
HBV DNA <60–80 IU/ml (%)	19	72–3	90	51–63	93

Abbreviations: HBV, hepatitis B virus; PEG-IFN α , pegylated interferon alpha.

Data from EASL practice guidelines (see 'Further reading').

Table 212.3c Pegylated interferon alpha versus nucleoside/nucleotide analogues: Advantages and disadvantages

	Pegylated interferon alpha	Nucleoside/nucleotide analogues
Advantages	Finite duration No resistance High rates of anti-HBe and anti-HBs seroconversion	Well tolerated Potent antiviral effect Oral administration route
Disadvantages	Subcutaneous injections Poorly tolerated Risk of adverse events	Usually indefinite duration of treatment Long-term safety issue and risk of resistance

Data from EASL practice guidelines (see 'Further Reading').

- haemophiliacs and those receiving regular blood products
- individuals in high-risk professions (healthcare personnel, those in endemic areas, prisoners and prison staff, and those who work in laboratories)
- sex workers and others at high risk of sexually transmitted diseases
- those with chronic liver disease

Acute HBV exposure in non-vaccinated individuals who are immunocompromised requires passive immunization with anti-HBV immunoglobulin. This may be administered with the first dose of vaccine (given at a separate site). Infants of hepatitis B mothers should receive the immunoglobulin and full active vaccine course, with the first dose given at birth.

Guidelines regarding healthcare professionals and hepatitis B

The goal of assessing a healthcare professional identified as being HBV positive is to determine infectivity and hence risk of transmission to co-workers and patients. Healthcare professionals identified as being HBsAg positive should have their HBeAg titres checked. Should they be positive for HBeAg, then restrictions upon practice will be imposed on them (especially against exposure-prone procedures).

If a healthcare professional is anti-HBe negative or has HBeAg negativity, the HBV DNA level should be checked. If viral DNA titres are $>10^3$ ml $^{-1}$, then restrictions should be imposed. Those whose viral DNA load does not exceed 10^3 ml $^{-1}$ and who are HBeAg negative need not have restrictions imposed, **but** should have retesting performed every 12 months.

Healthcare workers with chronic HBV infection and who are responsible for undertaking exposure-prone procedures should be treated if they are HBeAg positive or if the HBV DNA load is $>10^3$ ml $^{-1}$. Healthcare workers should not perform exposure-prone procedures while on IFN or on antiviral therapy. Individuals having undergone any treatment with IFN or antivirals need to show that they have a viral DNA load not exceeding 10^3 ml $^{-1}$ 1 year after stopping therapy before returning to unrestricted practice.

Treatment of hepatitis C

Acute HCV infection is difficult to detect; however, given the high rates of chronicity, individuals with HCV infection, when identified, should be considered for antiviral treatment. In contrast to the response during chronic infection, response rates during the acute phase can be as high as 90% when treatment is initiated within the first 2–4 months.

In chronic HCV infection, the primary goal of treatment is to eradicate HCV infection in order to prevent the complications of HCV-related chronic liver disease. Extra-hepatic manifestations such as mixed (type III) cryoglobulinemia may also respond to hepatitis C treatment. Specific end points include:

- achievement of a sustained virologic response (SVR), which is defined as viral levels persistently undetectable within 12 weeks (SVR12) or 24 weeks (SVR24) months after the end of therapy; achievement of SVR has shown to be a reliable indicator of viral clearance
- preventing decompensation to cirrhosis, end-stage liver disease, or HCC.

Treatment is indicated for all treatment-naïve and treatment-experienced patients with compensated and decompensated liver disease. Priority for treatment is given to:

- patients with significant fibrosis or established cirrhosis, including decompensated disease
- patients with HIV co-infection
- patients with HBV co-infection
- patients with an indication for liver transplantation
- patients with recurrence of HCV infection after liver transplantation
- patients with clinically significant extra-hepatic manifestations
- patients with debilitating fatigue
- individuals at risk of transmitting HCV (active IV drug users; men who have sex with men with high-risk sexual practices; women who are of childbearing age and wish to get pregnant; haemodialysis patients; incarcerated individuals)

Table 212.4 Virological response classification in chronic hepatitis C infection while on treatment

Classification	Description
Rapid virological response	Undetectable HCV RNA at Week 4 of treatment, maintained until the end of therapy
Early virological response	HCV RNA detectable at Week 4 but undetectable at Week 12, maintained up to end of treatment
Delayed virological response	More than 2 log ₁₀ drop but detectable HCV RNA at Week 12; HCV RNA undetectable at Week 24, maintained up to end of treatment
Partial non-response	More than 2 log ₁₀ IU/ml decrease in HCV RNA level from baseline at 12 weeks of therapy, but detectable HCV RNA at Weeks 12 and 24
Non-response	Less than 2 log ₁₀ IU/ml decrease in HCV RNA level from baseline at 12 weeks of therapy
Virological breakthrough	Reappearance of HCV RNA at any time during treatment after virological response
End-of-treatment response	Undetectable HCV RNA at the end of treatment (24 weeks with G2/3 patients, and 48 weeks with G1 patients)
Relapse	Detectable HCV RNA within 6 months of stopping therapy after a previous EOTR
Sustained virological response	Undetectable HCV RNA level till 6 months after treatment course completed

Abbreviations: EOTR, end-of-treatment response; G1, genotype 1; G2, genotype 2; G3, genotype 3; HCV, hepatitis C virus.

Note: Applicable to pegylated-interferon and ribavirin regimens.

Additionally, moderate fibrosis is a justification for treatment, whereas treatment can be deferred in those with no or very mild disease on biopsy, or non-invasive fibrosis and an absence of extra-hepatic manifestations.

Historically, the drugs used to treat chronic HCV infection were restricted to PEG-IFN α and oral ribavirin. The major side effects with ribavirin are haemolysis, rapid development of anaemia, and thrombocytopenia. For anaemia, ribavirin dose reduction and/or the use of erythropoietin is the preferred management approach. Other side effects include rash, glossitis, and nausea. Side effects of IFN can be profound and, for unknown reasons, develop more commonly in patients with HCV than in those with HBV. Commonly recognized side effects include flu-like symptoms, lethargy, headaches (up to 55%), severely altered mood, and depression. In contrast to the case in patients with hepatitis B, cirrhotic liver disease is not a contraindication to IFN therapy in hepatitis C, provided there are no signs of decompensation.

Before initiating treatment, the genotype of the virus with which the patient is infected should be sequenced. This is essential when evaluating an individual's response to treatment, and in determining the duration of therapy. Although six HCV genotypes have been classified, only the first three will be discussed here:

- patients infected with genotype 2 or genotype 3 (commoner in the USA) have a higher chance of achieving SVR (65%–82%) than those infected with genotype 1, and treatment is usually administered for 24 weeks
- genotype 1 (the commonest strain in the UK) is harder to eradicate and generally requires a 48-week course of treatment; moreover, SVR rates were, up until recently, only 40%–46% with standard treatment; however, with the advent of newer agents and advanced translational research, success rates approaching those seen in patients infected with genotype 2 or 3 are now being seen

In addition to HCV genotype, other predictors of SVR, particularly for patients infected with genotype 1, include:

Favourable genetic polymorphisms near the gene L28B: IL28B encodes for the protein interferon lambda-3 (IFN- λ 3). Both IFN- λ and IFN- α activate the same intracellular pathway, which results in expression of many IFN-stimulated genes. Individuals who are infected with genotype 1, are of European ancestry, and carry the favourable CC alleles have been reported to achieve SVR rates as high as 69%, whereas those with CT alleles achieve an SVR rate of 33%, and those with TT alleles achieve a rate of 27%. The CC polymorphism also confers a higher rate of disease response and lower rates of disease relapse in individuals infected by genotypes 2 or 3.

Baseline HCV RNA levels: Lower baseline HCV RNA levels (<400 000–800 000 IU/ml) are associated with higher rates of SVR.

On-treatment virological response: While the patient is on treatment, HCV RNA should be assessed at baseline, Week 4, Week 12, Week 24, and, if continued, Week 48. HCV RNA should also be assessed during the 6 months after the treatment course has been completed, in order to assess SVR. The likelihood of achieving SVR is directly correlated to the time taken to achieve viral negativity

(<50 IU/ml; see Table 212.4), being greatest in those patients who achieve a rapid virological response (i.e. viral negativity at 4 weeks of treatment). Treatment durations may be modified based on the virological response; however, a detailed discussion of this area is beyond the scope of this book.

Body mass index: Body weight reduction prior to therapy is recommended and has been associated with better SVR rates.

Insulin resistance: Insulin resistance is associated with fibrosis progression, and an increased HOMA-IR index is an independent predictor of treatment failure.

Race: Black patients are less likely to respond to therapy; this is explained in part by a lower frequency of the favourable IL28B polymorphism in this population.

Until 2011, the combination of PEG-IFN α and ribavirin for 24 or 48 weeks was the approved treatment for chronic hepatitis C. With this regimen, patients infected with HCV genotype 1 had SVR rates of approximately 40%–50%; higher SVR rates were achieved in patients infected with HCV genotypes 2, 3, 5, or 6 (60%–80%), and intermediate SVR rates were achieved in those with HCV genotype 4. However, treatment algorithms are rapidly evolving and heavily influenced by ongoing clinical trials. To this effect, newer generation protease inhibitors, polymerase inhibitors, and inhibitors of HCV RNA replication (e.g. NS5A inhibitors) have entered clinical practice, and enable SVR rates of 80%–95% as part of durable, IFN-free regimens (see Tables 212.5, 212.6, and 212.7) with a limited side-effect profile.

Orthotopic liver transplantation is the treatment of choice in anyone who has end-stage liver disease and, in fact, is the leading cause for transplantation in the US. Recurrence of hepatitis C is almost universal, with progression to fibrosis or cirrhosis occurring in 10%–30% within 5 years of transplantation. Once cirrhosis develops post transplant, complications tend to occur more rapidly than in the native liver. Viral re-entry inhibitors are currently being evaluated in early phase clinical trials, and it is hoped that they will be of benefit in treating HCV infection of the donor liver.

Vaccination for HCV

There is no effective hepatitis C vaccine at present. IV drug users should be advised to use clean needles if they refuse to abstain from

Table 212.5 Emerging antiviral therapies for chronic hepatitis C virus infection

Drugs	Mechanism of action
Simeprevir Paritaprevir	Inhibits the protease NS3/4A
Daclatasvir Ledipasvir Ombitasvir	Inhibits the non-structural protein NS5A responsible for viral replication
Sofosbuvir Dasabuvir	A pro-drug, the metabolite of which serves as a defective substrate for NS5B; a protein involved in viral replication
Ritonavir	Booster of other proteases (CYP3A4 inhibitor)

Table 212.6 Approved recommendations for chronic hepatitis C virus infection (for treatment-naïve patients and those with prior treatment failure with pegylated interferon alfa and ribavirin) **without cirrhosis**

their habit. Vaccination against HAV and HBV is recommended to all those at high risk, to prevent co-transmission.

Treatment of hepatitis B and C co-infection

Most patients in this category have quiescent hepatitis B, and antiviral therapy needs to be directed toward hepatitis C only. If both are active, then the individual should be on the recommended treatment regimens for HBV and HCV, bearing in mind the potential for drug–drug interactions. A flare of clinical hepatitis is not unusual when treating patients with hepatitis B.

213 Autoimmune hepatitis

Satish Keshav and Alexandra Kent

Definition of autoimmune hepatitis

Autoimmune hepatitis (AIH) is a condition characterized by hepatic inflammation associated with elevated levels of circulating immunoglobulin and autoantibodies to hepatic antigens.

Aetiology of AIH

In AIH, human leukocyte antigen (HLA) Class II displayed on the surface of hepatocytes facilitates the presentation of normal liver cell membrane constituents to cytotoxic T-lymphocytes, which, in turn, infiltrate liver tissue, release cytokines, and destroy hepatocytes. Subsequently, AIH is characterized by raised transaminases, the presence of autoantibodies, raised IgG and, histologically, interface hepatitis. There are two types of AIH according to serology: Type 1 is characterized by the presence of antinuclear antibodies (ANAs) and/or anti-smooth muscle antibodies (anti-SMAs), whereas type 2 has the anti-liver–kidney microsomal type 1 antibody (anti-LKM). The immunological basis of AIH is further confirmed by its association with other autoimmune diseases (see Box 213.1) and response to steroids and immunosuppressive therapy.

The exact aetiology leading to the immunological response is unknown, although genetic and environmental factors are known to be involved.

Genetic factors in AIH

In Europe and the USA, susceptibility to AIH type 1 is conferred by the presence of HLA-DR3 and HLA-DR4, and AIH type 2 by HLA-DR7 and HLA-DR3. HLA-DR7 confers a more aggressive disease.

Environmental factors in AIH

Studies have suggested the immune response is triggered by viral infections (e.g. EBV, hepatitis A or B) or drug reactions (e.g. nitrofurantoin, interferon).

Typical symptoms of AIH, and less common symptoms

Patients can present with an acute hepatitis, chronic hepatitis, or established cirrhosis. Approximately one-third present with an acute hepatitis, with typical symptoms of jaundice, fever, and right upper quadrant tenderness. Rarely, AIH presents as acute fulminant hepatic

failure. Many patients have cirrhosis at presentation, with up to 20% of patients showing signs of decompensated liver disease. Many patients will present with a chronic hepatitis and be diagnosed following investigations into asymptomatic raised transaminases. Other symptoms associated with chronic hepatitis include fatigue, mild pruritus, anorexia, abdominal discomfort, myalgia, arthralgia, and amenorrhoea.

Demographics of AIH

The incidence of type 1 AIH is between 0.1 and 1.9 per 100 000 population per year, with a higher incidence in Northern Europeans. Type 2 AIH is more common in Southern Europe, the USA, or Japan; 70%–80% of patients are female, with the disease predominantly affecting children and young people. However, AIH can affect all ages and both genders, and therefore should be considered as a differential diagnosis in all patients presenting with deranged transaminases.

Natural history of AIH, and complications of the disease

AIH is a progressive disease and, without treatment, most patients will die within 10 years; 20%–40% of patients will progress to cirrhosis despite treatment with immunosuppression. However, patients who achieve clinical remission have the same life expectancy as that of the general population. Complications of AIH are mainly related to progressive disease and cirrhosis. However, AIH is associated with various other autoimmune conditions, and therefore patients may suffer with complications associated with these conditions (see Box 213.1). Hepatocellular carcinoma is less common in AIH cirrhosis than in other causes of cirrhosis, but is still recognized.

Approach to diagnosing AIH

The symptoms and signs of liver disease can be non-specific. The typical indicator of autoimmune liver disease is the presence of liver dysfunction and, therefore, all patients presenting with liver dysfunction should be tested for the following serological markers of autoimmune disease: ANA, anti-SMA, anti-mitochondrial antibody (AMA), anti-LKM, and perinuclear antineutrophil cytoplasmic antibody (pANCA). A combination of elevated IgG, liver damage, and hepatic autoantibodies (e.g. anti-SMA) is highly indicative of AIH. It is critically important to make the diagnosis of AIH, as early treatment can be life-saving.

Other diagnoses that should be considered aside from AIH

As AIH can be associated with acute or chronic hepatitis, many other causes of liver disease should be considered, as dealt with in Chapters 209 and 210. Histological features are those of acute or chronic hepatitis, with no features specific to the disease.

'Gold-standard' diagnostic test for AIH

The diagnosis of all autoimmune liver diseases is based on characteristic histological, serological, biochemical, and clinical findings. However, generally the gold standard required to diagnose AIH is considered to be a liver biopsy. Although a liver biopsy may not provide direct evidence of AIH, it helps exclude other diagnoses (e.g. viral or drug-induced hepatitis).

Box 213.1 Autoimmune diseases associated with autoimmune liver disease

- haemolytic anaemia
- pernicious anaemia
- Graves' disease
- autoimmune thyroiditis
- inflammatory bowel disease
- coeliac disease
- fibrosing alveolitis
- rheumatoid arthritis
- Sjögren's syndrome
- systemic sclerosis
- proliferative glomerulonephritis
- pericarditis
- myocarditis

Prognosis for AIH, and how to estimate it

Thirteen to twenty per cent of patients will have spontaneous resolution of disease, and it is impossible to predict these patients. However, without treatment most patients will die within 10 years; 20%–40% of patients will progress to cirrhosis despite treatment with immunosuppression. HLA-DR3-positive patients are more likely to have active disease, respond less to therapy, and are more likely to require liver transplantation at some point than patients with other HLA types.

Treatment of AIH, and its effectiveness

Indications for treatment of AIH are listed in Table 213.1. The standard treatment is high-dose prednisolone (60 mg per day), reduced slowly over the course of 6–8 weeks (usually by 5–10 mg per week), while monitoring liver function tests. It should be maintained at the lowest dose possible to reduce side effects. Patients requiring long-term steroid therapy should be commenced on azathioprine as a steroid-sparing agent. Immunosuppression has been shown to improve survival, achieving remission in 65% of patients within 18 months, and 80% of patients by 3 years. It is unknown how long treatment should be continued for before being withdrawn, and most centres would advocate a minimum of 2 years to allow for histological improvement, which lags behind clinical and biochemical improvement by 3–6 months. However, 80% of these patients relapse following drug withdrawal. Drug reinstatement is usually successful. There is limited evidence to support the use of alternative immunosuppressants including ciclosporin, tacrolimus, mycophenolate mofetil, cyclophosphamide, and methotrexate. Patients with decompensated cirrhosis should be referred for consideration of liver transplantation.

Primary biliary cholangitis

Definition of primary biliary cholangitis

Primary biliary cholangitis (PBC) is an autoimmune disease, characterized by destruction of the bile ducts, leading to cholestasis and progressive liver disease.

Aetiology of PBC

CD4 and CD8 lymphocytes mediate progressive destruction of small and medium bile ducts. The disease is autoimmune in nature, as evidenced by circulating autoantibodies (AMA), raised IgM, granulomas found in the liver and regional lymph nodes, and the association with other autoimmune diseases. It has been associated with haplotype HLA-DR8 and, for some populations, HLA-DPB1. There is a significantly increased risk in first-degree relatives (500–1000 fold), suggesting genetic factors play an etiological role, although no specific gene has been identified as yet. Increased expression of HLA Class II antigens makes hepatocytes more vulnerable to T-cell-mediated attack. The bile contains toxic substances (e.g. bile acids and copper), and this means that cholestasis results in further destruction of bile ducts and hepatocytes.

Typical symptoms of PBC, and less common symptoms

Twenty-five to fifty per cent of patients are asymptomatic and will be diagnosed after investigations into abnormal liver function tests. Presenting symptoms and signs include fatigue (30%–65%), pruritus

(20%–55%), hyperpigmentation (40%), right upper quadrant discomfort (10%–15%), hepatomegaly (25%), splenomegaly (15%), jaundice (10%), and sicca syndrome (50%). As the disease progresses, patients may present with signs and symptoms of chronic liver disease. Furthermore, they may have symptoms from associated autoimmune diseases.

Demographics of PBC

Ninety per cent of PBC sufferers are women, and they are commonly affected between the ages of 30 and 60. Epidemiological studies show 1 in 4000 people are affected, with 1 in 1000 women over the age of 40 years affected. The disease is more common in the UK and Scandinavia.

Natural history of PBC, and complications of the disease

PBC patients tend to be diagnosed at an earlier stage than in the past, and this means treatment is instituted earlier, with a resultant improvement in prognosis. However, PBC is a progressive disease, and the extent to which medication can slow progression varies between studies. Complications include osteoporosis, deficiency of fat-soluble vitamins, hypercholesterolaemia, steatorrhoea (related to reduced bile-salt excretion), and asymptomatic bacteriuria (35%). Symptoms from associated autoimmune conditions may occur, including hypothyroidism in 20% and autoimmune thrombocytopenia. Finally, symptoms and signs of chronic liver disease, and the associated complications occur, including hepatocellular carcinoma, which occurs in ~6% of PBC patients.

Approach to diagnosing PBC

Patients with PBC usually present with abnormal liver chemistry, in particular, with an elevated bilirubin. AMA is highly sensitive and specific for PBC. Early diagnosis of PBC allows appropriate monitoring, and prevention of complications of cirrhosis.

Other diagnoses that should be considered aside from PBC

The differential diagnosis of PBC includes causes of cholestasis, for example biliary obstruction (gallstones, pancreatic tumour, cholangiocarcinoma), primary sclerosing cholangitis, or sarcoidosis.

'Gold-standard' diagnostic test for PBC

The gold-standard diagnostic test for PBC is a liver biopsy, and would be advocated prior to commencing therapy. The majority of patients undergo percutaneous liver biopsies, but a transjugular approach can be used in high-risk situations (e.g. coagulopathy). Imaging does not provide diagnostic features of autoimmune liver disease, but is important in the setting of cholestatic liver tests in order to exclude biliary obstruction.

Prognosis of PBC, and how to estimate it

PBC is a progressive disease, and studies have shown the median time from diagnosis to death or liver transplantation is only 9.3 years. Factors associated with decreased survival include raised bilirubin, presence of cirrhosis, presence of associated autoimmune diseases, and loss of bile ducts. Bilirubin level is the most reliable determinant of prognosis:

- serum bilirubin >2 mg/dl (34.2 µmol/l): mean survival rate = 4.1 years
- serum bilirubin >6 mg/dl (102.6 µmol/l): mean survival rate = 2.1 years
- serum bilirubin levels >10 mg/dl (171 µmol/l): mean survival rate = 1.4 years

Treatment of PBC, and its effectiveness

Unfortunately, the treatment options for PBC are still limited. Ursodeoxycholic acid (UDCA) is the major treatment option for patients with PBC, being effective in up to 30% of patients. It has been shown to normalize liver function tests and slow disease progression in trials, reducing the need for liver transplantation or death.

Table 213.1 Indications for treatment in autoimmune hepatitis

Absolute	Relative
AST 10× upper limit of normal	AST or IgG less than absolute criteria
AST 5× upper limit of normal and IgG ≥2× upper limit of normal	Symptoms: fatigue, arthralgia, jaundice
Bridging or acinar necrosis on liver biopsy	Interface hepatitis

Abbreviations: AST, aspartate aminotransferase.

There have been many studies investigating the efficacy of immunosuppressants in PBC (cyclosporin, azathioprine, prednisolone, penicillamine, budesonide, chlorambucil) but, as yet, there is no evidence to support their use in patient care. In patients unresponsive to UDCA, methotrexate or colchicine is occasionally used, as studies have shown that these agents can provide an improvement in liver parameters. However, there is no evidence on survival benefit, and efficacy has not been duplicated in further trials.

Primary sclerosing cholangitis

Definition of sclerosing cholangitis

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease with obliterative inflammatory fibrosis of the bile ducts.

Aetiology of PSC

The exact aetiology of PSC is unknown, although bacteria, toxins, viral infections, and immunologic and genetic factors have all been proposed. Immune-mediated destruction of the hepatobiliary tract is the most likely cause, possibly secondary to transient bacterial infection. Supporting evidence for an immunological cause include an increased number of T-cells in the portal tracts, with a concurrent decrease in the total number of circulating T-cells, although the ratio of CD4 lymphocytes to CD8 lymphocytes in the circulation is increased. Furthermore, there is an increase in IgG and IgM, in 48% and 80% of patients, respectively, and 60%–82% of patients are positive for pANCA. There is a close association between PSC and inflammatory bowel disease (IBD), more specifically ulcerative colitis (UC). Only 3%–4% of patients with ulcerative colitis have PSC, but 75% of patients with PSC have UC. Studies have suggested a genetic component, with increased incidence in first-degree relatives, and it has been associated with HLA-B8 and HLA-DR3.

Typical symptoms of PSC, and less common symptoms

The presentation of PSC is variable, ranging from being asymptomatic, to presenting with non-specific symptoms of lethargy, fatigue, pruritus, abdominal pain, nausea, or fevers, to presenting with

cholestasis and associated cholangitis. Many patients are diagnosed following investigations into abnormal liver function tests or hepatomegaly, which is found in ~50% at presentation.

Demographics of PSC

PSC is a rare condition, with an incidence of <1 per 100 000, and is more common in Northern Europe, with a mean age of 40 years and a male predominance (70%).

Natural history of PSC, and complications of the disease

PSC is a progressive disease which will eventually develop into cirrhosis. Many patients will suffer with one or more complications related to biliary strictures, which may require endoscopic therapy. Cholangiocarcinoma develops in 10%–15% and there is no infallible method for cancer screening, with limited evidence for the use of the tumour marker CA 19-9, which can also rise during episodes of cholestasis. Furthermore, malignant strictures are often indistinguishable from PSC benign strictures. The risk of colorectal cancer in patients with concurrent UC and PSC is significantly higher, and patients should be entered into a colon surveillance programme (usually annual). Although liver transplantation can give tremendous relief of symptoms, PSC will recur in 10%–20% of patients.

Approach to diagnosing PSC

The diagnosis of PSC is usually made by imaging and predominantly occurs in the context of IBD.

Other diagnoses that should be considered aside from PSC

PSC should be differentiated from any cause of hepatitis or cholestasis.

'Gold-standard' diagnostic test for PSC

Endoscopic retrograde cholangiopancreatography used to be the most effective method for diagnosing PSC, but has now been superseded by MRI of the biliary tree, as this procedure has a much better safety profile. Classically, multiple strictures will be seen, separated by

Table 213.2 Investigations for autoimmune liver disease

	AIH	Primary biliary cholangitis	Primary sclerosing cholangitis
Transaminases	↑↑↑ (200–300 U/l)	Normal/↑	Normal/↑
Alkaline phosphatase	Normal	↑↑	↑↑↑
Bilirubin	Normal	Normal/↑↑	Normal/↑
Immunoglobulins	Raised IgG	Raised IgM	Raised IgG (48%) and IgM (80%)
Autoantibodies	Type 1: ANA, anti-SMA, anti-actin antibody, anti-SLA, anti-LPA, pANCA, AMA Type 2: anti-LKM, anti-liver cytosol-1	AMA (90%–95%) ANA (20%)	pANCA Anti-biliary epithelial cells (60%) AMA, ANA, anti-SMA
Histology	Mononuclear cell infiltrate, piecemeal necrosis, and bridging necrosis Majority will have some evidence of fibrosis Acute-onset AIH has more interface, lobular hepatitis, and necrosis, but less fibrosis and cirrhosis Steatosis is not common	Early damage of the bile duct basement membrane Reactive hyperplasia of the epithelial lining Lymphocytic and plasma cell infiltration, with eosinophilic condensation in the portal tracts Epithelioid aggregates or granulomas may be found Fibrosis and cirrhosis eventually develop	Periductal fibrosis with inflammation, bile duct proliferation, and ductopenia Periductal concentration of mononuclear cells and ductular proliferation Can resemble AIH
Other abnormal blood parameters's	Normochromic anaemia Mild leucopenia Eosinophilia Thrombocytopenia Raised ESR	Raised lipids and cholesterol Raised ESR	
Radiology	No specific diagnostic features	No specific diagnostic features	

Abbreviations: AIH, autoimmune hepatitis; AMA, anti-mitochondrial antibody; ANA, antinuclear antibody; anti-LKM, anti-liver–kidney microsomal type 1 antibody; anti-LPA, anti-liver–pancreas antigen antibody; anti-SLA, anti-soluble liver antigen antibody; anti-SMA, smooth muscle antibody; ESR, erythrocyte sedimentation rate; pANCA, perinuclear antineutrophil cytoplasmic antibody.

dilated segments, giving the biliary tree a beaded appearance. PSC is less well diagnosed on a liver biopsy, with findings often non-specific and non-diagnostic. However, it is useful to exclude other causes of cholestasis and for staging of the disease.

Prognosis of PSC, and how to estimate it

PSC is an insidiously progressive disease, with a median survival of 9–11 years from diagnosis, although in symptomatic patients this may be further reduced.

Treatment of PSC, and its effectiveness

Multiple treatments have been used in trials for the treatment of PSC, but with little success. The only medication currently used is UDCA, which can improve biochemical abnormalities, although the evidence for decreasing overall disease progression or improving survival is limited. More recently, evidence suggests that UDCA reduces the incidence of colorectal cancer, supporting its continuing use. Biliary strictures can be treated endoscopically with balloon dilatation or stent insertion, and associated cholangitis should be treated with antibiotics promptly. Patients often need nutritional and fat-soluble vitamin supplements. Patients should be observed closely for complications of chronic liver disease, and

referred early to tertiary centres for consideration of orthotopic liver transplant, which has been performed successfully in PSC patients.

Other relevant investigations for autoimmune liver disease

See Table 213.2 for a summary of investigations in autoimmune liver disease. As these diseases progress, investigations may reflect progressive liver disease with a reduction in synthetic function (low albumin, prolonged prothrombin time), excretory function (raised bilirubin), or portal hypertension (thrombocytopenia). In such situations, patients should also be screened for complications of chronic liver disease with upper gastrointestinal endoscopy for varices, and alpha-fetoprotein for hepatocellular carcinoma.

214 Genetic liver disease

Satish Keshav and Palak Trivedi

Introduction

This chapter will discuss three of the major inherited forms of liver disease (all autosomal recessive):

- hereditary haemochromatosis
- Wilson's disease
- alpha-1-antitrypsin deficiency

Hereditary haemochromatosis

Definition of hereditary haemochromatosis

Hereditary haemochromatosis is characterized by excessive absorption of dietary iron, with a pathological increase in total body iron that accumulates in tissues and organs, disrupting their function. The liver, adrenal glands, heart, pituitary, and pancreas are most affected. The disease is usually caused by mutations in the HFE gene, although similar conditions are now recognized, being caused by other genes that regulate iron absorption and distribution. Normal total body iron is approximately 4 g, with 3.5 g in circulating red blood cells, and the rest in the bone marrow, the reticuloendothelial system, including the liver, and other tissues such as muscle and nerves (Figure 214.1). Secondary haemochromatosis may occur, for instance with iron overload as a consequence of multiple transfusions. Excessive deposition of iron in the liver may also occur in liver disease due to alcohol excess and other etiologies; however, levels rarely exceed those found in hereditary haemochromatosis. Circulating ferritin levels generally reflect body iron stores, and a ferritin level consistently and repeatedly greater than 1000 $\mu\text{g/l}$ is almost pathognomonic of hereditary haemochromatosis and is rarely observed in any other condition.

Aetiology of hereditary haemochromatosis

Hereditary haemochromatosis is the commonest genetic disorder in the Caucasian population within the UK and the USA. The main gene responsible for the disorder is HFE, on Chromosome 6, which encodes an MHC Class-I related protein responsible for regulating iron absorption. The commonest mutations of the HFE gene in hereditary haemochromatosis are:

- C282Y: cysteine to tyrosine mutation at position 282; this mutation is present in almost 90% of patients with hereditary haemochromatosis

- H63D: histidine to aspartate mutation at position 63
- S65C: serine to cysteine mutation at position 65

The latter two mutations have less of a clinical effect than the first one but can present with first in a compound heterozygote. Genetic mutations in other iron transport proteins such as haemojuvelin and ferroportin may also lead to hepatic iron overload.

Typical symptoms of hereditary haemochromatosis, and less common symptoms

The manifestations of hereditary haemochromatosis are those of chronic iron overload but signs/symptoms may be difficult to differentiate from those for other diagnoses of specific organ systems; symptoms include:

- non-specific fatigue and malaise
- slate-grey pigmentation, or bronzing of the skin
- hepatomegaly
- liver cirrhosis with an increased risk of hepatocellular carcinoma (HCC)
- insulin resistance and type 2 diabetes due to pancreatic iron deposition (suspect in any individual who has diabetes and abnormal liver biochemistry, although non-alcoholic fatty liver disease is more commonly responsible for abnormal liver enzymes in this setting)
- erectile dysfunction, hypogonadism, and testicular atrophy, due to iron deposition in the pituitary gland
- cardiomyopathy, dysrhythmias, and cardiac failure
- arthritis and arthralgia, due to chondrocalcinosis, **not** iron deposition; usually present in the first and second metacarpophalangeal and proximal interphalangeal joints
- adrenal insufficiency due to deposition in the adrenal glands (occasional finding)

Given the increase in iron stores, affected individuals are prone to infections from siderophoric organisms such as *Yersinia enterocolitica* and *Listeria monocytogenes*, as well as salmonella and klebsiella pneumonia. In addition, hereditary haemochromatosis may be asymptomatic, in which case it can be diagnosed either from abnormal iron studies or from family screening. The clinical symptoms tend to manifest later in women than men (given the indirect venesecting effects of menstruation in the former). The age of presentation is between 40 and 50 years but may be much later. Physical findings may not manifest in early disease, and diagnosis may only be suspected on family history and results of investigations.

Figure 214.1 Iron distribution in the human body.

Demographics of hereditary haemochromatosis

The reported frequency of homozygosity of the C282Y mutation is 0.4%, although a frequency of up to 1% may be observed in Northern European populations. Due to the variable penetrance of this mutation, not all individuals have features of iron overload.

Penetrance is higher in men than women. Elevated liver enzymes are found in approximately 30% of males homozygous for C282Y; liver fibrosis in 18%; and cirrhosis in 6%. In contrast, 5% of females homozygous for C282Y may have liver fibrosis, and only 2% have cirrhosis. Anywhere between 10% and 33% of C282Y homozygotes eventually develop morbidity associated with hereditary haemochromatosis.

Natural history of hereditary haemochromatosis, and complications of the disease

Survival is normal if diagnosis has been made prior to the onset of irreversible liver damage. However, those who have established cirrhosis are at risk of developing HCC in up to 45% of cases. This is discussed in more detail in Chapter 218.

Approach to diagnosing hereditary haemochromatosis

Suspect hereditary haemochromatosis in any first-degree relative of a known case, or in any individual with abnormal liver function tests (LFTs) and diabetes. Iron studies should be part of the workup of any chronic liver disease screen; the most widely used biochemical surrogate for iron overload is serum ferritin.

Serum ferritin is usually >400 ng/ml in patients with clinical disease. The ferritin may be very high, over 1000 ng/ml, and this makes a presumptive diagnosis of hereditary haemochromatosis in the appropriate clinical setting. Ferritin is an acute phase protein, and values may be elevated in inflammatory states (e.g. Still's disease), sepsis, alcoholic excess, and acute hepatitis unrelated to hereditary haemochromatosis. Values greater than 1000 ng/ml, however, are unusual outside hereditary haemochromatosis.

In hereditary haemochromatosis, serum iron is high, the total iron binding capacity is low, and the transferrin saturation is >45%. However, serum iron concentration and transferrin saturation do not quantitatively reflect body iron stores and should therefore not be used as surrogate markers of tissue iron overload.

Other diagnoses that should be considered aside from hereditary haemochromatosis

Chronic viral hepatitis, certain porphyrias, non-alcoholic fatty liver disease, and excess alcohol intake can be associated with abnormal iron studies and may even have excess iron deposition in the liver. Iron deposition, however, is rarely in the quantities seen in hereditary haemochromatosis.

Non-alcoholic fatty disease is an important differential in an individual with deranged LFTs and diabetes mellitus. Another differential, African iron overload (Bantu haemosiderosis), was initially thought to be caused by excessive amounts of iron being ingested through the consumption of alcoholic beverages brewed in ungalvanized iron drums. However, there may also be a genetic element (not HFE) linked to the iron protein ferroportin.

Transfusion haemosiderosis is the accumulation of iron, mainly in the liver, in patients who receive frequent blood transfusions (e.g. thalassaemia). Another differential is myelodysplastic syndrome, which results in the disordered production of red blood cells. This leads to increased iron recycling from the bone marrow and accumulation in the liver.

'Gold-standard' diagnostic test for hereditary haemochromatosis

Should iron studies be abnormal, genetic studies looking for HFE mutations are the next step. If homozygosity for the C282Y is detected, or an individual is a compound heterozygote (C282Y/H63D) with normal liver chemistry **and** below 40 years, then no further tests are necessary.

Those older than 40 years or with abnormal liver chemistry **and** ferritin >1000 ng/ml should proceed to liver biopsy for determining

the extent of fibrosis/cirrhosis. Although the latter holds little prognostic value, it is important to ascertain as advanced histological liver disease warrants surveillance for oesophageal varices and HCC.

Liver biopsy with Perl's stain is diagnostic.

Other relevant investigations for hereditary haemochromatosis

CT scanning can detect excessive iron in massively 'iron-loaded' patients. Other investigations are specific to other organ involvement (e.g. echocardiography or cardiac MRI for myocardial involvement).

Prognosis for hereditary haemochromatosis, and how to estimate it

Most patients feel better after venesection, with marked improvement of constitutional symptoms. Survival can be normal if the diagnosis is made before irreversible liver damage has occurred. Liver enzymes improve typically on depletion of hepatic iron stores. Hepatomegaly may also resolve and a noticeable improvement in histology will be observed. Cardiac function may improve, although the presence of cardiac failure is a poor sign.

The following features may not improve despite venesection:

- advanced, already developed cirrhosis (with complications of decompensated liver disease) and the subsequent risk of HCC; these are the commonest reasons for death
- arthropathy
- hypogonadism
- diabetes mellitus; however, some degree of improvement in glycaemic control may be noticed once regular venesection has been commenced

Treatment for hereditary haemochromatosis, and its effectiveness

The mainstay of medical treatment for hereditary haemochromatosis is venesection, with initially twice-weekly phlebotomy with one whole unit of blood (each unit bearing ~200–250 mg of iron). The aims of treatment are:

- haematocrit <50%
- transferrin saturation <35%–40%
- ferritin <50 ng/ml

Once these targets have been achieved, venesection intervals can be prolonged (e.g. 2–3 monthly). Note that desferrioxamine (an iron-chelating agent) has been used to treat excess iron in the body but is not currently licensed for this use.

Complications from end-organ damage (e.g. heart failure) should be addressed. In addition, the following conservative treatment measures should be instituted:

- limit alcohol intake
- reduce intake of vitamin C (which enhances the gastrointestinal absorption of iron)
- increase intake of substances that inhibit iron absorption (e.g. tea (tannin) and calcium)
- vaccinate against hepatotropic viruses (hepatitis A and B)

Family screening for hereditary haemochromatosis

All first-degree relatives should be offered screening with genetic testing, transferrin saturation, and ferritin. Incomplete penetrance means not everyone with the genetic anomaly will develop iron overload. Venesection is indicated for the indications already outlined. Heterozygotes should only have liver biopsy if hepatic enzymes and iron studies are abnormal.

Wilson's disease

Definition of Wilson's disease

Wilson's disease (hepatolenticular degeneration) is an autosomal recessive genetic disorder in which copper accumulates in tissues. Wilson's may present primarily with neuropsychiatric features or with liver disease, and both typically coexist in patients.

Aetiology of Wilson's disease

The gene responsible for Wilson's disease is ATP7B on Chromosome 13. It encodes a transmembrane copper transport protein. Altered function of this gene impairs excretion of copper into bile and promotes accumulation in the liver and in nerve tissue.

Typical symptoms of Wilson's disease, and less common symptoms

A spectrum of liver diseases may be encountered in patients with Wilson's disease, and clinically evident hepatic involvement may precede neurologic manifestations by >10 years. The majority of individuals with neurological symptoms have some degree of liver disease at presentation.

Symptoms of liver disease at presentation can be highly variable. The commonest presentation is with liver disease or neuropsychiatric disturbance; however, patients may be asymptomatic and only detected by family screening. Wilson's disease typically affects young adults (ages 5–35) but can affect individuals of any age.

Acute hepatitis and fulminant liver failure are often accompanied by a Coombs-negative haemolytic anaemia, acute renal failure, deep jaundice with only mildly elevated transaminases, and an alkaline phosphatase (ALP) level that is normal/lower than expected in the context of other liver test abnormalities. Although preexisting cirrhosis may be present in most cases, the clinical presentation is acute, progressing rapidly to hepatic failure. Acute liver failure (ALF) occurs predominantly in women (4:1) and accounts for 6%–12% of all patients with ALF referred for emergency transplantation.

Many patients present with signs of chronic liver disease and cirrhosis, with a presentation that may be indistinguishable from that observed in other etiologies. Haemolysis may be the only presenting feature in the early stage in up to 12% of patients. This becomes more marked as liver disease progresses due to hepatocyte death and copper release, which exacerbates haemolysis.

Neuropsychiatric symptoms are predominantly those pertaining to a basal ganglia disorder (parkinsonism, ataxia, dystonia, and tremor), although some patients may just present with mild cognitive impairment, behaviour changes, and general clumsiness. Psychiatric problems include depression, anxiety, and psychosis.

Kayser–Fleischer (KF) rings may be visible around the iris. They are due to copper deposition in Descemet's membrane of the cornea and are found in 95% of patients with neurological disease, and in approximately half without. KF rings may only be visible on slit lamp examination, although they are frequently absent in young children with hepatic disease.

Wilson's disease is also associated with sunflower cataracts resulting from the deposition of brown or green pigmentation in the anterior and posterior lens capsules. Significant visual loss is unusual. Type 2 renal tubular acidosis is recognized as leading to nephrocalcinosis and arthropathy.

Demographics of Wilson's disease

The incidence worldwide of Wilson's disease is 1 in 30 000. Most mutations in families are unique or rare and there are no common mutations.

Natural history of Wilson's disease, and complications of the disease

Patients with liver disease tend to come to medical attention earlier, either as children or as teenagers. Those with neurological and psychiatric symptoms tend to present in their twenties or older. Some are identified only because relatives have been diagnosed with Wilson's disease. In the few presenting with fulminant hepatic failure, the condition is inevitably fatal without transplantation.

Approach to diagnosing Wilson's disease

When one presents with symptoms from Wilson's disease, it is highly likely that cirrhosis is already present. Most patients have only mildly abnormal liver chemistry. If liver damage is significant, albumin levels may be decreased and the prothrombin time may be prolonged. ALP may be relatively low in patients with Wilson's-related ALF.

Initial investigations should encompass:

- serum caeruloplasmin (low; <0.1 g/l)
- 24-hour urinary copper (high; >0.64 μmol per 24 hours)

Other diagnoses that should be considered aside from Wilson's disease

The differential diagnoses include conditions with altered mental status or cognition in the presence of deranged liver function, and certain types of haemolytic anaemia. The following diagnosis should also be considered:

- alcohol withdrawal (e.g. delirium tremens, Wernicke–Korsakoff encephalopathy)
- thrombotic thrombocytopenic purpura (by definition, the prothrombin time should not be prolonged)

Screening should be performed for the other causes of acute and chronic liver failure. The acute presentation may mimic many features of viral hepatitis, or an autoimmune hepatitis (AIH), including hypergammaglobulinaemia; positivity for anti-smooth muscle antibodies, antinuclear antibodies, or anti-liver kidney microsomal type 1 antibody (~60%); and an active histological hepatitis or cirrhosis.

'Gold-standard' diagnostic test for Wilson's disease

For many patients, a combination of tests reflecting disturbed copper metabolism is needed, as no single diagnostic modality is specific. Although the combination of KF rings and low serum caeruloplasmin (<0.1 g/l) alone is often sufficient to establish a diagnosis, KF rings may not be present in the absence of neurological involvement. Moreover, caeruloplasmin levels are not always reliable, because they may be low for reasons other than Wilson's disease (e.g. AIH; severe hepatic insufficiency in advanced liver disease, in coeliac disease, or in patients who are heterozygous carriers of ATP7B mutations but do not show copper overload disease). The Leipzig score, based on all available tests assessing copper metabolism, provides good diagnostic accuracy (Table 214.1).

Acceptable diagnostic alternatives to the gold-standard test for Wilson's disease

Total serum copper is usually decreased in proportion to the decreased caeruloplasmin. Non-caeruloplasmin-bound copper ('free copper') in untreated patients is often >200 $\mu\text{g/l}$, but may be elevated in ALF (due to release from dying hepatocytes) of any aetiology, or in disorders of chronic cholestasis. A 24-hour urinary copper >1.6 μmol per 24 hours (100 μg per 24 hours) is taken as diagnostic but may be lower than this in up to 23% of children and asymptomatic siblings. Lower levels (>0.64 μmol per 24 hours) can be suggestive of Wilson's disease and should prompt further testing if clinical suspicion remains high. In the paediatric population, the pencillamine test may be applied, whereby pencillamine is administered orally and after 12 hours; a subsequent urine protein excretion with >5x the normal urobilinogen level in 24 hours is considered diagnostic. However, this test has not been standardized in adults.

Liver biopsy with staining for copper-associated protein, together with the typical clinical context, can be reliable and diagnostic. Hepatic copper accumulation (>4 $\mu\text{mol/g}$ dry weight) is the hallmark of Wilson's disease; however, the hepatic parenchymal copper concentration can be inhomogeneous in distribution in later stages of Wilson's disease; thus, the concentration can be underestimated due to sampling error.

Linkage analysis has been used in family studies for presymptomatic testing. However, due to the large number of mutations that require screening in individuals without affected family members, such analysis is not practical.

Other relevant investigations for Wilson's disease

CT/MRI brain scanning may be used to detect low attenuation in the basal ganglia. However, abdominal imaging is neither sensitive nor specific for Wilson's disease.

As Wilson's disease is autosomal recessive, all first-degree relatives should be screened for caeruloplasmin and 24-hour urinary copper.

Table 214.1 Leipzig 2001 scoring system for diagnosing Wilson's disease*

Diagnostic parameter	Score
Kayser–Fleischer rings	
• Present	2
• Absent	0
Neurological symptoms/lesions detectable on MRI brain	
• Severe	2
• Mild	1
• Absent	0
Serum caeruloplasmin	
• >0.2 g/l	0
• 0.1–0.2 g/l	1
• <0.1 g/l	2
Coombs-neg. haemolytic anaemia	
• Present	1
• Absent	0
Liver copper (in the absence of cholestasis)	
• >4 µmol/g	2
• 0.8–4.0 µmol/g	1
• <0.8 µmol/g	–1
• Rhodanine-positive granules	1
Urinary copper (in the absence of acute hepatitis)	
• Normal	0
• 1–2× ULN	1
• >2× ULN	2
• Normal but >5× ULN after D-penicillamine chelation	2
Mutation analysis	
• Both chromosomes detected	4
• Only one chromosome detected	1

Prognosis of Wilson's disease, and how to estimate it

Lifelong copper chelation therapy is necessary in all patients with Wilson's disease. Patients are at risk of liver failure even in stable chronic disease. The development of fulminant hepatic failure is inevitably fatal without liver transplantation.

Treatment and its effectiveness

The mainstay of medical treatment is chelation therapy, and an argument can be made for early liver transplantation. D-penicillamine is the drug of choice. However, ALF occurs if this drug is stopped abruptly. Due to the side effects of penicillamine (both drug-induced lupus and drug-induced myasthenia can occur in up to 20% of cases), many individuals are switched to trientine hydrochloride or tetrathiomolybdate.

Zinc may be used to maintain stable copper levels in those whose results have returned to normal or in those parts of the world where primary agents are not available. Zinc monotherapy appears to be effective and safe in neurologic Wilson's disease and in asymptomatic siblings, but caution is needed in patients with advanced or symptomatic hepatic disease. Hepatic deterioration has been reported when zinc was commenced and may relate to less efficient de-coppering.

Liver transplantation is the only cure for Wilson's disease but is used only in particular scenarios because of the numerous risks and complications associated with the procedure. It is reserved mainly in patients with fulminant liver failure.

Alpha-1-antitrypsin deficiency

Definition of alpha-1-antitrypsin deficiency

Reduced circulating levels of alpha-1-antitrypsin, a liver-derived protease inhibitor, and accumulation within the hepatocytes of the abnormal, poorly degraded protein, are the defining features of alpha-1-antitrypsin deficiency. Excessive activity of proteases, such as elastase, in pulmonary alveoli, unopposed by protease inhibitors, leads to emphysema, whereas accumulation of alpha-1-antitrypsin in hepatocytes causes liver dysfunction.

Aetiology of alpha-1-antitrypsin deficiency

Mutations leading to alpha-1-antitrypsin deficiency alter the configuration of the alpha-1-antitrypsin molecule so that it cannot be released efficiently from hepatocytes. As a result, serum levels of the protein are decreased, leading to low concentrations of it in pulmonary alveoli, where it normally would serve as protection against proteases.

The gene for alpha-1-antitrypsin is located on Chromosome 14; over 100 different mutations in this gene have been described in various populations. The alpha-1-antitrypsin genotype of a patient can be determined through protein phenotyping via protein gel electrophoresis; the normal alpha-1-antitrypsin isoform is encoded by the 'M' allele, and common variants are encoded by the 'S' and 'Z' alleles. Circulating levels of alpha-1-antitrypsin depend on the patient's genotype and determine the severity of the condition. Alpha-1-antitrypsin serum levels for various genotypes are as follows, where Pi stands for protease inhibitor:

- PiMM: 100% of normal serum levels
- PiMS: 80% of normal serum levels
- PiSS: 60% of normal serum levels
- PiMZ: 60% of normal serum levels
- PiSZ: 40% of normal serum levels
- PiZZ: 10%–15% of normal serum levels (severe deficiency)

Typical symptoms of alpha-1-antitrypsin deficiency, and less common symptoms

The commonest respiratory effects of alpha-1-antitrypsin deficiency are dyspnoea, cough, wheeze, and premature emphysema localized to the basal lung areas. The disease affects individuals aged 30–35 years, particularly smokers.

The liver is rarely involved, except in severe deficiency. In this situation, disease usually presents in the first two decades of life. Adults with liver involvement may not have any symptoms until the onset of chronic liver disease with decompensation.

Demographics of alpha-1-antitrypsin deficiency

Alpha-1-antitrypsin deficiency is present in 1 in 3000–5000 individuals. The highest-risk populations are those residing in Northern Europe, Liberia, and Saudi Arabia; 5% carry the PiZ allele. Women and men are equally affected. The enzyme deficiency is congenital and has a bimodal distribution with respect to symptoms. It can rarely be seen in neonates as a cause of neonatal jaundice and hepatitis. It can present in infants as cholestatic jaundice and in children as hepatic cirrhosis or liver failure.

Natural history, and complications of alpha-1-antitrypsin deficiency

Patients with alpha-1-antitrypsin deficiency are subject to all the complications characteristic of patients with COPD from cigarette smoking. Chronic liver disease is uncommon but often hastened by excessive alcohol consumption. When present, hepatic involvement usually manifests in the first two decades of life. HCC has also been reported in alpha-1-antitrypsin deficiency.

Approach to diagnosing alpha-1-antitrypsin deficiency

It is useful to consider a diagnosis of alpha-1-antitrypsin deficiency in anyone who is being worked up for chronic liver disease. Early onset emphysema is particularly suggestive of the diagnosis.

Other diagnoses that should be considered aside from alpha-1-antitrypsin deficiency

Respiratory disease with cor pulmonale leading to congestive hepatomegaly is a more common cause for dual lung/liver pathology than alpha-1-antitrypsin deficiency is. Liver cirrhosis is unusual in these circumstances. As respiratory disease tends to dominate the clinical picture in adults, other conditions that may have to be considered include:

- bronchiectasis
- bronchitis
- chronic bronchitis
- COPD
- Kartagener syndrome
- vasculitides

'Gold-standard' diagnostic test for alpha-1-antitrypsin deficiency

The gold-standard test for alpha-1-antitrypsin deficiency is genotype and protein-phenotype assessment.

Acceptable diagnostic alternatives to the gold-standard test for alpha-1-antitrypsin deficiency

Moderately reduced levels of alpha-1-antitrypsin in the circulation may indicate heterozygosity and do not require further investigation, particularly if enzyme levels are only slightly low.

Other relevant investigations for alpha-1-antitrypsin deficiency

Family screening should be performed by measuring alpha-1-antitrypsin levels and by phenotype testing. Chest radiography (plain-film and high-resolution CT scanning) can be useful as, in alpha-1-antitrypsin deficiency, emphysematous areas are distributed uniformly throughout the acinus and, for reasons that are not known, are found more commonly in the basilar portions of the lung. In contrast, centrilobular emphysema is characteristic of cigarette smoking and predominantly affects the respiratory bronchioles in the central portion of the lobule, initially at the apex of the lung. Spirometry is another useful investigation.

Prognosis of alpha-1-antitrypsin deficiency, and how to estimate it

The prognosis of alpha-1-antitrypsin deficiency depends entirely on the severity of underlying lung or liver disease, as well as how patients are identified. Patients found as a result of screening often have a prognosis near that of healthy people. Those identified because of their symptoms face a more limited future. Specific features that confer a poor prognosis include:

- severe airflow obstruction
 - FEV₁ >50%: 5-year mortality rate, 4%
 - FEV₁ 35%–49%: 5-year mortality rate, 12%
 - FEV₁ <35%: 5-year mortality rate, 50%
- smoking
- male sex
- PiZZ genotype: individuals with this genotype have a 16% likelihood of surviving to age 60, with the most common causes of death being emphysema (~70%) and chronic liver disease (~10%); the latter is often hastened by excessive alcohol consumption

The quoted mortality rate is approximately 3% per year. HCC has also been reported in deficiency.

Treatment of alpha-1-antitrypsin deficiency, and its effectiveness

Conservative treatment of alpha-1-antitrypsin deficiency

Conservative treatment of alpha-1-antitrypsin deficiency involves:

- abstinence from alcohol and tobacco
- standard emphysema treatment (e.g. bronchodilators, inhaled steroids)
- pulmonary rehabilitation
- long-term oxygen, where indicated
- preventing severe respiratory tract infections (e.g. via yearly influenza and pneumococcal vaccinations)

Replacement therapy in alpha-1-antitrypsin deficiency

Individuals who have alpha-1-antitrypsin deficiency and who show signs of developing significant emphysema can be treated with alpha-1-proteinase inhibitor (e.g. Prolastin®), which is a purified human plasma protein concentrate replacement for the missing enzyme. This should be performed only under specialist supervision.

Surgery for treating alpha-1-antitrypsin deficiency

The only definitive treatment for alpha-1-antitrypsin deficiency is transplantation.

215 Drug-induced liver disease

Satish Keshav and Palak Trivedi

Definition of the disease

Drugs are an important and common cause of hepatic injury. This is unsurprising, as the liver is a major site for drug clearance, biotransformation, and excretion.

A careful history of drugs taken (prescribed, over the counter, herbal, or illicit) is vital when assessing anyone with abnormal liver function tests. Although toxic or idiosyncratic adverse reactions may occur with many therapeutic agents, drug-induced jaundice is not so common.

Aetiology of the disease

Abnormalities seen in drug-induced liver disease cover a wide spectrum, from acute inflammation, to cholestasis, to fulminant necrosis. The pattern of the disease depends on the agent.

Intrinsic liver injury can be caused by hepatotoxins (drugs or their respective metabolites) leading to direct damage to the liver by covalently bonding to cellular macromolecules (hydroxyl radicals, hydrogen peroxide, or lipid peroxides). This type of injury is usually dose dependant but occurs infrequently. The classical example is acetaminophen/paracetamol (see Chapter 209).

More commonly, reactions are idiosyncratic and not predictable. Simvastatin, for example, may cause a mild rise in liver enzymes, but occasionally a more severe acute cholestatic hepatitis may occur through changes in mevalonic acid metabolism. Isoniazid and halothane are other well recognized examples of drugs that can cause idiosyncratic drug-induced hepatitis and may produce chronic inflammation if consumption continues. Progressive fibrosis and cirrhosis can develop with methotrexate.

Immune mechanisms (hypersensitivity) are responsible for some drug reactions. Only a few have concomitant evidence of an allergic reaction (rash, eosinophilia, etc.).

Polymorphisms of certain cytochrome p450 and acetylator enzymes may also influence an individual's risk of drug-induced liver injury, by affecting the rate of production of toxic metabolites.

Cholestatic reactions may either be of the inflammatory or non-inflammatory (so-called bland) subtype:

- chlorpromazine, allopurinol, and flucloxacillin may cause an acute periportal necro-inflammatory reaction with biochemical cholestasis and features of inflammation on biopsy
- certain steroids (oral contraceptives) cause relatively pure impairment of bile outflow with no associated inflammatory change; this arises due to the effect of sex hormones on bile canalicular transport

Oral contraceptives may also be associated with the development of hepatic adenomas, focal nodular hyperplasia, gallstones, and veno-occlusive disease.

Typical symptoms of the disease, and less common symptoms

Symptoms of drug-induced liver injury vary, depending on the type of liver injury caused. For example, allergic hepatitis (e.g. in response to phenytoin) may present with systemic symptoms such as pharyngitis, lymphadenopathy, and atypical lymphocytosis. Jaundice, when present, may persist for a limited period after withdrawal of some agents, particularly drugs that cause inflammatory cholestasis. Chronic hepatitis can occur in response to amiodarone, nitrofurantoin, methyl dopa, dantrolene, and co-amoxiclav and its individual components.

Demographics of the disease

Over 600 medicines have been reported to cause liver injury. Drug-induced hepatic injury is the one of the most frequent reasons cited for withdrawing a drug from the market. In the US, it accounts for 2%–5% of admitted cases of jaundice and over 50% of cases of acute liver failure, most due to acetaminophen poisoning.

Natural history, and complications of the disease

The natural history and the complications of the disease depend on the drug in question (see Table 215.1).

Approach to diagnosing the disease

The diagnosis is suspected from the history of liver dysfunction or jaundice, which may occur soon after first or early exposure to a drug. Occasionally, liver damage can present many months after starting the drug.

A good drug history assessing aspects of not only prescribed medication but also herbal, over-the-counter, and illicit drug use is vital. It is also important to ascertain a temporal association in cases of acute dysfunction, as most reactions occur within days to weeks of starting a new drug.

Other diagnoses that should be considered

Diagnosis requires exclusion of viral, toxic, cardiovascular, inherited, autoimmune, and malignant causes of liver injury. When drug-induced liver injury is suspected, withdrawal of the offending agent and close observation often provide adequate circumstantial evidence for a diagnosis.

'Gold-standard' diagnostic test

Reliable evidence of exposure, and an expected pattern of injury, are usually sufficient, provided that the injury ceases and liver injury recedes on stopping the drug. Occasionally, it is necessary or worthwhile to reintroduce the drug and monitor for recurrent injury.

Acceptable diagnostic alternatives to the gold standard

Liver biopsy should be reserved for situations when discontinuation of the drug is not followed by prompt improvement, the disease remains in question, and/or the severity necessitates urgent intervention (e.g. immunosuppression, liver transplantation).

Other relevant investigations

The following investigations are largely aimed at assessing liver damage and liver function while excluding the wide range of differential diagnoses:

- full blood count (including differential)
- renal function
- liver enzymes (alanine transaminase and alkaline phosphatase)
- liver synthetic function (bilirubin, albumin, clotting)

Table 215.1 Drugs and hepatotoxicity		
Type of liver injury	Features	Drug examples
<i>Deranged LFTs alone</i>		
Microsomal enzyme induction	No clinical features Raised ALP/γGT	Warfarin Phenytoin
Hyperbilirubinaemia	Jaundice (rarely occurs)	Rifampicin
<i>Steatosis</i>		
Acute fatty change	Clinical features of hepatitis, liver failure	Tetracycline NSAIDs Catabolic steroids Valproate
Steatohepatitis	Features of chronic liver disease	Amiodarone Parenteral nutrition
<i>Cholestasis</i>		
Bland cholestasis	Pruritus ALP > 2× normal	COCP Androgens Phenytoin
Inflammatory cholestasis	Systemic symptoms ALT and ALP raised	Erythromycin Flucloxacillin Co-amoxiclav Chlorpromazine Allopurinol Amitriptyline Azathioprine Captopril Carbamazepine
Cholestasis with bile duct injury	Destructive lesions of bile ducts, similar to acute cholangitis	Flucloxacillin Chlorpromazine
Vanishing bile duct syndrome*	Chronic cholestasis > 3 months Resembles primary biliary cholangitis (AMA negative)	Chlorpromazine Flucloxacillin Amitriptyline
<i>Hepatocellular necrosis (variable inflammation). ALT >5 times normal</i>		
Focal necrosis	Can resemble viral hepatitis histologically	Isoniazid Halothane
Bridged necrosis		Isoniazid Methyldopa
Zonal necrosis		Paracetamol Halothane (severe)
Massive necrosis	Fulminant hepatic failure	Halothane (fatal) NSAIDs Valproate
<i>Chronic parenchymal damage (deranged LFTs >3/12)</i>		
Chronic hepatitis	Clinical and biochemical features of chronic liver disease Liver failure may occur	Methyldopa Nitrofurantoin Sodium dantrolene Minocycline can induce autoimmune hepatitis that is indistinguishable from the spontaneous variety
Fibrosis and cirrhosis	Portal hypertension (LFTs may be normal)	Methotrexate Retinoids Hypervitaminosis A
<i>Vascular problems</i>		
Sinusoidal dilatation	Can be an isolated finding Hepatomegaly may be the only feature	COCP
Non-cirrhotic portal hypertension	Splenomegaly Varices (features of portal hypertension)	Azathioprine
Hepatic venous outflow tract obstruction	Budd–Chiari syndrome and related	COCP 6MP
Nodular regenerative hyperplasia	Features of portal hypertension	Azathioprine

(continued)

Table 215.1 (Continued)		
Type of liver injury	Features	Drug examples
<i>Hepatic granulomas</i>		
Non-caseating granuloma (usual presentation)	Mixed LFT picture Can present with cholestasis or even cholangitis	Allopurinol Isoniazid Phenytoin Sulfonamides Chlorpromazine Quinidine Penicillins Diltiazem Nitrofurantoin Gold COCP Diazepam Phenytoin
<i>Hepatic tumours</i>		
Focal nodular hyperplasia	Hamartomas	COCP
Hepatic adenoma		Androgens COCP
Hepatic carcinoma		Androgens COCP

*Histology shows chronic portal inflammation and degeneration of the bile duct referred to as progressive ductopenia.

Abbreviations: γ GT, gamma-glutamyl transferase; 6MP, 6-mercaptopurine; ALP, alkaline phosphatase; ALT, alanine transaminase; AMA, anti-mitochondrial antibody; COCP, combined oral contraceptive pill; LFT, liver function test; NSAID, non-steroidal anti-inflammatory drug.

- hepatic viral serology
- autoantibody and immunoglobulin screen
- copper and iron studies

- alpha-1 antitrypsin (to exclude other causes of liver disease)
- liver ultrasound
- chest X-ray (to look for pulmonary infiltrates associated with certain drug toxicities (e.g. sulphasalazine))

Box 215.1 Dose-related and dose-independent side effects

Dose-dependent hepatotoxicity

- halothane:
 - rarely used now
 - partly related to dose (should be avoided for anaesthetics <6 weeks apart)
- methotrexate:
 - varying grades of damage from fibrosis to portal inflammation
 - toxicity is usually associated with excess alcohol use
 - dose-dependent fibrosis (unusual if total dose <2 g)
 - jaundice may occur in terminal stages, with liver function remaining normal earlier on
- paracetamol
 - >10 g per 24 hours
 - >6 g per 24 hours if underlying liver disease (e.g. from alcohol, malnutrition) is present

Dose-independent hepatotoxicity

- isoniazid
- valproate
- rifampicin
- NSAIDs
- azathioprine
- co-amoxiclav
- chlorpromazine
- glibenclamide
- nitrofurantoin
- dantrolene sodium
- methylodopa
- verapamil
- allopurinol

Prognosis and how to estimate it

The prognosis depends on the offending agent, the pattern of distribution, and the presence of coexisting liver disease.

Treatment and its effectiveness

Exclude other causes of hepatic dysfunction and jaundice. Minor elevations in transaminases (2–3 times the normal limit) after starting potentially hepatotoxic drugs (e.g. anti-mycobacterial agents) are not an indication for stopping the drug, as improvement usually occurs. Remember, not all injury is dose dependent. (Box 215.1)

If enzymes continue to deteriorate or the patient develops jaundice, then all potential drugs leading to hepatic dysfunction should be stopped. Monitor liver enzymes until a normal level is reached. Although most hepatotoxic effects resolve completely after withdrawal of the drug, in rare cases persistent loss of small bile ducts can occur. If liver enzymes fail to return to normal after 8 weeks and the history is uncertain, proceed to liver biopsy.

216 Miscellaneous liver diseases

Satish Keshav and Palak Trivedi

Non-alcoholic fatty liver disease

Definition of non-alcoholic fatty liver disease

Non-alcoholic fatty liver disease (NAFLD) comprises a spectrum of disorders which are characterized by the deposition of lipid material in hepatocytes in the absence of a history of excess alcohol ingestion.

Aetiology of NAFLD

There are many conditions that can lead to the development of NAFLD (see Table 216.1).

Typical symptoms of NAFLD, and less common symptoms

Most patients with NAFLD remain asymptomatic, with the diagnosis of NAFLD being made incidentally. Occasionally, individuals may present with non-specific symptoms such as malaise or with right upper quadrant discomfort. Hepatomegaly is not an uncommon clinical finding on examination. Individuals with steatohepatitis may eventually progress to cirrhotic liver disease and demonstrate all the symptoms/signs of decompensated liver disease.

Demographics of NAFLD

With the obesity pandemic sweeping across the world, and the rising number of individuals with type 2 diabetes, the incidence of NAFLD has dramatically increased. NAFLD is now the commonest diagnosis in patients with incidental abnormal liver biochemistry, both in secondary care (60%–70%) and in primary care (26%). The true overall prevalence can be difficult to measure, given the large proportion of asymptomatic individuals, but is estimated to affect up to 20%–30% of the adult population and >90% in the morbidly obese. The implications of such rates on the future burden of NAFLD are heightened by a reported prevalence of 3% and 53% in the general and obese paediatric populations, respectively. The reported prevalence

is higher in patients of European or Hispanic descent; this is largely a reflection of ethnic differences in lipid metabolism and insulin resistance. The more clinically relevant form of NAFLD, non-alcoholic steatohepatitis (NASH), is less common and affects 2%–3% of the general population, and 37% of the morbidly obese.

Natural history of NAFLD, and complications of the disease

The spectrum of NAFLD ranges from simple steatosis, in which there is a mildly elevated level of serum alanine transaminase (ALT) or aspartate transaminase (AST; ≤ 100 IU/l or less than $3 \times$ urobilinogen) and/or an isolated rise in gamma-glutamyl transpeptidase (with fatty appearances of the liver detected on ultrasound), through to NASH, which is indistinguishable from alcoholic hepatitis histologically.

Simple steatosis was historically thought to be a benign condition. However, despite progression from simple steatosis to advanced liver fibrosis being rare, patients with simple steatosis have increased mortality, which is largely attributable to cardiovascular causes.

Steatohepatitis may progress to cirrhosis with complications of decompensated liver disease. Individuals who have impaired glucose tolerance or with a raised BMI are at a higher risk of progression to fibrosis. Changes in aminotransferases do not necessarily parallel the changes in fibrosis.

Approach to diagnosing NAFLD

A diagnosis of NAFLD should be suspected in any individual who is overweight (BMI > 25 kg/m²), is diabetic or hyperlipidaemic, and has abnormal liver biochemistry. There is no specific cut-off regarding the quantity of alcohol consumption that is allowable for individuals to be included in the NAFLD group as opposed to the alcoholic hepatitis group; however, an arbitrary limit is set at 24 units/week.

Table 216.1 Causes and associations with non-alcoholic fatty liver disease

Metabolic	Drugs	Surgical	Miscellaneous
Inherited:	Amiodarone	Jejunioleal bypass [‡]	Inflammatory bowel disease
● lipoproteinemias	Oestrogens	Biliopancreatic diversion	Jejunal diverticuli
● Wilson's disease	Tamoxifen	Extensive bowel resection	
● tyrosinemia	Glucocorticoids		
● galactosemia	Tetracycline		
● glycogen storage diseases	Valproic acid		
Acquired:			
● metabolic syndrome*			
● obesity [†]			
● type 2 diabetes			
● hypertriglyceridaemia			
● coeliac disease			
● lipodystrophy			
● severe malnutrition			

*Characterized by insulin resistance, centripetal obesity, dyslipidaemia, and microalbuminuria; this is the disorder most consistently associated with non-alcoholic fatty liver disease.

[†]Non-alcoholic fatty liver disease may also occur in 2%–3% of lean individuals.

[‡]The risk of developing steatohepatitis and even subacute hepatic failure has been seen to be high following jejunioleal bypass, with up to 95% patients developing steatosis at the end of the first year. The association of jejunioleal bypass with hepatic dysfunction has prompted proximal gastric bypass as a method of choice for bariatric surgery. The head-to-head comparison of these two surgical modalities has indicated that proximal gastric bypass is more effective and safer than jejunioleal bypass. However, changes suggestive of steatohepatitis were observed following both jejunioleal and proximal gastric bypass surgeries. The predominant mechanism behind the hepatocellular injury is thought to be metabolic stress induced by rapid weight loss in the post-bypass period.

Most individuals diagnosed will be asymptomatic, with deranged liver biochemistry being diagnosed incidentally. The ratio of ALT:AST is usually >1 in NAFLD but this ratio is reversed in the presence of fibrosis or cirrhosis.

Other diagnoses that should be considered aside from NAFLD

Other diagnoses that should be considered aside from NAFLD include:

- alcoholic liver disease
- hereditary haemochromatosis (in a diabetic with deranged biochemistry)
- Wilson's disease (in a young patient with modest elevations in serum liver enzymes, and a fatty liver on ultrasound)
- other causes (see Chapter 210)

Gold-standard diagnostic test for NAFLD

Non-invasive imaging can assess the amount of fatty infiltration within the liver but not the presence of inflammation, fibrosis, or cirrhosis. Liver biopsy is currently the most accurate way of determining the presence of steatosis, degree of fibrosis, and severity of liver injury. However, liver biopsy is invasive and costly, and findings may be indistinguishable from alcoholic hepatitis and prone to sampling error. Common histological changes include:

- ballooning degeneration
- Mallory's hyaline (highly eosinophilic cytoplasmic inclusions found in hepatocytes)
- sinusoidal fibrosis

Acceptable diagnostic alternatives to the gold-standard test for NAFLD

Ultrasound in NAFLD

In NAFLD, the liver is hyperechogenic or bright liver (only when >30% of the liver parenchyma has become steatosis). However, ultrasound cannot distinguish a simple fatty liver from steatosis with hepatitis.

Assessment of steatosis in NAFLD

Vibration-controlled transient elastography with a controlled attenuation parameter (recorded in decibels per metre) measures the degree of ultrasound attenuation by hepatic fat at the central frequency of the Fibroscan® probe and can be performed simultaneously with liver stiffness measurement. Median parameter values correlate with the percentage of hepatocytes with lipid droplets and histological steatosis grade:

- Stage 0 steatosis: ~250 dB/m
- Stage 1 steatosis: ~300 dB/m
- Stage 2–4 steatosis: ≥320 dB/m (301–338 dB/m)

Assessment of fibrosis in NAFLD

Transient elastography or Fibroscan® assessing liver stiffness has been validated as a tool in assessing the severity of liver fibrosis in NAFLD. A value <10 kPa excludes the presence of advanced fibrosis, although values may be underestimated with increasing subcutaneous adiposity.

Biomarkers of liver fibrosis in NAFLD

An AST:ALT ratio more than 0.8 or a NAFLD fibrosis score (<http://nafldscore.com>) less than -1.455 excludes advanced fibrosis (negative predictive value >90%).

Other relevant investigations for NAFLD

Evaluation of cardiovascular risk in NAFLD

The following investigations should be performed to evaluate cardiovascular risk in NAFLD:

- waist circumference
- BMI
- blood pressure

Laboratory tests directed at identifying the underlying cause of NAFLD

The following laboratory tests may be performed to identify the underlying cause of NAFLD:

- fasting glucose and postprandial (post 2 hours) glucose to detect impaired glucose tolerance
- fasting lipid screen
- thyroid function
- coeliac serology
- iron studies (may reveal moderate elevations in ferritin with reduced transferrin saturation; levels are seldom as deranged as in untreated haemochromatosis)
- other laboratory tests to exclude other causes of chronic liver disease

Prognosis of NAFLD and how to estimate it

Liver disease is the third leading cause of death amongst people with NAFLD, behind cardiovascular-related mortality and extra-hepatic malignancy. A greater death rate is seen in those individuals with increasing age at diagnosis, cirrhosis, and diabetes. Liver-related outcomes are dependent upon the degree of hepatic fibrosis, with all-cause mortality being 13% over 7.6 years.

Simple hepatic steatosis does not usually follow a progressive course, although such patients are at risk of adverse cardiovascular events. The rate of progression from steatohepatitis to advanced fibrosis/cirrhosis is the same as that observed in patients with steatohepatitis secondary to alcohol. Longitudinal studies of patients with NASH undergoing repeat biopsies have shown that one-third of these patients progress, one-third remain stable, and one-third improve, as determined by histology, over a 3-year period without pharmacologic intervention. End-stage/decompensated NASH cirrhosis accounts for ~3% of patients undergoing liver transplantation.

The rate of development of primary liver malignancy in NAFLD is thought to be comparable to those with other primary liver diseases. However, there is emerging evidence that non-cirrhotic patients may also be at risk of developing hepatocellular carcinoma (HCC).

Biomarkers for prognostication in NAFLD

The fatty liver index (FLI) is a validated algorithm derived from the serum triglyceride level, the gamma-glutamyl transferase level, BMI, and waist circumference, and was originally designed as a non-invasive marker of hepatic steatosis. However, it has recently been shown that FLI also correlates with 15-year liver-related death as well as all-cause mortality.

Other laboratory scoring systems which assist in predicting liver-related morbidity, death, and need for transplantation include the enhanced liver fibrosis test and the aminotransferase-to-platelet ratio.

Treatment of NAFLD and its effectiveness

The management of NAFLD is complex and requires a multidisciplinary approach encompassing dietetic input, management of cardiovascular risk factors, and diabetes, as well as assessment and targeted therapy directed towards liver disease. The cornerstones of treatment are directed towards weight loss through diet and exercise, and control of comorbidities (e.g. tight glycaemic control, lipid-lowering therapies, and exclusion of gluten exposure in patients with coeliac disease; see Box 216.1).

Box 216.1 Factors increasing the likelihood of fibrosis with non-alcoholic fatty liver disease

- age >45
- BMI > 28 kg/m²
- type 2 diabetes, or insulin resistance
- systemic hypertension
- ALT > 2× normal upper limit
- AST:ALT > 1
- hypertriglyceridaemia

Abbreviations: ALT, alanine transaminase; AST, aspartate transaminase; BMI, body mass index.

Lifestyle changes for the management of NAFLD

Weight reduction by lifestyle modification with diet and exercise should be recommended to all, as this will:

- favourably improve the cardiovascular profile
- improve hepatic steatosis
- ameliorate hepatic inflammation (only with >7%–9% weight loss)

Pharmacological therapies for the management of NAFLD

Multiple pharmacological therapies have been trialled in the management of NAFLD and NASH, although most are used off-label.

Orlistat

Orlistat has been shown to lower aminotransferase levels, total cholesterol, triglycerides, and low-density lipoprotein, with an improvement in insulin resistance. Histologically, improvement is also seen with regard to fatty infiltration and inflammatory indices.

Antiglycaemics

Glitazones improve transaminase levels and steatosis and reduce inflammation (but not fibrosis) in the liver, but only as long as therapy continues. Due to adverse publicity regarding the effect of glitazones on cardiovascular mortality, further trials regarding their safety as therapeutic drugs are underway.

Some studies have shown short-term radiological and biochemical improvement with metformin, although histological changes have yet to be proven. However, there is emerging evidence that metformin has inherent anticancer effects, with >60% reduction of HCC in diabetics.

Glucagon-like peptide-1 analogues reduce serum transaminases and radiological evidence of steatosis, but not independently of weight loss and improvement in glycohemoglobin levels. Their therapeutic potential in non-diabetic individuals with NAFLD is currently the subject of a large, multicentre clinical trial.

Lipid-lowering agents

Fibrates and statins should be considered where indicated in view of their cardiovascular protective effects and are safe in patients with liver disease. Statins may also have inherent chemoprotective effects with respect to HCC.

Antihypertensives

Certain agents targeting the renin–angiotensin system have been shown to improve hepatic steatosis and, through the induction of hepatic-stellate-cell apoptosis, may also possess inherent antifibrotic properties.

Vitamin E

Vitamin E is associated with a reduction in serum transaminases and a significantly higher rate of improvement in steatosis, steatohepatitis, and lobular inflammation but not fibrosis.

Bariatric surgery for the treatment of NAFLD

Bariatric surgery should be considered for severely obese persons (BMI >40, or >35 if comorbidity is present) and for those who clearly wish to lose weight. It induces long-term weight loss and decreases morbidity, the incidence of cancer, and mortality. Compelling data show a sustained decrease in steatosis in >90% of patients, and an improvement of steatohepatitis and fibrosis in >80%.

Liver abscesses

Definition of liver abscess

There are two main types of liver abscess: pyogenic and amoebic. Fungal abscesses are rare and usually caused by *Candida* spp. in immunocompromised individuals. Tubercular abscesses also represent a rare hepatic manifestation of *Mycobacterium tuberculosis* infection.

Aetiology of liver abscesses

Pyogenic abscesses usually arise by portal vein seeding from the following intra-abdominal infections:

- diverticulitis
 - Crohn's disease and ulcerative colitis

- bowel perforation
- delayed diagnosis of appendicitis
- subphrenic abscess or gall bladder empyema
- haematogenous spread (e.g. endocarditis, pyelonephritis with bacteraemia)

Gram-negative infections are usually the cause, with *Escherichia coli* and *Enterobacter* spp. being the commonest cultured organisms. Anaerobic organisms are a close second. It is not uncommon for a patient with a liver abscess to also have a polymicrobial infection.

Amoebic liver abscesses are usually caused by the organism *Entamoeba histolytica*. Predisposing factors include:

- living in endemic areas
- poor hygiene and overcrowding
- immunosuppression

Liver abscesses can also be caused by biliary tract disease (35%) related to cholangitis or cholecystitis. In addition, parasitic infections by roundworms or liver flukes can be causative. Pancreatobiliary malignancy can account for abscesses **originating** in the biliary tree.

Typical symptoms of liver abscesses, and less common symptoms

Symptoms of pyogenic liver abscesses

The features of pyogenic liver abscesses are relatively non-specific, with fever, rigours, right upper quadrant pain, and, occasionally, weight loss. On examination, there may be right upper quadrant tenderness or features of an underlying condition such as appendicitis. Jaundice may indicate the presence of biliary disease.

Symptoms of amoebic liver abscesses

Coupled with a travel history to an endemic area, there may be an antecedent history of diarrhoea, but 90% of infected people will be asymptomatic in the initial stages of amoebic infection before liver abscesses develop. Once hepatic involvement is present, the majority will present with symptoms that develop quickly over a couple of weeks. These include right upper quadrant pain, fever, and a variety of constitutional symptoms. Involvement of the diaphragm can lead to referred right shoulder pain or symptoms of pleurisy. Pain is more common with point tenderness on examination. Hiccups may herald impending rupture.

Demographics of liver abscesses

The estimated annual incidence for pyogenic liver abscesses is around 2–3 per 100 000 people per year in the UK. Worldwide, 40–50 million people are affected with amoebic liver abscesses annually (with the majority found in the developing world). The right lobe is affected in isolation in 60% of cases.

Natural history of liver abscesses, and complications of the disease

Natural history of pyogenic liver abscesses, and complications

Untreated cases of pyogenic liver abscesses can lead to overwhelming, fulminant sepsis. The abscess may rupture into adjacent areas (e.g. pleural or peritoneal space with development of subphrenic, perihepatic, or subhepatic abscesses). Metastatic septic embolic may occur. One rare association is endophthalmitis (infection of intra-ocular fluid), particularly in the presence of klebsiella infection. Larger abscesses may result in the compression of hepatic venous drainage, causing a Budd–Chiari-type picture. Even with appropriate treatment, this condition can yield mortality rates approaching 30%.

Natural history of amoebic liver abscesses, and complications

Amoebic liver abscesses have a much better prognosis with treatment, with considerably lower mortality rates, compared to pyogenic liver abscesses. Impending rupture may be indicated by the presence of hiccups. Rupture into the lung parenchyma may result in a lung abscess or bronchopleural fistula. Haematogenous spread leading to infected emboli has been reported, but this is comparatively rare. Clinical improvement is usually noted within the first week of therapy, with a marked lag in radiological resolution.

Approach to diagnosing liver abscesses

Ultrasound of the liver is always indicated when a patient is febrile and has a derangement in liver biochemistry. Ultrasound enables distinction between solid and fluid-filled structures, but patient body habitus may cause difficulty leading to diagnostic inaccuracy.

Other diagnoses that should be considered aside from liver abscess

The differential for liver abscess includes the multitude of conditions giving rise to fever, right upper quadrant pain/tenderness, and deranged liver biochemistry, such as:

- cholecystitis
- right lower lobe pneumonia
- pulmonary tuberculosis
- hepatic malignancy
- ascending cholangitis
- acute alcoholic hepatitis
- hepatic infarction
- hepatic adenoma (radiological differential)
- hepatic haemangioma (radiological differential)

Another radiological differential is hydatid cystic disease (caused by *Echinococcus* spp.). Primary hosts are usually dogs, with sheep and cattle acting as secondary hosts. This disease usually causes asymptomatic hepatomegaly and normal liver function tests. Serology is often negative. On ultrasound, one may see multiple daughter cysts. If the patient is asymptomatic, leave them alone, as rupture may cause massive anaphylaxis. If the patient is symptomatic, a suitable alternative to surgery is albendazole. Surgery is indicated for increasing size or pressure symptoms.

Gold-standard diagnostic test for liver abscesses

Gold-standard diagnostic test for pyogenic liver abscesses

Ultrasound-guided aspiration confirms the diagnosis of pyogenic liver abscess in 90% of cases.

Gold-standard diagnostic test for amoebic liver abscesses

Ultrasound, with positive antibodies to *Entamoeba histolytica*, is diagnostic for amoebic liver abscesses in over 90% of cases.

Acceptable diagnostic alternatives to the gold-standard diagnostic tests for liver abscesses

Acceptable diagnostic alternatives to the gold-standard diagnostic test for pyogenic liver abscess

Blood cultures are positive in 50% of cases of pyogenic liver abscesses. Helical CT may aid in the diagnosis of smaller abscesses and perhaps give further clues to the underlying source for the abscess.

Acceptable diagnostic alternatives to the gold-standard diagnostic test for amoebic liver abscess

Aspiration of an amoebic liver abscess will reveal a thick, 'anchovy sauce'-like paste which is odourless (unlike that from a pyogenic abscess). Aspiration is indicated when pyogenic or secondary infection cannot be excluded, the abscess is very large, or the patient is not responding to treatment or is in severe pain. Unfortunately, aspiration does not usually yield diagnostic material in most cases.

Serological tests (e.g. immunoelectrophoresis, complement fixation, haemagglutination assays) are positive in patients with invasive disease only (not asymptomatic carriers). These tests are extremely sensitive (except the complement fixation test). Depending on the test used, the titres may remain positive for some time after the infection (e.g. indirect haemagglutination may remain positive for many years).

The biliary tree is not usually involved in amoebic liver abscesses, as bile is toxic to amoebae. Compression of the biliary system may give rise to jaundice but, in the presence of a cholangitis, suspect ascending secondary bacterial infection.

Other relevant investigations for liver abscesses

Other relevant investigations for liver abscesses include:

- full blood count (to look for neutrophil leucocytosis, or anaemia of sepsis or chronic disease)

- serum liver biochemistry
- blood cultures (essential in any febrile patient)
- hot (fresh) stool (for trophozoites)
- a plain chest film (may show a flat right hemidiaphragm)
- cholangiography (if indicated; to demonstrate the site of biliary obstruction)

Prognosis for liver abscess, and how to estimate it

Prognosis for pyogenic liver abscesses

If untreated, pyogenic liver abscesses are associated with high mortality.

Prognosis for amoebic liver abscesses

With good treatment, the mortality of amoebic liver abscesses falls to 1%–3%.

Treatment of liver abscesses, and its effectiveness

Treatment of pyogenic liver abscesses

Treatment of pyogenic liver abscesses includes the following:

- broad-spectrum antibiotic cover (e.g. IV metronidazole and IV ceftriaxone) while awaiting microbial sensitivities
- urgent percutaneous drainage of a single abscess or the larger abscess in the case of multiplicity
- surgical drainage, if there is evidence of the causative disease process (e.g. peritonitis from viscus perforation), if the abscess is very large (>5 cm), if the location of the abscess makes percutaneous drainage difficult, or if previous treatment via percutaneous drainage and antibiotics has failed

Treatment of amoebic liver abscesses

A 10-day course of IV metronidazole is effective in the majority of cases. This should be followed by a further 10-day course of diloxanide, to prevent recurrence.

Consider aspiration with/without drainage if abscesses are >5 cm or located on the left side of the liver (left-sided liver abscesses have a higher mortality and an increased frequency of leaking into peritoneum and pericardium), or if a response is not detected in the first 5 days.

Amphotericin or fluconazole can be used to treat fungal abscesses (seek specialist microbiology advice).

Nodular regenerative hyperplasia

Definition of nodular regenerative hyperplasia

Nodular regenerative hyperplasia (NRH) is the diffuse transformation of normal hepatic parenchyma into smaller regenerative nodules in the presence of little or no fibrosis. This leads to nodules pressing directly onto one another with small atrophic hepatocytes in between (cf. cirrhosis, which has nodules separated by fibrous tissue).

Aetiology of NRH

NRH is hypothesized to be due to alterations in blood flow, with frequent observations of portal and central vein anomalies. This pathological entity has been explained by uneven microcirculatory perfusion, leading to atrophy of the poorly perfused areas, and compensatory (regenerative) hypertrophy of the areas of maintained perfusion. The nodular areas are thus hypothesized to be hypertrophied areas which develop in response to slightly increased blood flow.

Etiological associations of NRH have been provided in Table 216.2.

Typical symptoms of NRH, and less common symptoms

NRH can remain asymptomatic for many years before incidental deranged liver biochemistry is found in the absence of other identifiable causes. Tests of synthetic function may often be normal. Non-specific features may be malaise, abdominal pain, and fatigue. In other cases, the features that dominate are fundamentally those of (non-cirrhotic) portal hypertension and decompensated liver disease,

Table 216.2 Associations of nodular regenerative hyperplasia

Rheumatological	Haematological	Hepatobiliary disease (without cirrhosis)	Cardiovascular	Other
Systemic sclerosis	Hodgkin's and non-Hodgkin's lymphoma	Primary biliary cholangitis	Congestive cardiac failure	Thiopurines and other drugs (probably the most important cause)
Polyarteritis nodosa	Chronic lymphocytic leukaemia	Budd–Chiari syndrome	Hypertension	Type 2 diabetes mellitus
Polymyalgia rheumatica	Waldenström's macroglobulinaemia		Severe coronary artery disease	Renal transplantation
Rheumatoid arthritis	Multiple myeloma		Hereditary haemorrhagic telangiectasia	Coeliac disease
Felty's syndrome				Certain anticonvulsants.
SLE				

although ascites is less common than in cirrhosis. Examination findings may reveal the presence of hepatosplenomegaly.

Demographics of NRH

Older studies of autopsy figures have shown that NRH is present in 5.3% of those over 80, with most patients having systemic disease. Case series reviews point towards NRH being the cause for >25% of cases of non-cirrhotic portal hypertension.

Natural history of NRH, and complications of the disease

There is little documentation regarding the true course of NRH, given the large percentage of asymptomatic disease. The medical literature tends to focus on the symptomatic cases, thus giving a slightly skewed view on the condition. In the same breath, it is not fully known whether NRH is **fully** reversible following treatment of the underlying cause.

Complications, when present, are essentially those of decompensated liver disease. Extra-hepatic portal vein thrombosis has been reported to occur in >70% of cases.

Approach to diagnosing NRH

Although NRH can be suspected based on abnormal liver function tests (usually a cholestatic picture) in the absence of other underlying causes, a significant proportion of patients will have normal biochemistry. Further suspicion is raised in the presence of unexplained portal hypertension in the absence of cirrhosis. Ultrasound may demonstrate nodularity in the liver.

Other diagnoses that should be considered aside from NRH

NRH and cirrhotic liver disease can be difficult to distinguish, but differentiation is important, as treatment for the two and consequent prognoses are different. Other nodular disorders of the liver include:

- malignancy (see Chapter 218)
- liver cysts
- hepatic adenoma
- focal nodular hyperplasia

Gold-standard diagnostic test for NRH

The gold-standard diagnostic test for NRH is liver histology with reticulin stain.

Acceptable diagnostic alternatives to the gold-standard test for NRH

Increasingly, advanced MRI and CT techniques are being employed to evaluate nodular liver disease. However, confirmation of NRH can only be reached through tissue diagnosis.

Other relevant investigations for NRH

Other investigations in NRH are directed at excluding other causes of chronic liver disease, identifying possible underlying causes, and assessing portal hypertension (see Chapter 210).

Prognosis of NRH, and how to estimate it

See 'Natural history of NRH, and complications of the disease'.

Treatment of NRH, and its effectiveness

Treatment is guided towards the underlying diagnosis and complications of portal hypertension and should be along standard lines. Antiplatelet and anticoagulant therapy should be managed in a specialist setting, given the risks of variceal bleeding with portal hypertension. The need for liver transplantation is rare.

217 The liver in systemic disease

Satish Keshav and Palak Trivedi

Introduction

The liver may be involved in systemic diseases that primarily affect other organs. In most cases, the systemic disease should be treated effectively first.

The liver in cardiovascular disease

Definition of cardiovascular-disease-related liver disease

Circulatory disturbances can cause liver dysfunction by ischaemia (due to arterial hypoperfusion) and hepatic venous congestion. Liver congestion usually occurs in the setting of acute or chronic right-sided cardiac failure causing hepatic venous congestion and sinusoidal stasis, and is also termed 'passive congestion of the liver' (cf. Budd–Chiari syndrome). In ischaemic hepatitis, patients develop a dramatic transaminitis, raised bilirubin, and raised lactate dehydrogenase (LDH) after a very short time (e.g. 24–48 hours) following a period of haemodynamic compromise leading to liver hypoperfusion. Hepatic infarction is relatively rare compared to ischaemic hepatitis (due to the fact that the liver has a dual blood supply, which is provided by the hepatic portal vein and the hepatic arteries) and represents focal liver injury, which is usually iatrogenic. In contrast, the bile ducts receive their blood supply solely from the hepatic artery and peribiliary plexus. Any interruption of blood flow to the latter damages the perihilar intra-hepatic and extra-hepatic bile ducts, leading to ischaemic cholangiopathy.

Aetiology of cardiovascular-disease-related liver diseases

Hepatic congestion mainly results from the causes of right-sided heart failure, such as:

- congestive cardiac failure
- tricuspid regurgitation (pressure from the right ventricle is transmitted directly through to the hepatic veins so the degree of congestive hepatopathy can be severe)
- right ventricular failure (and, hence, the causes of pulmonary hypertension (e.g. mitral stenosis, severe respiratory disease))
- pericardial constriction

Many conditions can predispose to hepatic ischaemia; some are provided in Table 217.1.

Typical symptoms of cardiovascular-disease-related liver disease, and less common symptoms

In congestive hepatic disease, individuals may be asymptomatic but with deranged liver function tests (LFTs). There may be pain from stretching of the Glisson's capsule. Look for ascites, peripheral oedema, and signs of hepatosplenomegaly on examination.

In ischaemic hepatitis and hepatic infarction, a haemodynamic insult is usually apparent before the appearance of liver injury. Patients may show features of an acute hepatitis (e.g. fever, right upper quadrant pain, vomiting, and jaundice). Suspect ischaemic hepatitis and hepatic infarction in the post-transplant patient.

In ischaemic cholangiopathy, patients may present with the features of biliary obstruction (pale stools, dark urine, jaundice, and pruritus). There may also be features of a cholangitis with fever, vomiting, and rigours.

Demographics of cardiovascular-disease-related liver disease

No accurate data are available on the demographics of cardiovascular-disease-related liver disease.

Natural history of cardiovascular-disease-related liver disease, and complications of the disease

The natural course of congestive liver disease depends on that of the underlying cardiac disorder. Liver function tends to return to normal within 1 week of improvement in cardiac failure. Long-standing liver congestion and sinusoidal stasis may result in the accumulation of deoxygenated blood; parenchymal atrophy; necrosis; collagen deposition; and, ultimately, fibrosis. This rare eventuality is termed cardiac cirrhosis.

In ischaemic hepatitis, typically, there will be elevation of liver enzymes (transaminitis peaks at 24–72 hours post insult) following the hypoperfusion insult, coupled by a rise in LDH. The transaminase level will settle within a week or so following resolution of haemodynamic compromise. Following the decline in liver enzymes, the

Table 217.1 Causes of hepatic ischaemia

Ischaemic hepatitis	Focal hepatic infarction	Ischaemic cholangiopathy
Any cause of left ventricular dysfunction: <ul style="list-style-type: none"> • acute myocardial infarction • cardiac dysrhythmia • cardiac tamponade • restrictive cardiomyopathy Causes of shock: <ul style="list-style-type: none"> • dehydration • haemorrhage • burns • dehydration Focal interruption of blood supply to liver: <ul style="list-style-type: none"> • sickle cell crisis • portal venous thrombosis • post-transplantation arterial thrombosis • any cause of left ventricular dysfunction 	Hepatic artery thrombosis: <ul style="list-style-type: none"> • atherosclerosis • prothrombotic states • post liver transplant Embolic phenomenon: <ul style="list-style-type: none"> • therapeutic embolization • tumour embolization • infective endocarditis Iatrogenic: <ul style="list-style-type: none"> • hepatic artery ligation during transplantation • chemoembolization Toxaemia of pregnancy Vasculitides (esp. polyarteritis nodosa) Amphetamine use Dissection of the aorta	Paroxysmal nocturnal haemoglobinuria (hypercoagulability) Iatrogenic: <ul style="list-style-type: none"> • post liver transplantation • vascular injury post biliary surgery • chemoembolization • radiotherapy AIDS related

bilirubin rises while synthetic function (clotting and albumin) usually remain unchanged. The liver recovers completely.

Ischaemia-related, non-anastomotic biliary strictures and necrosis of bile ducts are well-described complications of liver transplantation. The natural course and, consequently, prognosis of ischaemic cholangiopathy depends on the location of the blockage and underlying aetiology. In proximal hepatic artery blockade via hepatic artery ligation/embolization (outside the transplant setting), limited consequences are seen due to rapid development of collateral 'shunt' vessels and a retrograde portal supply.

In the transplanted liver, proximal blockade (thrombosis) is generally followed by severe morbidity from biliary damage. The transplanted liver differs from the non-excised liver in that excision interrupts arterial blood supply from transcapsular peripheral arteries, and therefore compromises collateralization through this route. In contrast, distal occlusion of smaller hepatic arteries has been shown (in experimental data) to cause significant ischaemic biliary injury.

Approach to diagnosing cardiovascular-disease-related liver disease

Congestive hepatic disease is more common with right-sided heart failure and should be included in the differential workup of deranged liver function in the presence of underlying cardiopulmonary disease. A clue is provided by Doppler studies of liver vasculature, with loss of the normal triphasic flow in the hepatic veins.

In contrast, suspect ischaemic hepatic injury in those with an acute hepatitis with predominant transaminitis in the presence of left ventricular dysfunction, systemic shock, or sickle cell crisis, or post liver transplant. A haemodynamic insult is usually apparent clinically before the appearance of liver injury, although transient minor reductions of hepatic perfusion may produce ischaemic injury and not be clinically apparent. The precipitating cause is usually evident before focal hepatic infarction ensues.

Ischaemic cholangiopathy should be suspected post transplant in the presence of clinical cholangitis with obstructive LFTs.

Other diagnoses that should be considered aside from cardiovascular-disease-related liver disease

Differential diagnoses of an ischaemic hepatic injury include an acute hepatitis, such as drug-induced liver injury, viral hepatitis (not just from hepatotropic viruses, such as the hepatitis A and B viruses, but also EBV, rubella, CMV, and mumps), and alcohol. These should be screened for in any case of acute hepatitis.

Three features distinguish ischaemic hepatitis from acute viral hepatitis: LDH elevation is more marked in ischaemia; serum aspartate aminotransferase (AST) and alanine aminotransferase (ALT) concentrations rapidly return to normal in ischaemic hepatitis upon correction of the underlying cause; and ischaemic hepatitis is more often complicated by renal dysfunction. It can be sometimes be difficult to differentiate between focal hepatic infarction and pyogenic liver abscess radiologically, in which case, attempt at aspiration may be helpful. Other entities which can mimic the presence of an ischaemic cholangiopathy include the various causes of biliary stricturing disease, biliary obstruction, and cholangitis (e.g. biliary, pancreatic, or duodenal malignancy; biliary stones). Another important diagnosis to consider is primary sclerosing cholangitis, although other coexisting features may also be present (e.g. history of inflammatory bowel disease or other autoimmune disease).

Gold-standard diagnostic test for cardiovascular-disease-related liver disease

Characteristic features of congestive liver disease are present on histological analysis, but biopsy is rarely needed, as other clues point towards the diagnosis. The gross histological appearance of congestive liver disease has earned it the name 'nutmeg liver'. There will be a central red area (sinusoidal congestion, bleeding into atrophic areas surrounding an enlarged hepatic vein) intermixed with a yellow area (representing fatty liver). In the absence of cardiac cirrhosis, there will be no inflammatory change. Chronic cardiac failure will cause

the accumulation of collagen, with fibrous bands extending outwards from the central veins. This is the appearance of cardiac sclerosis; eventually, a micronodular cirrhosis will result.

In contrast, no real gold-standard diagnostic test for ischaemic hepatitis is available, so the diagnosis is made from the accumulation of clinical signs, biochemical tests, and, occasionally, histological tissue. Biopsy shows hepatocyte necrosis in Zone 3 (the region most poorly perfused by the hepatic artery), with architectural collapse around the central vein. With a prolonged insult, necrosis may reach the mid-zone of hepatocytes.

Concerning ischaemic cholangiopathy, following a history of the condition, definitive diagnosis can be made on cholangiography.

Other relevant investigations for cardiovascular-disease-related liver disease

In patients with congestive liver disease, echocardiography with right-sided and pulmonary pressures is essential. Doppler hepatic venous studies are also helpful. LFTs show that serum bilirubin is elevated mostly in the unconjugated form. Bilirubin concentrations rapidly (i.e. within days) return to normal following improvement of right-sided heart failure. In those who show a transaminitis, the change in AST is more marked than that in ALT. Elevated serum alkaline phosphatase (ALP) is observed in 10%–20% of patients with right-sided heart failure, but ALP levels return to normal within 1 week after improvement of heart failure. Other investigations focus on diagnosing the cause of cardiac failure. A high LDH favours the diagnosis of ischaemic hepatitis over that of an acute viral hepatitis. In hepatic infarction, an abdominal CT scan may reveal a wedge-shaped low-attenuation area indicating the infarct.

Prognosis for cardiovascular-disease-related liver disease, and how to estimate it

The prognosis for congestive liver disease depends on the aetiology of the underlying cardiac failure, as well as its severity and reversibility. Ischaemic hepatitis usually has a benign prognosis, once resolution of the underlying problem has taken place. However, if it is superimposed on underlying cirrhotic liver disease or cardiac failure, fulminant liver failure may occur. There is limited data on the management of ischaemic cholangiopathy and, thus, outcome after treatment. If it occurs in the first 4 weeks or so post liver transplant, retransplantation is indicated.

Treatment of cardiovascular-disease-related liver disease, and its effectiveness

In congestive liver disease, right upper quadrant discomfort rapidly resolves with **effective** diuretic treatment; the remainder of management rests on cardiac failure therapy. In ischaemic liver disease, treatment rests on that of the underlying condition. Little data are available regarding the effectiveness of treatment of ischaemic cholangiopathy but there is some evidence for endoscopic dilatation and stenting of strictures. Disease occurring in the first month post transplantation warrants urgent retransplantation.

Sepsis-induced liver dysfunction

Definition of sepsis-induced liver dysfunction

The liver is a key organ in sepsis, both as source of inflammatory mediators and as a victim of the inflammatory response. The two main characteristics that illustrate this 'dual' role are:

- the heterogeneous cellular makeup of the liver: Kupffer cells, hepatocytes, and cells lining the sinusoidal endothelium are all involved in the immune response
- the liver's unique blood flow: the portal vein receives blood from the splanchnic circulation; in sepsis there can be marked vasoconstriction and translocation of harmful pathogens across this vascular bed

As an active participant in the response to sepsis, the liver will scavenge, attempt to inactivate bacterial products, and modify its metabolic functions towards amino acid synthesis and increased

gluconeogenesis. There will be increased production and release of coagulation factors, complement, and acute phase proteins.

As a victim in sepsis, the liver can suffer primary dysfunction related to shock and hypoperfusion (see discussion of ischaemic hepatitis in 'The liver in cardiovascular disease'), or secondary dysfunction, which is more related to microcirculatory changes in the hepatic circulation. Secondary dysfunction is insidious in its presentation and is characterized by functional and structural hepatic injury, as well as bacterial and endotoxin spillover, with the liver becoming the source of soluble mediators in the systemic inflammatory response syndrome. Cholestasis is also a common complication in patients with extra-hepatic bacterial infections and sepsis and is increasingly recognized as a cause of jaundice in hospitalized patients, as part of the secondary dysfunction triggered by a burst of inflammatory mediators.

As hypoxic liver injury has already been discussed (see 'The liver in cardiovascular disease'), the bulk of the discussion in this section primarily focuses on sepsis-induced jaundice and cholestasis.

Aetiology of sepsis-induced liver dysfunction

Sepsis-induced jaundice occurs most frequently with Gram-negative bacteria. The primary site of infection is usually intra-abdominal (e.g. peritonitis, diverticulitis) but can be from a pneumonia or endocarditis. Other specific extra-hepatic infections known to cause jaundice are pneumococcus, clostridia, legionella, and typhoid infections.

Jaundice can occur in isolation in patients with sepsis, but is frequently associated with other elements of cholestasis. As the principal clinical manifestation of cholestasis is also jaundice, literature to date has primarily focused on the sepsis syndrome of jaundice with cholestasis. Accurate epidemiological documentation regarding the incidence of isolated jaundice (without cholestasis) in sepsis remains unclear. Possible causes of jaundice in sepsis are:

- aberrant processing of bilirubin by hepatocytes
- increased bilirubin load from haemolysis
- hepatocellular injury
- cholestasis (decreased bile acid transport secondary to lipopolysaccharide and various cytokines)
- antibiotics/drugs

Typical symptoms of sepsis-induced liver dysfunction, and less common symptoms

Functional cholestasis with jaundice usually predominates as the liver manifestation in sepsis. Ischaemic hepatitis or progressive sclerosing cholangitis can be found in severe cases, with the presentation varying according to the severity of the infection. Primary hepatic dysfunction can lead to disseminated intravascular coagulation; reduced lactate and amino acid clearance; and reduced gluconeogenesis and glycogenolysis, thus leading to hypoglycaemia. A raised LDH with transaminase leakage can be seen, reflecting hepatocyte injury. Reduced perfusion appears to be the primary initiating event here (caused by reduced cardiac output with the vasoconstriction of hepatic artery and portal veins that is observed in sepsis). Secondary hepatic dysfunction may be silent and involve localized hepatic areas, which become inflamed as a consequence of bacterial detoxification by Kupffer cells. This induces activation of the coagulation, kallikrein, and complement cascades.

Demographics of sepsis-induced liver dysfunction

Sepsis and bacterial infection are responsible for up to 20% of cases of jaundice seen in all patient groups. Sepsis with jaundice is more likely to present in children than in adults.

Natural history of sepsis-induced liver dysfunction, and complications of the disease

Cholestasis usually resolves with the appropriate antibiotics. Persistent/worsening hyperbilirubinemia can indicate ongoing sepsis and is associated with a worse outcome. Persistently high ALP and gamma-glutamyl transpeptidase (γ GT) levels should raise suspicion of progressive sclerosing cholangitis due to sepsis. Ischaemic hepatitis usually resolves on correction of haemodynamic instability and hypoxia.

Approach to diagnosing sepsis-induced liver dysfunction

Sepsis-related cholestasis gives rise to a hyperbilirubinemia (mostly conjugated) with a modest rise in ALP and transaminases in the presence of a normal LDH. Resolution should occur with appropriate antibiotic therapy. Ischaemic hepatitis is discussed in 'The liver in cardiovascular-disease-related liver disease'.

Other diagnoses that should be considered aside from sepsis-induced liver dysfunction

Other diagnoses that should be considered aside from sepsis-induced liver dysfunction are:

- antibiotic-induced liver dysfunction (see Chapter 215)
- progressive sclerosing cholangitis: this can occur following severe sepsis, burns, or severe trauma; patients with this disease have rising levels of ALP and γ GT, and deep jaundice over several months; as this disease tends to involve the smaller bile ducts, diagnosis is usually confirmed on cholangiography (severe intra-hepatic stenosis); prognosis is usually poor
- cholecystitis
- structural biliary tract obstruction
- parenteral nutrition
- liver abscess

Gold-standard diagnostic test for sepsis-induced liver dysfunction

Biopsy is occasionally needed for diagnosis of sepsis-induced liver dysfunction and demonstrates the following characteristic findings in cholestasis:

- Kupffer cell hyperplasia
- portal mononuclear cell infiltrates
- an increased amount of smooth endoplasmic reticulum as a result of cholestasis; this may lead to hepatocytes having a ground-glass appearance
- focal hepatocyte dropout

Acceptable diagnostic alternatives to the gold-standard test for sepsis-induced liver dysfunction

A thorough history, examination, and investigation of the septic illness, coupled with exclusion of other common causes of jaundice, usually suffice in achieving the diagnosis.

Other relevant investigations for sepsis-induced liver dysfunction

Other relevant investigations for sepsis-induced liver dysfunction include:

- split bilirubin (to help evaluate the cause of jaundice in sepsis)
- hepatobiliary ultrasound
- full septic screen, including
 - blood
 - urine
 - lines and drains
 - recent operation sites
 - lumbar puncture (if appropriate and safe)
 - chest X-ray

Prognosis for sepsis-induced liver dysfunction, and how to estimate it

In the absence of systemic signs of sepsis, the cholestasis that can accompany an extra-hepatic bacterial infection is usually mild and of no prognostic significance. Should sepsis develop (with systemic features), jaundice is associated with a poor prognosis, and most patients with sepsis-associated cholestasis die from extra-hepatic causes associated with sepsis-related multiple organ failure. It is crucial that emphasis is placed on identifying the focus of infection and providing treatment by appropriate antibiotic therapy and other anti-infective strategies (e.g. aspiration or drainage of collections).

Treatment of sepsis-induced liver dysfunction, and its effectiveness

The cornerstone of the treatment of sepsis-induced liver dysfunction rests on appropriate antibiotic therapy and effective management of the complications of sepsis. Ursodeoxycholic acid has been shown to improve parameters in other cholestatic diseases, but its use in sepsis-induced cholestasis is still under investigation.

The liver in malignancy

Definition of malignancy-related liver disease

There are many ways in which an oncological process may affect hepatic function. For example, tumours in and around the liver can affect function by directly reducing the volume of healthy, functioning tissue or by causing biliary obstruction. In addition, portal venous infiltration or hypercoagulability may compromise vascular supply. Paraneoplastic phenomena have been well documented, and humoral and immunological factors related to the primary malignancy are known to contribute to further cholestasis and inflammatory hepatic changes. Underlying malignancy may also affect hepatic drug metabolism (tumour cells release a host of cytokines as part of an inflammatory response which reduce the activity of certain cytochrome enzymes). Other ways that malignancy can affect hepatic function include:

- chemotherapy-induced hepatotoxicity
- graft-versus-host disease
- metastases of cancer cells to the liver

In-depth discussion regarding the latter two points is beyond the scope of this section and will not be discussed further.

Aetiology of malignancy-related liver disease

The chronic myeloproliferative disorders (including polycythaemia rubra vera and essential thrombocythemia) tend to cause damage or blockage to the hepatic circulation and can lead to:

- Budd–Chiari syndrome
- portal vein thrombosis (PVT)
- nodular regenerative hyperplasia (see Chapter 216)

These topics will form the bulk of the discussion in this section.

Other haematological malignancies that lead to liver disease

Acute leukaemia in liver disease

Hepatic involvement is mild in the initial stages of leukaemia, and so patients may initially be asymptomatic. Acute lymphocytic leukaemia (ALL) generally gives rise to portal tract infiltration only, whereas infiltration in acute myeloid leukaemia (AML) involves the sinusoids also.

Chronic leukaemia in liver disease

Mild-to-moderate hepatomegaly, together with extensive infiltration by lymphocytes with consequent impairment of liver function, is observed in chronic lymphoid leukaemia (CLL). Half of all cases of chronic myeloid leukaemia at presentation will show hepatomegaly. During blast crises, infiltration of sinusoids can cause massive liver enlargement.

Myelofibrosis in liver disease

Liver enlargement is present in most patients, in keeping with extramedullary haemopoiesis and increased hepatic blood flow. Nodular regenerative hyperplasia (see Chapter 216: Miscellaneous liver diseases) may accompany intra-hepatic portal vein obstruction.

Lymphoma in liver disease

In lymphoma, infiltration of the liver by malignant cells, leading to hepatomegaly, may be seen. A mild transaminitis and a relatively greater increase in ALP can also occur due to tumour infiltration. These are more common in non-Hodgkin's than in Hodgkin's lymphoma. Cholestasis not due to extra-hepatic duct obstruction or infiltrative disease has also been described. Acute liver failure may also occur.

Myeloma in liver disease

Sinusoidal and portal infiltration occurs in up to 50% of cases. There may also be nodular regenerative hyperplasia. Extramedullary haemopoiesis may also contribute to hepatomegaly and deranged LFTs.

Specific solid tumours in the liver

Stauffer syndrome is a constellation of signs and symptoms of liver dysfunction that arises due to the presence of renal cell carcinoma, but it is not due to tumour infiltration into the liver and/or intrinsic liver disease: it is a true paraneoplastic syndrome. It leads to elevated LFTs, which result from cholestasis (i.e. a cessation of bile flow). The symptoms resolve if the renal cell cancer is successfully treated.

Typical symptoms of malignancy-related liver disease, and less common symptoms

Budd–Chiari syndrome (hepatic venous outflow obstruction, of the hepatic vein, the inferior vena cava (IVC), or both) causes congestion, necrosis, and, eventually, fibrotic change and cirrhosis. Features include abdominal pain, hepatomegaly, jaundice, ascites, and hepatic failure with features of decompensation. PVT (in any part of the portal circulation, including the mesenteric system, the splenic vein, and the intra-hepatic veins) can also present with features of portal hypertension and hepatic decompensation (e.g. variceal bleeding and ascites).

Demographics of malignancy-related liver disease

Hepatomegaly is found in the majority of individuals with ALL or AML, at the time of diagnosis. CLL is largely an incidental finding, with most patients being asymptomatic, so most of the demographics on hepatic involvement in CLL come from post-mortem studies; one study revealed that 98% of patients with CLL had hepatic leukaemic infiltration at autopsy. In myeloma, sinusoidal and portal infiltration occurs in up to 50% of cases and, in 10% of cases, there will be immunoglobulin light chain deposition or amyloid in the space of Disse; there may also be non-specific changes, such as haemosiderosis, in a smaller percentage of patients. Budd–Chiari syndrome is rare in Western countries. The exact frequency of PVT in malignancy is unknown; however, it occurs in approximately 5% of patients with cirrhosis and portal hypertension.

Natural history of malignancy-related liver disease, and complications of the disease

The natural history of malignancy-related, veno-occlusive liver disease is not well known and its manifestation can change from asymptomatic presentation to fulminant liver failure in a matter of days to weeks. A chronic form of Budd–Chiari progresses over a matter of months, and rapid deterioration with encephalopathy, renal failure, coma, and death can occur in untreated disease. In extensive PVT, the patient may present with mesenteric ischaemia. The natural history of hepatic involvement in other haematological malignancies is dependent on the underlying disorder.

Approach to diagnosing malignancy-related liver disease

In Budd–Chiari syndrome, obstruction of hepatic venous drainage leads to elevated sinusoidal pressure, dilatation, and congestion. This leads to portal hypertension. When all three hepatic veins are obstructed, drainage from the caudate lobe (through separate spigelian veins) directly into the IVC becomes the only route of drainage, and this leads to caudate hypertrophy. This can be observed on Doppler ultrasound, CT, or MRI angiography. Absence of flow in the hepatic veins, as well as other features of portal hypertension, may also be seen.

In PVT, simple imaging may identify splenomegaly with or without hepatomegaly and an enlarged azygous vein. Ultrasound may demonstrate a lack of normal portal flow or the presence of a thrombus in the portal vein.

Table 217.2 Predisposing factors for hepatic veno-occlusive disease

Myeloproliferative disorders	Prothrombotic disorders	Other malignancies	Vascular disorders	Infections	Other
Polycythaemia rubra vera Essential thrombocythemia Myeloid leukaemia	Factor V Leiden Protein C deficiency Lupus anticoagulant Paroxysmal nocturnal haemoglobinuria Homocystinuria	Hepatocellular carcinoma Adrenal cancer Renal cancer Leiomyosarcoma	Behçet's syndrome Sjögren's syndrome	Amoebic abscesses Pyogenic abscesses Echinococcus infections	Pregnancy Oral contraceptives Cirrhotic liver disease Splenectomy

Other diagnoses that should be considered aside from malignancy-related liver disease

Other diagnoses that should be considered aside from malignancy-related liver disease include:

- other predisposing factors for hepatic veno-occlusive disease (see Table 217.2)
- congestive cardiac failure
- constrictive pericarditis
- IVC web (a common cause of Budd–Chiari syndrome in the East)

The main cause of PVT in children is sepsis with dehydration and consequent haemoconcentration. In adults, cirrhosis, pancreatic cancer, and hepatomas are other major causes.

Gold-standard diagnostic test for malignancy-related liver disease

Hepatic venography may show the characteristic ‘spider-web’ appearance of intra-hepatic veins in Budd–Chiari syndrome. This may also demonstrate non-patency of the IVC. Contrast-enhanced CT can identify portal vein patency and any thrombi within.

Acceptable diagnostic alternatives to the gold-standard test for malignancy-related liver disease

A liver biopsy is also crucial in Budd–Chiari syndrome. Pathological findings are a high-grade venous congestion and centrilobular liver cell atrophy. There may be thrombi within the terminal hepatic venules. The presence of necrosis or end-stage fibrosis indicates a need for urgent decompression.

Other relevant investigations for malignancy-related liver disease

Other relevant investigations for malignancy-related liver disease include:

- ascitic fluid analysis (serum ascites: albumin gradient <1.1)
- endoscopy, to identify varices
- other tests as part of a chronic liver disease screen
- investigations for possible underlying malignancy and other possible causes

Prognosis for malignancy-related liver disease, and how to estimate it

The following features have been shown to indicate a favourable prognosis in Budd–Chiari syndrome:

- younger age at diagnosis
- a low Child–Pugh score

- the absence of ascites, or easily controlled ascites
- a low serum creatinine level

The 5-year survival rate for Budd–Chiari syndrome is 38%–87%, following portosystemic shunting. The 5-year survival rate following liver transplantation is 70%. The prognosis is poor in patients who have Budd–Chiari syndrome and remain untreated or have venous occlusion caused by malignancy. There is high mortality in untreated cases of Budd–Chiari syndrome, with death resulting from progressive liver failure at 3 months to 3 years from the time of diagnosis.

In contrast, PVT has a much better prognosis, with 75% of patients alive after 10 years and an overall mortality rate of less than 10%. In the presence of cirrhosis and malignancy, the prognosis is understandably worse and is dependent upon the underlying condition.

Treatment for malignancy-related liver disease, and its effectiveness

The aims of treatment in Budd–Chiari syndrome are threefold:

- to relieve hepatic congestion
- to preserve histology
- to preserve synthetic function

Diuretics are helpful for the management of ascites, and chronic anticoagulation may prevent further clot formation. Thrombolysis is only useful in the acute situation, but is risky. In cases of portal hypertension, decompression of the hepatic vasculature should be offered. Transjugular intra-hepatic portosystemic shunts can be used as a bridge to transplantations, but is not without complication. Surgical decompression is also an option, and transplantation is recommended for those in fulminant liver failure. Medical therapy cannot prevent progression of liver disease or reverse hepatic congestion.

As most patients with PVT present with variceal bleeding, this should be an essential focus of treatment, both during an acute episode and also in prevention of further bleeding events (see Chapters 23, 210, and 206). Mesenteric ischaemia warrants further surgical intervention.

218 Liver cancer

Satish Keshav and Palak Trivedi

Definition of the disease

Primary hepatocellular carcinoma (HCC) arises from hepatocytes and is one of the commonest solid-organ malignancies in the world, particularly in the Far East and in sub-Saharan Africa. Cholangiocarcinoma arises from the biliary epithelium. The incidence is rising in the West, and primary sclerosing cholangitis (PSC) is an important risk factor (15% lifetime risk).

Other forms of liver cancer include metastatic cancer, hepatoblastoma, haemangiosarcoma, and gall bladder cancer. Metastatic cancer is much more common in the West than any primary liver cancer, accounting for 90% of liver cancers, and its common primary sites are the colon, the stomach, the breasts, and the lungs. Hepatoblastoma is an uncommon malignancy in children, originating from immature liver cell precursors. Haemangiosarcomas are also rare; these are malignant tumours arising from the blood vessels in the liver and can be very rapidly growing. Gall bladder cancer arises from the gall bladder epithelium. Gallstones and PSC are risk factors for gall bladder cancer; in particular, PSC confers a risk >160 times that of the control population.

The remainder of this chapter will primarily focus on HCC.

Aetiology of the disease

The great majority of HCC develops in cirrhotic liver, and all causes of cirrhosis are associated with an increased risk of HCC. Secondary metastases are said to be less frequent in cirrhotic liver. Chronic hepatitis C is associated with about one-third of HCC cases worldwide. Chronic hepatitis B is associated with over half of all HCC cases worldwide. Viral integration into the hepatocyte DNA may confer a direct oncogenic effect and, in those infected early in life, HCC may develop in the absence of established cirrhosis.

Other causes of HCC include alcoholic liver cirrhosis (alcohol also confers increased risk in patients with coexisting viral hepatitis), haemochromatosis, which is associated with a 45% lifetime risk in cirrhotic individuals, fatty liver disease, and alpha-1-antitrypsin deficiency. Cirrhosis from autoimmune hepatitis, primary biliary cholangitis (PBC), or PSC also increases the risk of HCC, although the incidence is clearly dwarfed by viral and metabolic liver diseases in particular.

A rare, autosomally recessive glycogen storage disorder, von Gierke disease, may cause hepatic adenomas that can transform to HCC. In contrast, hepatic adenomas associated with the use of the oral contraceptive pill (OCP) rarely or never transform.

Another important aetiological factor for the development of HCC is exposure to aflatoxins, which are produced by many species of the fungal genus *aspergillus*. Aflatoxin-producing *aspergillus* can colonize and contaminate foods such as cereals, groundnuts, and sunflower seeds during periods of prolonged storage.

Typical symptoms of the disease, and less common symptoms

HCC should be considered in any patient who has established cirrhosis and develops features of hepatic decompensation, ascites, an increased liver size, or jaundice over a very short period of time. Rarely, a hepatic arterial bruit may be audible; however, this can also be heard in acute alcoholic hepatitis.

HCC can have distinct patterns of growth:

- nodular: multiple nodules of varying size throughout the liver (this is the most common form)

- solitary: larger, solitary masses (more common in younger patients; these can be massive)
- diffuse: widespread infiltration of minute tumour foci

Demographics of the disease

HCC accounts for ~80% of primary liver cancers. The incidence is increasing and, at present, is about 2–3 per 100 000 in Europe and the US. Much higher rates of 90 per 100 000 are observed in the Far East. The incidence of HCC increases progressively with advancing age in all populations, reaching a peak at 70 years. The mean age of onset in Chinese and black patients is much earlier. The age differences and higher incidence of HCC in Asia and Africa (85% of all HCC cases worldwide) are largely related to viral hepatitis. In addition, the disease is more prevalent in men than in women (4:1).

Natural history, and complications of the disease

The median survival for those diagnosed with HCC is poor. This is usually because of advanced disease being present at time of symptom presentation. This issue is discussed further in 'Prognosis and how to estimate it'.

Approach to diagnosing the disease

International guidelines advocate that individuals with established liver cirrhosis be surveyed for HCC via ultrasound scanning every 6 months (Table 218.1). Select individuals with chronic hepatitis B infection in the absence of cirrhosis are also at risk of HCC, although the evidence base for offering surveillance to non-cirrhotic individuals with chronic liver disease is contentious.

Finding the following features on initial assessment should always raise suspicion of HCC, particularly in the context of existing cirrhotic liver disease:

- hepatomegaly, with or without bruit
- haemorrhagic ascites
- acute rise in alkaline phosphatase
- secondary polycythaemia (a paraneoplastic phenomenon)
- pyrexia of unknown origin

Table 218.1 Groups in whom surveillance for hepatocellular carcinoma is recommended by international guidelines

Population group	Incidence of hepatocellular carcinoma (%/year)
Non-cirrhotic hepatitis B males >age 40	0.2
Non-cirrhotic hepatitis B females >age 50	0.2
African/North American blacks with hepatitis B	0.2
Cirrhotic hepatitis B carriers or non-cirrhotic carrier with family history of hepatocellular carcinoma	2.5–8.0
Hepatitis C cirrhosis	2.0–8.0
Stage 4 primary biliary cholangitis	3.0–11.0
Genetic haemochromatosis and cirrhosis	3.0–4.0
Alpha-1-antitrypsin deficiency and cirrhosis	Unknown, but probably >1.5

Other diagnoses that should be considered

The differential diagnosis must distinguish between other causes of hepatic decompensation in a patient with previously stable chronic liver disease (see Chapter 210), other tumours of the hepatobiliary system (malignant and benign), and abscesses and anomalies on ultrasound scanning that may simulate a focal liver mass. It includes:

- cholangiocarcinoma
- hepatic adenoma:
 - increased risk with oestrogen use (was rarely seen prior to the use of OCPs)
 - can spontaneously rupture during menstruation or pregnancy
 - can progress to HCC
 - although surgical resection is usually offered, hepatic adenomas have been known to remit once the etiological agent (usually OCP) has been removed
- haemangioma:
 - this is a common benign hepatic tumour (develops in 20% of the normal population), occurring more commonly in women as a single, asymptomatic mass
 - usually located in the right lobe, existing as a blood-filled vascular sinusoid
 - risks of tumour growth or bleeding are minimal
 - intervention is usually not needed
- focal nodular hyperplasia:
 - a round, non-encapsulated mass with a vascular scar and with fibrous septa radiating from the scar like 'bicycle spokes from a central hub', with hepatocytes in-between
 - the second most common benign liver tumour
 - although not thought to cause the anomaly, OCPs have been shown to enhance its growth once the lesion is already present, and should be stopped
 - resection is not usually necessary
- focal fatty infiltration:
 - often seen in alcoholism, obesity, diabetes, retroviral disease, and starvation
 - can look similar to focal liver lesions; once the underlying disease process is corrected, this appearance rapidly disappears
- liver abscesses and cysts (discussed in further detail in Chapter 216).

Gold-standard diagnostic test

A single, universally acceptable diagnostic test for liver cancer does not exist. Ultrasound scanning (USS) has a sensitivity of 58%–89% and a specificity of >90% and is the first imaging modality of choice when suspecting HCC. However, diagnosing HCC radiologically on a background of nodular cirrhosis can be challenging. Once concern of HCC has been raised with USS, additional radiological modalities should be employed in order to confirm the diagnosis (Figure 218.1).

Current guidelines advocate that lesions <1 cm in diameter should be followed up with a repeat USS in 4 months. Lesions 1–2 cm in diameter should be followed up by means of two consecutive radiological tests: a four-phase-contrast CT and a contrast-enhanced MRI. However, some experienced centres may rely on only one modality if the lesion appears 'bright' during the arterial phase before 'washing out' in the late/venous phase. This radiological finding is characteristic of an HCC lesion, which receives its blood supply from the hepatic artery, and thus helps to differentiate HCC from relatively hypovascular tumours (e.g. metastasis). Lesions >2 cm in diameter require confirmation by only one of the contrast-enhanced investigations.

Acceptable diagnostic alternatives to the gold standard

Liver biopsy, even with expert histopathology, is not as reliable as might be expected because well-differentiated HCC can resemble the surrounding cirrhotic liver parenchyma. Moreover, liver biopsy may lead to 'tumour seeding' along the biopsy tract. Nonetheless, this remains a useful tool in investigating indeterminate lesions or in situations which preclude more advanced imaging techniques (e.g. contrast allergy, pacemaker insertion).

Other relevant investigations

Alpha-fetoprotein (α FP) is the most widely used serum biomarker, although its use as a marker is no longer advocated for surveillance. When combined with USS, α FP provides additional detection of HCC in only 6%–8% of cases. When used as a diagnostic test, α FP values of 20 ng/ml show good sensitivity but poor specificity.

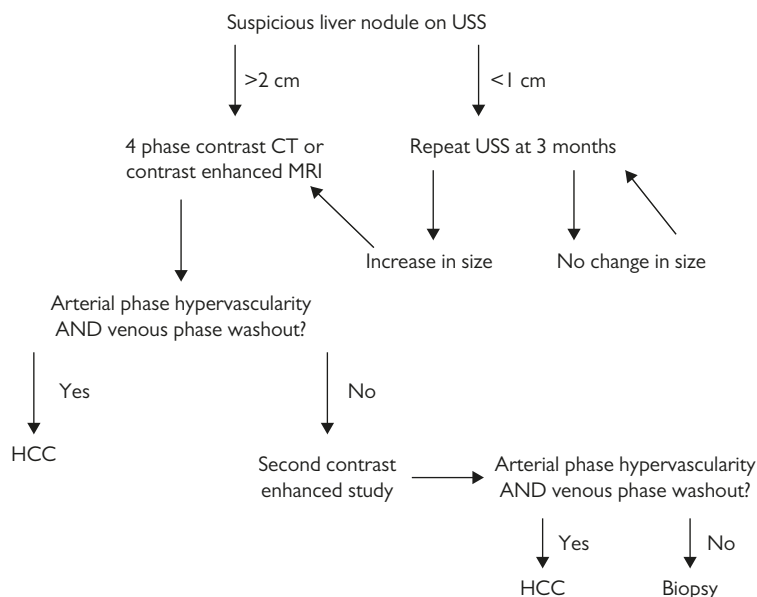

Figure 218.1 Approach to diagnosing hepatocellular carcinoma; HCC, hepatocellular carcinoma; USS, ultrasound.

Conversely, when using a cut-off of 200 ng/ml, the specificity is high but sensitivity falls to 22%. Furthermore, only 10%–20% of small tumours may lead to an elevated serum α FP level.

Efforts to uncover the underlying aetiology (e.g. hepatitis B virus, hepatitis C virus) should be made, as this has implications for further treatment as well as for family screening. Full-body staging CT should also be undertaken as part of the workup to identify distant metastasis.

Prognosis and how to estimate it

Based on data reporting the natural history of the disease, the main clinical prognostic factors in HCC patients are related to tumour number; the size of the nodules; the presence of vascular invasion and/or extra-hepatic spread; liver function (Child–Pugh's score, bilirubin, albumin); portal hypertension; and the pre-morbid state. Aetiology has not been identified as an independent risk factor. When a HCC is detected due to symptoms, survival can be as little as 12 weeks. However, in broad terms, 5-year survival when picked up through screening programmes can approach 50%.

In untreated disease, death can occur due to liver failure or metastatic disease. Unfortunately, most patients have non-resectable disease with prognosis depending more on the state of the liver rather than on tumour size alone. The tumour size, however, helps predict the likelihood of major venous involvement, whereas the Child–Pugh score is useful in predicting perioperative survival following surgical resection.

Treatment and its effectiveness

The Barcelona Clinic Liver Cancer (BCLC) score is the most widely used staging system in the West. It is very useful in deciding amongst potential treatment options and correlates best with patient outcome. A detailed discussion of the different staging systems is beyond the scope of this chapter, although we turn the reader's attention to the recent European Association for the Study of the Liver guidelines for further reading. Using the BCLC criteria, available treatment options can be stratified depending on the size, number, and location of tumours; the presence or absence of cirrhosis; operative risk factors based on extent of cirrhosis and comorbidity; overall performance status; portal vein pressure/patency; and presence of metastases.

Any decision regarding treatment should take place in a specialist centre with expertise in dealing with HCC, and in a multidisciplinary meeting with radiologists, hepatologists, surgeons, oncologists, specialist nurses, and histopathologists. However, a brief discussion of the different modalities is provided in this section. Up until recently, surgical resection and liver transplantation were the only chances of cure. However, newer treatment modalities show promise in those patients not meeting criteria for surgical intervention. Local ablative therapies in particular can be used either as a bridge to transplant by reducing tumour progression, or as a palliative procedure to extend disease-free survival.

Surgical treatments

Resection

Resection is the operation of choice in patients with tumours <2 cm in diameter and with well-compensated liver disease. Amongst patients who undergo successful resection, long-term survival is possible, with 5-year survival rates of up to 74% in patients without significant decompensation. Unfortunately, less than 5% of candidates are suitable for this procedure at time of diagnosis, and those with cirrhosis tolerate resection less well. Moreover, up to 75% of cirrhotic patients will develop intra-hepatic recurrence within 5 years, due to either de novo HCC or local intra-hepatic metastasis. Clinically evident portal hypertension is a significant predictor of poor outcome with significant resection, and resection of more than two liver segments is thus contraindicated in individuals with Child–Pugh Class B or C. Selection criteria for resection include:

- non-cirrhotics/Child–Pugh Class A
- solitary lesion <2 cm in diameter
- lack of vascular involvement or extra-hepatic spread

A distinctive variant of HCC known as the 'fibrolamellar variant' is a slow-growing tumour occurring in the third decade. Patients seldom have a history of previous liver disease. This most commonly occurs in the left lobe, presenting as pain. Histologically, neoplastic hepatocytes are separated by thin layers of fibrosis. It is important to recognize these variants, as nearly one-half are amenable to resection. Post-transplant survival appears to be equivalent to that of 'classical' HCC.

Transplantation

Transplantation has the potential to not only eliminate the cancer but also cure underlying liver disease; thus, it is often the treatment of choice in patients with cirrhosis. Only about 5% of HCC patients are suitable; however, down-staged disease following embolization or radiofrequency ablation (RFA) may confer suitability for transplantation. This option should be considered in the following cases:

- solitary lesion \leq 5 cm in diameter
- nodular disease with <3 nodules, each \leq 3 cm in diameter
- no metastatic or regional node involvement
- no vascular invasion

Carefully selected individuals with established cirrhosis and a single HCC lesion \leq 5 cm in diameter, or up to three HCC lesions all \leq 3 cm in diameter, have a 4-year overall survival rate of 85% and a tumour-free survival rate of 92% with liver transplantation (these are known as the Milan criteria). Survival for patients with much larger tumours is below 50%.

Ablative therapies

Tumour ablation is probably as effective as surgical resection in cirrhotic patients. Possible approaches that can be considered include percutaneous ethanol injection (PEI) and RFA.

PEI into the tumour can lead to complete ablation in up to 70% of lesions \leq 3 cm in diameter. This requires several sessions but 3-year survival rates of 40%–79% have been achieved depending on the severity of underlying liver disease. However, PEI can result in tumour seeding, and treated lesions have a high rate of local recurrence (33%–43%). This technique is rarely used nowadays and has largely been superseded by more advanced modalities.

RFA is useful for smaller tumours and, compared with PEI, is associated with an improved recurrence-free survival at 24 months (64% vs 43%). Complication rates are low but may include fever, pain, bleeding, pleural effusion, haematoma, and an intermittent transaminitis.

Embolization

Trans-arterial embolization, or trans-arterial chemo-embolization (TACE), is now the most widely used treatment for non-resectable HCC. The rationale is that intra-arterial infusion of a cytotoxic agent (usually doxorubicin or cisplatin), followed by embolization of the tumour-feeding blood vessels, will result in a strong cytotoxic and ischaemic antitumour effect. Patients require well-preserved liver function and, before instituting definitive therapy, it is best to treat the complications of cirrhosis, using diuretics with or without paracentesis, for ascites; lactulose, for encephalopathy and control of variceal bleeding; and antibiotics, for spontaneous bacterial peritonitis.

The efficacy of TACE appears to be dependent on careful patient selection, although a reduction in tumour burden can be achieved in 16%–61% of treated patients. A 2-year survival rate of 63% has been achieved in patients with Child–Pugh A cirrhosis, an absence of cancer-related symptoms, and large or multinodular HCC with no vascular invasion or extra-hepatic metastasis. However, patients with portal vein invasion achieve 2-year survival rates of only 31%. This is still superior to that of the untreated control group (2-year survival, 11%). TACE has thus been established as the standard of care for patients with multinodular HCC, relatively preserved liver function, an absence of cancer-related symptoms, and no evidence of vascular invasion or extra-hepatic spread.

The tolerability of conventional TACE seems to be affected by the type of regimen and the frequency of the treatment. The most

common complication is postembolization syndrome, which is characterized by fever, elevated alanine aminotransferase levels, and abdominal pain; it occurs in 32%–80% of treated patients. TACE is contraindicated in patients with advanced cirrhosis and hepatic decompensation because the ischaemic damage associated with embolization can lead to a rapid decline in liver function with worsening encephalopathy, increased ascites, and, ultimately, death.

Synergistic and combination therapies

Locoregional therapies have long been used in the setting of combined treatment strategies. An accepted indication is the use of interventional treatment in patients awaiting transplantation, to prevent tumour progression when the waiting time exceeds 6 months. Moreover, preliminary data suggests that both RFA and TACE may be able to 'down-stage' patients with larger tumours to the point of patients meeting the Milan transplant criteria.

The combined use of TACE and tumour ablation techniques is very popular in the treatment of HCC tumours of intermediate size (i.e. 3–7 cm in diameter). Despite promising results, no robust randomized controlled trial comparing the efficacy of combined techniques over monotherapy has been completed so far.

Newer modalities

Many patients with advanced HCC are not candidates for surgical resection, liver transplantation, or localized ablation. Unfortunately, HCC is a relatively chemotherapy-resistant tumour. Moreover, chemotherapy is usually not well tolerated and seems to be less efficacious in patients with HCC with underlying hepatic dysfunction. Younger patients with well-compensated cirrhosis

have better outcomes with chemotherapy than older patients or those with alcoholic cirrhosis, and may be a candidate for entry into clinical trials.

Sorafenib (a multitargeted oral kinase inhibitor) has recently been shown in a Phase III trial to slightly prolong survival (up to 14.7 months) in select patients with HCC.

Anti-angiogenesis agents (e.g. bevacizumab) work by disrupting the formation of blood vessels that feed tumours. The highly vascular nature of HCC suggests that the use of such agents may be effective in combination with the chemotherapy agents gemcitabine and oxaliplatin. However, bevacizumab is not currently licensed for use in the UK.

Palliative care

For patients with Child Class C cirrhosis and contraindications to transplantation or entry to clinical trials, any further intervention has the potential to result in progressive hepatic decompensation. In these patients, treatment focuses on managing pain, ascites, oedema, and encephalopathy. Patients with large tumours have a short life expectancy, and care should be designed to preserve and enhance quality of life. Early referral to palliative care practitioners should be considered.

PART 10

Neurological disorders

219 Normal neurological function

Dirk Bäumer

Introduction

A basic understanding of the anatomy and physiology of the nervous system is necessary in order to understand and diagnose neurological disease. This chapter will give a brief outline of those aspects of neuroanatomy and neurophysiology which are helpful in daily clinical practice and form the basis of the clinical neurological method outlined in Chapter 220.

Consciousness

A simple operational definition of consciousness includes awareness of the self and the environment, and responsiveness to external stimulation. This implies content (awareness of something) as well as arousal and alertness. Arousal is thought to be mediated by the ascending reticular activating system (RAS), which is located in the upper brainstem and diencephalon (medial thalamus) and has reciprocal connections with wide parts of the cerebral cortex. Localized lesions of the RAS or interruption of its diffuse connections will lead to diminished arousal, which manifests as disturbance of consciousness. This could be a mild reduction of attention; confusion; drowsiness; or coma.

Cognition

Intact arousal and attention are prerequisites for all other cognitive processes, including memory and executive function, which can be secondarily impaired by attentional deficits. Attention, memory, and executive function are examples of functions that are anatomically distributed over different parts and both hemispheres of the brain.

Episodic memory function is dependent upon structures in the diencephalon (mamillary bodies and thalamus), basal forebrain nuclei, and medial temporal lobe structures including the hippocampal formations and their related structures on both sides. These structures are connected in the 'circuit of Papez' of the extended limbic system. Note that the thalamus comprises a group of nuclei with diverse functions not only in cognition but also in the relay of motor, sensory, and visual information.

Executive function—goal-directed behaviour, planning, initiating action, monitoring action, and shifting attention to different tasks—is attributed to the frontal lobes, as are social cognition, inhibitory control, and aspects of emotion.

Other functions are localized and/or lateralized to more specific brain regions, such as, for example:

- language: dominant hemisphere (peri-Sylvian region)
- praxis (i.e. the ability to perform learned skilled motor acts) and calculation: dominant parietal lobe
- visuospatial skills, constructional ability, and prosody (the rhythm and intonation of speech): non-dominant hemisphere

See Table 219.1 for an abbreviated list of the localization of cognitive functions and deficits arising from lesions.

Motor function

Voluntary movements require efficient interplay between higher cortical centres, the basal ganglia and cerebellum, and the descending motor pathways, including the pyramidal tract. The activity of the lower motor neurons, which synapse directly onto the muscle, is further modified at spinal level.

In a simplified scheme, movements are thought to be initiated in the supplementary motor area in the frontal lobes, with access to

stored motor programmes in a wider range of the cortex. Before the signals initiating planned movement leave the brain via the corticospinal (pyramidal) tract, they are adjusted and fine-tuned through feedback loops with both the basal ganglia and the cerebellum.

The main basal ganglia input from the cortex is the striatum; its main output is via the medial globus pallidus and thalamus back to the cortex—the cortical–striatal–pallidal–thalamic–cortical motor loop. A number of other loops exist, for example for eye movements (see 'Eye movements'). The function of the basal ganglia as a whole is to facilitate and initiate movement, and a number of basal ganglia (or 'extrapyramidal') disorders lead to either too much or too little movement.

The cerebellum receives cortical inputs from the frontal lobes via the pontocerebellar tracts and the middle cerebral peduncle, as well as information from the vestibular and proprioceptive systems; inputs are continually integrated, and outputs are adjusted, to allow for smooth and coordinated movements. Cerebellar efferents back to the cerebral cortex are mainly via the superior cerebellar peduncle, from where tracts cross the midline to reach the contralateral thalamus. Because the cerebellar outflow paths are crossed, and the descending motor pathways are crossed again, the cerebellar hemispheres control the ipsilateral limbs.

The corticospinal tract is the only descending motor tract directly connecting with the lower motor neurons in the spinal cord. It originates predominantly, but not exclusively, from the motor cortex, where body areas are represented topographically in the 'motor homunculus'. Body parts with the most delicate movements, including the hand and the face, have a proportionally larger representation than proximal muscles. The corticospinal tract descends through the internal capsule into the brainstem, giving off collaterals to the basal ganglia and cerebellum. It then crosses to the other side (decussates) in the lower medulla. In the spinal cord, it runs in the anterior and posterolateral white matter tracts before synapsing with the alpha motor neurons in the anterior horn (grey matter).

Lower motor neuron axons pass through the anterior roots, nerve roots, and peripheral nerves (and plexuses in the cervical and lumbosacral regions) before connecting with muscle fibres at the neuromuscular junction. The neurotransmitter used here is acetylcholine.

The number of muscle fibres innervated by each motor neuron (the motor unit) varies from muscle to muscle and can be high (up to 1000) in the case of proximal muscles, and low (about 20 in the case of extraocular muscles).

The activity of the alpha motor neuron determines muscle tone. This in turn is modulated by a monosynaptic reflex with afferents coming from the muscle spindle—the basis for the tendon reflex. If a muscle is stretched by tapping a tendon, muscle spindle afferent sensory fibres are activated. After passing through the posterior spinal root, these synapse directly onto and activate the alpha motor neuron. The sensitivity of the muscle spindle is set by intra-fusal muscle fibres innervated by gamma motor neurons. Both alpha and gamma motor neurons are under supraspinal control from descending tracts. These are mostly inhibitory, so that a lesion of the descending tracts will lead to an exaggeration of muscle tone and tendon reflexes.

In an analogous fashion, lower motor neurons in the brainstem are under control of the corticobulbar tract. Their cell bodies are located in cranial nerve motor nuclei. Importantly, unlike spinal motor neurons, brainstem motor neurons are often under bilateral cortical control. This is true for the motor neurons innervating the 'bulbar' musculature of pharynx and tongue, as well as motor neurons innervating the upper face and the muscles controlling eye closure (hence, the sparing of the forehead in 'upper motor neuron' facial weakness).

Table 219.1 Abbreviated list of the localization of cognitive functions and deficits arising from lesions

Structure	Function	Deficit
<i>Frontal lobe</i>		
Primary and supplementary motor area	Motor control of contralateral face and limbs	Apraxia Hemiparesis Localized weakness (e.g. the 'cortical hand')
Frontal eye field	Initiation of voluntary gaze	Gaze deviation
Prefrontal cortex (highly connected with wide areas of the cortex, the limbic system, and the basal ganglia)	Executive abilities Social cognition Inhibitory control Emotion	Poor executive function Apathy or disinhibition Personality change
Broca's area (dominant hemisphere)	Speech	Expressive dysphasia
<i>Temporal lobe</i>		
Temporal neocortex	Language (Wernicke's area) Semantic memory (left) Hearing	Receptive dysphasia Poor semantic memory
Temporal optic radiation	Visual pathways	Upper homonymous quadrantanopia
Medial temporal lobes (hippocampi and related structures)	Episodic memory formation (verbal on left, non-verbal on right) Emotions (limbic system)	Memory dysfunction Disinhibition Aggression Placidity
<i>Parietal lobe</i>		
Parietal optic radiation	Visual pathways	Lower homonymous quadrantanopia
Sensory cortex	Sensation	Cortical sensory loss (e.g. two-point discrimination)
	Representation of motor tasks	Apraxia
Inferior parietal lobe/angular gyrus	Calculation	Left-right disorientation Acalculia Finger agnosia
	Integration of complex visual and somatosensory information	Inattention Visuospatial difficulties
<i>Occipital lobe</i>		
Visual cortex	Vision	Hemianopia Cortical blindness

Sensory function

In the peripheral nerves, pain and temperature sensation is conveyed through small nerve fibres, whereas touch, vibration, and joint-position sense tend to be transmitted in large fibres. Sensory nerve cell bodies are located in the dorsal root ganglia. Fibres enter the spinal cord through the dorsal roots. Within the cord, anatomically distinct tracts carry sensory information to the brain. The dorsal columns carry the 'large-fibre' information (touch, vibration, and joint-position sense). These tracts decussate in the medulla and reach the contralateral thalamus as the medial lemniscus. The 'small-fibre' information of pain and temperature is conveyed through the spinothalamic tracts. Axons carrying these impulses cross the midline several segments above the level of root entry; their fibres join the medial lemniscus only in the midbrain before reaching the thalamus. From the thalamus, sensory information of the contralateral side of the body reaches the sensory cortex 'homunculus'.

The different sensory pathways explain the frequent occurrence of dissociated sensory loss, for example loss of pain and temperature but not touch, vibration, or joint-position sense in selective neuropathies or in focal spinal cord and brainstem lesions.

Vision

Vision is one of the special senses. Visual information from the retina is conveyed to the occipital cortex via the optic nerves, optic tracts, and optic radiation. At the optic chiasm (which lies just above the pituitary gland), optic nerve fibres derived from the nasal half of each retina cross the midline and continue in the optic tract, together with the uncrossed temporal fibres of the other eye.

Lesions of the chiasm can therefore cause a deficit in the temporal field of each eye ('bitemporal hemianopia'), while lesions in the visual pathways behind the chiasm cause homonymous defects, for example of the left nasal and right temporal field.

Afferent fibres subserving the pupillary light reflex leave the optic radiation to reach the Edinger–Westphal nucleus of the third cranial nerve in the midbrain. Visual problems arising posterior to this point, that is, in the optic radiation or the visual cortex, therefore do not impact on the light reflex. The efferent, parasympathetic pupilloconstrictor fibres of the light reflex travel in the third nerve.

Eye movements

Eye movements depend on the intact function of the extraocular muscles and their neuromuscular junctions; the cranial nerves III, IV, and VI, and their brainstem nuclei; and internuclear as well as supra-nuclear pathways. For example, voluntary gaze to the left starts with cortical activation of the right frontal eye field. Impulses from there travel down to the contralateral pontine gaze centre, which activates the adjacent left sixth nerve nucleus, which is the origin of the abducens nerve innervating the left lateral rectus muscle, which turns the left eye to the left (abduction). To maintain conjugate gaze, the right eye also needs to turn left (adduction) at the same time. To achieve this, the left pontine gaze centre activates the contralateral (right) oculomotor nucleus, which is the origin of the third nerve innervating the right medial rectus, which turns the right eye inwards. The connection between the left sixth nerve nucleus in the pons and the right third nerve nucleus in the midbrain is the medial longitudinal fasciculus. Lesions here lead to a failure of the right eye to adduct and left eye nystagmus—this is called internuclear ophthalmoplegia.

Similar considerations apply for voluntary upgaze, which relies on intact midbrain function.

To maintain gaze on an object while moving the head, short-latency conjugate eye movements in the opposite direction are produced by the vestibulo-ocular reflex, which can be examined with the doll's head manoeuvre.

Balance

Balance is maintained by the integration of proprioceptive, visual, and vestibular information in the cerebellum and can therefore be upset by a variety of mechanisms.

Cerebrospinal fluid

Cerebrospinal fluid (CSF) is actively produced by the choroid plexus of the ventricular system at a rate of about 500 ml per day. CSF circulates from the lateral ventricles to the third ventricle, then via the aqueduct into the fourth ventricle, and from there through the foramina of Magendie and Luschka to the subarachnoid CSF spaces around the brain and spinal cord. The CSF is then reabsorbed via the arachnoid villi, which protrude into the sagittal sinus and other venous structures around the brain and cord. CSF pressure is a function of venous pressure; CSF pressure as measured by lumbar puncture in the recumbent position is usually between 6 and 20 cm H₂O, and is considered raised when above 25 cm H₂O.

Obstruction to CSF flow leads to hydrocephalus. The block can occur within the ventricular system or in the subarachnoid space, for example due to a fibrosing meningeal reaction around the base of the brain.

Nervous system function in ageing

Cross-sectional studies of intelligence in the population suggest a steady decline in cognitive function after the age of 30 but, from a practical point of view, only very a mild decline in processing speed, memory, and problem-solving becomes apparent in healthy elderly people after 70 years of age. In this population, the prevalence of mild cognitive impairment, a possible precursor to more specific dementias, is estimated to be between 14% and 18%, but signs might not always be easy to tell apart from a more benign senescent forgetfulness.

Other 'abnormal' neurological signs that may appear in up to 30% of otherwise healthy people over 70 include a glabellar sign, a snout reflex, altered eye movements with limited vertical gaze and abnormal pursuit, and a degree of muscle rigidity. Frequently, there is some thinness and weakness of muscles, seen more in proximal muscles than in distal muscles, and a loss of the ankle jerks. Vibration sense is often impaired, but proprioception is largely maintained. Walking becomes slow and cautious, with short steps and a slightly stooped posture. One might expect progressive hearing loss, a reduced sense of smell, and small pupils with a decreased reaction to light and decreased accommodation.

220 Diagnosis in suspected neurological disease

Dirk Bäumer

Introduction

It is not always clear that a symptom is due to a problem in the nervous system. Delirium, generalized weakness, and fatigue are frequently due to systemic illness. Transient loss of consciousness may have a neurological or cardiac cause. It is, therefore, important to keep an open mind before focusing on a primary neurological diagnosis in these presentations.

The principles of the neurological method are described in 'General approach', followed by their application in common clinical presentations.

General approach

Pattern recognition

Experienced neurologists often make a diagnosis on the basis of pattern recognition. For example, a patient with a unilateral tremor, slowness of movement, stiffness, and an expressionless face will be recognized as suffering from Parkinson's disease. However, in many cases, the cause of symptoms is not immediately obvious, and a careful analytical approach is needed to reach a diagnosis. It is helpful to ask where in the nervous system a problem may be located before thinking about the possible aetiology.

What part or parts of the nervous system are affected?

If a neurological problem is suspected, the first key question to be answered is 'where is the lesion?' in neuroanatomical terms. The degree of precision of localization on clinical grounds varies. It can sometimes be very specific (e.g. 'this is a problem in the dorsolateral medulla oblongata'), while at other times it may only be possible to make a general statement like 'this is a problem in the central nervous system'. Localization relies on the patient history as much as on the examination and, in cases of transient symptoms (like suspected seizures (see Chapter 39) or transient ischaemic attacks), it is in the history only. A clear history is, therefore, indispensable, and it is often worthwhile to spend some time on the review of old notes and obtaining a collateral history to clarify facts.

It may not be possible to explain all symptoms and signs on the basis of a single lesion, in which case multifocal pathology needs to be considered. With the help of the anatomical diagnosis, an attempt should be made to group the key features of a presentation into a syndromic classification. For example, if history and examination suggest a lesion affecting both spinothalamic tracts and pyramidal tracts below a certain spinal level, and there is nothing to suggest dorsal column involvement, then a diagnosis of an anterior spinal cord syndrome is made, and this will help to narrow the differential diagnosis. It will also avoid jumping to conclusions by immediately associating this constellation of signs with a spinal cord infarct without considering other possibilities.

What is the likely underlying pathology?

While occasionally the localization of the problem greatly narrows down the differential diagnosis (e.g. the dorsolateral medulla oblongata syndrome is almost always due to an infarct), usually the most important clues about the aetiology of a condition come from the history.

The mode of onset and the temporal evolution of symptoms help to make a judgement about the likely category of pathology:

- sudden onset: vascular cause (infarct, haemorrhage)
- subacute: infectious/inflammatory
- slowly progressive: neoplastic, degenerative
- fluctuating/relapsing–remitting: metabolic, inflammatory

The a priori likelihood of specific diagnoses is further influenced by the demographics of the patient, in particular age, sex, preexisting diseases, and degree of immunosuppression, as well as medication and substance use.

If there is evidence of multifocal pathology, the possibilities are that:

- some signs are old and related to disease not relevant to the current presentation (e.g. an extensor plantar response due to an old stroke in someone now presenting with a myopathy)
- the presentation defies 'Occam's razor' and is due to more than one acute problem rather than a single unifying diagnosis (e.g. pins and needles in both feet and one hand due to a peripheral neuropathy and unilateral carpal tunnel syndrome); this is Hickam's dictum
- the presentation is due to a single condition affecting several parts of the nervous system (e.g. mitochondrial disease, HIV infection, sarcoidosis, or vasculitis)

How can the diagnosis be confirmed?

A syndromic diagnosis together with demographic factors will usually lead to a differential diagnosis. To reach a final diagnosis, neurology employs a number of investigations, which are outlined in Chapter 221. The clinician should be reasonably familiar with the limitations of tests, all of which have false positive and negative rates. For example, an interictal EEG cannot be used to rule out epilepsy, and a CT brain scan can be normal in acute ischaemic stroke. If there are many differential diagnoses and, therefore, the list of possible investigations is long, it is important to find a balance between taking a pragmatic approach, limiting tests to looking for what is common, and not missing rare but potentially important diagnoses. In difficult cases, a repeat history and examination, perhaps after an interval, can be extremely helpful, as can be a second opinion from a colleague.

The following paragraphs are intended to give some more specific pointers of how to use the neurological method in common presentations, in particular in relation to the anatomical diagnosis.

The neurological approach to common presentations

The unconscious patient

Is this a neurological problem? The majority of cases of coma are due to metabolic–toxic encephalopathies, including hypoxia–ischaemia and poisoning, in which case the 'lesion' localizes to diffuse dysfunction of the cerebral cortex. This conclusion is often reached by the absence of signs pointing towards a focal lesion of the reticular activating system located in the upper brainstem and thalamus. Perhaps the most useful part of the examination is to look at the eyes and pupils:

- roving eye movements indicate an intact brainstem, implying diffuse cortical dysfunction as the cause of coma

- many spontaneous eye movement abnormalities occur in diffuse hemispheric dysfunction
- intrinsic brainstem lesions (e.g. haemorrhage or infarction) may cause skew deviation of the eyes, small or unequal pupils, and motility disorders like an internuclear ophthalmoplegia or absent oculocephalic reflex in the doll's head manoeuvre
- brainstem compression, for example by herniation, may cause a third nerve palsy with a fixed dilated pupil but otherwise intact brainstem reflexes

The patient with cognitive problems

Where is the lesion? Is this a problem predominantly of maintaining attention (a distributed cognitive function; see Chapter 112) or is it a more localized problem indicative of a focal brain lesion or specific dementia? Tests of attention include 'serial 7s' and digit span, and deficits here will impact on the performance in other domains, including memory, perceptuospatial skills, and executive function. How quickly did the problem develop? An acute or subacute onset of symptoms and fluctuations in performance throughout the day point towards a delirium. An insidious onset and slowly progressive course indicates a degenerative cause.

The patient with weakness

Where is the lesion? The assessment relies on both the distinction between lower and upper motor neuron lesions, and a broad classification of the pattern of weakness. **Lower motor neuron lesions** produce signs related to muscle denervation and are characterized by normal or reduced muscle tone, muscle wasting, fasciculations, and depressed or absent deep tendon reflexes. **Upper motor neuron lesions** always involve problems with a group of muscles, and the pattern is often 'pyramidal', with weakness affecting arm extensors more than flexors, and leg flexors more than extensors. Movements are slow and there is a reduction in control of fine finger movements. Because muscles are still innervated, there is no wasting or fasciculations. Muscle tone is increased due to lack of inhibition of spinal reflexes, resulting in spasticity, exaggerated deep tendon reflexes, clonus, and an extensor plantar response: the big toe 'goes up' after stroking the lateral plantar surface of the foot, a sign first described by Babinski in 1896.

Spasticity is velocity-dependent increase in tone and must be distinguished from extrapyramidal rigidity, in which the resistance to muscle stretch is constant. Slowness of movement in spasticity does not generally lead to true bradykinesia. This is defined as slowness with a progressive decrease of speed and amplitude of repetitive movements.

Distribution of weakness

Global weakness

When global weakness is observed, consider metabolic problems (such as hypokalaemia, disorders of the neuromuscular junction, a myopathy, or polyneuropathy). A brainstem problem, for example from basilar artery thrombosis, can present with weakness of all limbs, the bulbar muscles, and eye movements. Look for impairment of consciousness (upper brainstem), sensory disturbance, altered brainstem reflexes, and brisk reflexes in the limbs. Predominantly distal weakness points to a length-dependent neuropathy, while predominantly proximal weakness is often myopathic. Some diseases affect peripheral nerves and nerve roots in a non-length-dependent fashion and lead to proximal and distal weakness (e.g. Guillain-Barré syndrome).

Quadriparesis

When quadriparesis is observed, consider a cervical spinal cord lesion, a myopathy, or a polyneuropathy. Again, the reflexes will be most helpful in distinguishing a spinal cord lesion (upper motor neuron) from a neuropathy or myopathy (lower motor neuron). Acutely, reflexes may be absent in a spinal cord lesion. In this case, weakness above the neck (e.g. of neck flexion and the facial muscles) favours a neuropathy or myopathy. A sensory level and sphincter involvement favour a cord problem.

Paraparesis and bibrachial paresis

Paraparesis (weakness of both legs) is caused by thoracic or lumbar spinal cord lesions, in which case there is often a sensory level and sphincter impairment. Other possibilities include multiple radiculopathies, which are often asymmetrical, or 'paraparetic' forms of a neuropathy affecting mainly the legs. Finally, bilateral frontal lobe lesions can lead to a paraparesis.

Weakness of both arms (bibrachial paresis) is less common. It can be caused by a lesion located in the central cervical cord, the cervical anterior horn cells, the cervical nerve roots, or brachial plexus.

Hemiparesis

Hemiparesis (weakness on one side of the body) points to a problem in the brain or, less commonly, one side of the cervical cord. Facial weakness shows that the problem is in the brain. The presence of other signs will help to localize this further. Are there cortical signs, for example hemianopia, dysphasia, or neglect? If not, are there symptoms or signs pointing to a brainstem problem, such as vertigo, ataxia, or double vision? Brainstem lesions also frequently produce bilateral signs, or a hemiparesis with 'crossed' signs, for example contralateral ataxia or contralateral cranial nerve palsies. The latter may help to pinpoint the lesions to the brainstem level involved, depending on their site of origin (brainstem nuclei):

- midbrain: Cranial nerves III (oculomotor) and IV (trochlear)
- pons: Cranial nerves V (trigeminal), VI (abducens), and VII (facial)
- medulla: Cranial nerves VIII (vestibulocochlear; also pons), and IX–XII (glossopharyngeal, vagus, accessory, hypoglossal)

Single limb weakness

Single limb weakness can be due to peripheral mononeuropathies, a plexopathy, a radiculopathy, an anterior horn cell problem, or an upper motor neuron lesion in the spinal cord or brain. The pattern of weakness, the general features of upper versus lower motor neuron lesions outlined in 'The patient with weakness', and associated sensory features help to distinguish amongst the different causes.

Reaching a diagnosis in the patient with weakness

After establishing the anatomical diagnosis (or differential diagnosis) on clinical grounds, other features in the history are taken into account to reach a differential diagnosis of the underlying pathology. For example, the occurrence of a paraparesis with brisk reflexes, extensor plantar responses, sphincter disturbance, and a sensory level coming on over weeks in a patient with known prostate cancer would make cord compression by malignancy most likely, while the same syndrome developing acutely in someone admitted with aortic dissection suggests a spinal cord infarct.

The patient with sensory problems

As for the patient with weakness, one should try to localize sensory symptoms to a problem in a peripheral nerve (e.g. numbness of Fingers 1–3 in a median neuropathy), nerve roots (dermatomal distribution), plexus, spinal cord (sensory level), or brain (hemisensory loss and often 'cortical' sensory loss: intact light touch but impaired two-point discrimination and stereognosis). The sensory examination is difficult and can easily lead to spurious results. It is, therefore, often helpful to try and confirm an hypothesis, rather than to do a complete sensory examination of all nerves and dermatomes.

Occasionally, it is difficult to distinguish between sensory loss from a neuropathy and that from a spinal cord lesion. However, the reflexes are absent or depressed in the former case, but are brisk in the latter case.

The unsteady patient

The unsteady patient may have a problem of proprioception (large-fibre neuropathy or dorsal spinal cord disease) and get significantly worse in the dark, displaying a positive Romberg's test and impaired joint position sense. Removal of visual clues also worsens the unsteadiness of vestibular disorders, which, in addition, show an abnormal vestibulo-ocular reflex. Patients with cerebellar disease have problems integrating the visual, proprioceptive, and vestibular inputs with

reflex movements, leading to incoordination. This can affect gait and stance in isolation, or be combined with ataxia of the limbs, cerebellar dysarthria, and abnormal eye movements. Romberg's test is usually negative in cerebellar disease, and patients do not report vertigo.

The patient with abnormal movements

For the patient with abnormal movements, the usual approach is to classify abnormal movements into broad categories of tremor (a rhythmic sinusoidal oscillation of a body part), myoclonus (a very brief jerk), chorea (irregular, fidgety, purposeless movements flowing from one body part to another), tics (involuntary, stereotyped movements that can be suppressed briefly), and dystonia (abnormal posture). These movements can occur alone or in combination, and be due to a primary movement disorder, a hereditary degenerative disease with other features, or be secondary to lesions or systemic illness. It is important not to equate the phenotype of the movement with a specific disorder, but to reach a syndromic diagnosis first and then think about the possible aetiology. For example, chorea can occur in Huntington's disease, but can also occur in SLE, or as a medication side effect. Chorea affecting only one part of the body can be due to a focal lesion of the basal ganglia.

The patient with a functional disorder

Many patients present with symptoms and signs that are not explainable anatomically, inconsistent over time, distractible, and often associated with dissociative symptoms and other medical complaints. Overt psychiatric features may or may not be present. 'Hard'

neurological signs are absent but, of course, functional symptoms can occur in patients with an organic disorder. There are a number of signs supportive of a functional disorder, but the sensitivity and specificity of many is limited or unknown. For example, Hoover's sign is positive when a patient shows weakness of hip extension when tested directly, but strong (involuntary) hip extension when flexion of the contralateral hip is tested. While widely considered the most useful test for functional weakness, it can also be positive in patients with cortical neglect.

Summary

In conclusion, diagnosis in neurology is predominantly guided by the history, with physical examination and investigations used to confirm or refute hypotheses generated by it.

221 Investigation in neurological disease

Kannan Nithi and Sarosh Irani

Introduction

This chapter provides a brief overview of the more commonly available neurophysiology and neuroradiology techniques, guidance on how to perform a lumbar puncture, and a summary of biochemical, immunological, and genetic tests relevant to neurological disorders.

EEG

Surface-recorded EEG monitors underlying brain electrical currents generated by synaptic activity in cortical neurones. The actual traces obtained are only a low-resolution summation of this activity. An EEG will normally report the wake background rhythms, which are typically dominated by sinusoidal oscillations at a frequency of 8–12 Hz (alpha wave) activity over the occipital area, as well as any focal slow wave activity, sharp waves, or spike discharges.

EEG is used clinically in the investigation of epilepsy, states of altered consciousness, and in some cases of dementia.

Epilepsy

In adults, EEG still has a role in defining the epilepsy syndrome and directing further investigation and treatment. A baseline 'interictal' recording may reveal an underlying potential for idiopathic generalized epilepsy or a focal epilepsy syndrome. It should be noted, however, that a significant percentage of patients with a definite diagnosis of epilepsy have a normal interictal recording. Conversely, recordings in non-epileptic subjects can show abnormalities in 1%–10% of cases. Using a routine EEG to rule in or rule out epilepsy when the history is equivocal is, therefore, not recommended.

A recording during an attack has much higher sensitivity and specificity, first in confirming whether or not a clinical episode does represent an epileptic seizure and, second, in determining whether it is clearly of focal or generalized onset. The EEG may remain abnormal for several hours after an epileptic seizure.

Prolonged EEG recordings can be carried out in a home/work environment with an ambulatory system or in an inpatient setting (video telemetry). The latter may be helpful in patients being considered for epilepsy surgery and in identifying the small number of patients who may have a normal surface EEG during an epileptic seizure.

Altered consciousness

EEG in the context of altered consciousness often shows a non-specific disturbance of cortical rhythms. It can be of particular help in demonstrating the presence of non-convulsive status epilepticus (see Figure 221.1); in this situation, a patient may appear to be confused or unconscious with no clearly identifiable clinical epileptic features. Although certain EEG patterns, most notably triphasic waves, are classically associated with hepatic encephalopathy, even these are not entirely specific and are occasionally seen with other metabolic causes of altered consciousness. Therefore, in this setting, the EEG really only helps confirm the existence of an encephalopathic state, which is usually readily clinically apparent in any case. An EEG is sometimes requested in order to support a diagnosis of herpes simplex encephalitis but, again, it lacks the sensitivity and specificity to either refute or confirm this diagnosis. An EEG may be helpful in providing prognostic information in coma. However, the cause, depth, and duration of the coma, as well as the clinical signs, are of greater importance in this respect. Only one EEG pattern (complete generalized suppression greater than 24 hours after cardiac arrest) has a uniformly poor prognosis.

Dementia

EEG tends to show a progressive non-specific slowing of cortical rhythms in dementia syndromes. It can be of particular use in the diagnosis of sporadic Creutzfeldt–Jakob disease as, during the course of the disease, the EEG often becomes dominated by periodic generalized sharp-wave complexes.

Nerve conduction studies

The basic principle in nerve conduction studies (NCSs) is the application of an electrical stimulus at one point along a nerve (causing depolarization of the underlying nerve fibres) and recording, with surface electrodes, the potentials generated and propagated further along the nerve. Sensory and motor nerve fibres can be studied. The report will normally comment on the amplitudes (measured in microvolts), onset, and peak latencies (measured in milliseconds) of the sensory nerve action potentials; the amplitudes (measured in millivolts) and distal latencies of compound muscle action potentials (CMAPs); and motor conduction velocities (expressed as metres per second).

Some limitations of conventional NCSs should be noted: they do not assess the very smallest sensory nerve fibres, they may not be possible in the context of severe limb oedema, and abnormalities may lag some time behind the onset of clinical symptoms and signs. There is also a wide range of normal values for each of the parameters measured, allowing for age, sex, and skin temperature.

NCSs are used in the investigation of single nerve lesions (mononeuropathies) and more generalized polyneuropathies; when they are used in combination with needle EMG, they can be helpful in the investigation of lesions of the brachial and lumbosacral plexus, nerve root lesions (radiculopathies), and disorders of the neuromuscular junction.

Mononeuropathies

NCSs are often used to confirm the presence of an entrapment neuropathy, which is most commonly located in the median nerve in the carpal tunnel (see Figure 221.2), and the ulnar nerve at the elbow (see Figure 221.3); the degree of abnormality reported will often influence the decision regarding surgical intervention. In acute compressive lesions (e.g. 'Saturday night palsy' of the radial nerve), NCSs and EMG may not demonstrate any abnormality for several weeks following the precipitating event.

Polyneuropathies

NCSs may be used to document the presence and/or severity of peripheral nerve involvement in hereditary and acquired neuropathies. They are particularly helpful in identifying whether the underlying pathological process is likely to be due to primary axonal degeneration or to inflammation of the myelin sheath. The latter process, demyelination, is usually manifested by marked slowing of nerve conduction velocities (the report may also comment on prolongation of distal latencies, temporal dispersion, evidence of conduction block, and absence or dispersal of proximal nerve responses (F waves)). In the acute setting, NCSs can be particularly helpful in supporting a diagnosis of Guillain–Barré syndrome. Even here, studies can be normal, especially early on in the disease process.

Neuromuscular junction disorders

Application of repetitive nerve stimulation (RNS) of varying frequencies (usually 3–10 Hz) to motor nerve fibres in muscles at rest and after exercise can be used to identify disorders such as myasthenia

Figure 221.1 Upper non-convulsive status epilepticus; EEG recordings from a patient who had a past history of epilepsy, was no longer on anticonvulsants, and was admitted with an 'acute confusional state'. (A) This trace, taken 48 hours into admission, is dominated by frequent bursts of high-amplitude slow-wave activity. (B) This trace, recorded three days later after reintroduction of anticonvulsants, shows a marked improvement, mirrored by resolution of the confusional state.

Figure 221.2 Sensory nerve conduction study in a patient with carpal tunnel syndrome; the upper trace shows a delayed latency of onset of the sensory nerve action potential from the second digit, which is innervated by the median nerve. The lower trace shows a normal latency response from the fifth digit, which is innervated by the ulnar nerve.

gravis and botulism. Typically, in these disorders, RNS will show a decrement in the amplitudes of successive CMAP responses (the decrement is usually maximal by the fourth response), and this will be accentuated if the muscle to be studied is contracted maximally for a few seconds before stimulation.

Needle EMG

EMG records electrical potentials generated by contracting muscle fibres. Unlike NCSs, this activity is usually studied using needle rather than surface electrodes. A 0.3–0.7 mm concentric needle electrode, consisting of an insulated platinum wire within a steel cannula, is inserted directly into the muscle to be studied. The signal obtained has an auditory as well as visual component.

The EMG report will comment on any activity in the muscle at rest (normally electrically silent) as well as during increasing levels of voluntary muscle contraction. Abnormal spontaneous activity includes fasciculations, fibrillation potentials, and positive sharp-wave discharges, as well as more prolonged activity such as myotonia (see Figure 221.4). The morphology and recruitment pattern of motor units can be analysed qualitatively and quantitatively.

In clinical practice, EMG has, to a large extent, been superseded by histopathology and genetic testing in establishing a precise diagnosis in primary and acquired muscle disease. It does, however, still have a role in narrowing the differential diagnosis in muscle weakness and, in particular, determining whether weakness is due to a neuropathic or myopathic process. Similarly, although neuroimaging is now the modality of choice for the investigation of radiculopathy, EMG may help in the preliminary localization of the site of pathology. EMG remains an important investigation in the assessment of motor

neuron diseases, in particular, in providing objective evidence of denervation in limb muscles in cases of predominantly upper motor neuron/bulbar presentations.

A more specialized EMG recording (single-fibre EMG) is of particular use in the neurophysiological assessment of disorders of the neuromuscular junction, particularly when used in conjunction with RNS.

Evoked potential studies

Evoked potential studies are a way of measuring how sensory information is processed within the CNS. The stimuli applied may be visual, auditory, or somatosensory (see Figure 221.5).

In clinical medicine, the role of these studies is largely restricted to the investigation of multiple sclerosis (MS) and, in particular, demonstrating evidence of a 'clinically silent' demyelinating lesion (i.e. one with no associated clinical deficit).

Neuroradiology

This section will deal primarily with CT and MRI. There are a number of less commonly used, more specialized techniques (including magnetoencephalography, magnetic resonance spectroscopy, functional MRI, and DaT scanning) which may gain more widespread clinical use over the next few years. Imaging of acute stroke is covered in Chapter 227.

CT

CT is an X-ray-based technique which is readily available and remains the first-line radiological investigation in many acute neurological/

Figure 221.3 Ulnar entrapment neuropathy: recordings of compound muscle action potentials from the abductor digiti minimi. The upper trace shows a normal-amplitude response following stimulation of the ulnar nerve at the wrist. The lower trace shows a marked reduction in amplitude following stimulation in the ulnar groove at the elbow.

neurosurgical situations. CT is particularly helpful in identifying acute bleeding, and remains the imaging modality of choice in the initial workup of subarachnoid haemorrhage. CT is often the first radiological investigation in acute stroke and traumatic brain injury, although it is often followed by MRI. CT (with contrast) will usually identify the presence of significant space-occupying lesions, but subsequent MRI is nearly always needed in such situations, due to

its better resolution. In particular, CT may be inadequate if there is a strong clinical suspicion of a posterior fossa abnormality.

MRI

MRI is based on the properties of hydrogen nuclei (protons). In simple terms, an MRI can be regarded as displaying the relative amount of fat and water within the region being studied (see Figures

Figure 221.4 Myotonia: a needle recording from the tibialis anterior in a patient with myotonic dystrophy. The trace shows a prolonged burst of myotonia; the sound this produces is often compared to that made by a dive-bomber.

Figure 221.5 A posterior tibial evoked potential study: this trace shows the waveform of the cortical somatosensory evoked potential obtained by stimulation of the posterior tibial wave in a normal subject.

Demyelination in the central nervous system.

A. Multiple small ovoid periventricular hyperintense white matter lesions (T2 weighted axial image) in relapsing–remitting multiple sclerosis.

B. One large and three smaller confluent white matter lesions on coronal FLAIR.

C. Single large right hemispheric white matter lesion on T2 weighted axial image. This is an example of tumefactive multiple sclerosis.

D. Sagittal spinal cord T2-weighted image showing swelling in upper cervical cord with high signal within the central cord, extending over 3 vertebral segments. These features are consistent with the longitudinally extensive transverse myelitis (LETM) of neuromyelitis optica (NMO).

Figure 221.6 MRI findings in multiple sclerosis: demyelination in the CNS. (A) Multiple small, ovoid, periventricular, hyperintense white matter lesions (T2-weighted axial image) in relapsing–remitting multiple sclerosis. (B) One large and three smaller confluent white matter lesions on coronal FLAIR MRI. (C) Single large, right-hemispheric white matter lesion on T2-weighted axial image. This is an example of tumefactive multiple sclerosis. (D) Sagittal spinal cord T2-weighted image showing swelling in the upper cervical cord with high signal within the central cord, extending over three vertebral segments. These features are consistent with the longitudinally extensive transverse myelitis of neuromyelitis optica.

Cerebral angioma.

Tortuous parasagittal vasculature structure within the right hemisphere shown on T2 (A) and T1 (B)-weighted MRI and the angiogram (C).

Figure 221.7 Imaging of cerebral angioma: tortuous parasagittal vasculature structure within the right hemisphere shown on (A) T2- and (B) T1-weighted MRI and (C) an angiogram.

221.6–221.8). Following the application of a radiofrequency pulse in the magnetic field, hydrogen nuclei are perturbed and then relax back to their resting state by two mechanisms—spin–lattice relaxation (T1) and spin–spin relaxation (T2). Each tissue type has a characteristic T1 and T2 time, which are measured in milliseconds. Setting the MRI scanner to emphasize one or other of these produces distinctly different images.

A basic MRI image series will include T1-weighted images (in which fat is designated by a high signal, and water by a low signal) and T2 (in which fat is designated by a low signal, and water by a high signal). T1 images are best for delineating normal anatomy, providing grey/white matter contrast, and differentiating fat from water. T2 sequences are very sensitive to increases in water content (i.e. oedema), and thus are used for detecting pathology. T1 sequences pre- and post-administration of gadolinium contrast are also obtained in certain circumstances, notably to look for breaches in the blood–brain barrier (such breaches are characteristic of active/acute MS lesions), to help radiologically differentiate tumour types and grades, and to look for abnormal enhancement of the meninges. By altering the radiofrequency pulse sequence and other technical aspects of the acquisition protocol, a number of different MRI sequences result, each

with their own advantages and disadvantages (Table 221.1). It is often most informative to compare the behaviour of the area of interest across the different sequence types, and the specific set of sequences run will depend on the clinical scenario and the information needed from the MRI (see Table 221.1).

The sensitivity of MRI can lead to diagnostic uncertainty and undue patient anxiety when interpreting a report. Around 10% of MRI brain scans will reveal an incidental abnormality. In particular, the significance of the finding of high-signal lesions in white matter on T2 sequences needs to be interpreted in the clinical context, as it may be supportive of a diagnosis of MS or be purely a reflection of small vessel ischaemic changes.

Although MRI, (unlike CT), does not have the same health concerns with respect to radiation, there are contraindications to MRI scanning with respect to implanted devices/metal such as cardiac pacemakers and cerebral aneurysm clips. The concern with respect to cardiac devices is malfunction due to the magnetic field and heating of the leads whereas, for implanted metal, there may be direct tissue damage due to heating or displacement of the metal. Many currently available cardiac devices and prosthetic heart valves are MRI compatible.

Sporadic Creutzfeldt-Jacob disease.

Hyperintensities in the caudate and putamen nuclei and the posterior thalamus in addition to asymmetric cortical hyperintensities

Figure 221.8 Imaging in sporadic Creutzfeldt–Jacob disease, showing hyperintensities in the caudate and putamen nuclei and the posterior thalamus, as well as asymmetric cortical hyperintensities.

Table 221.1 The advantages and disadvantages of various MRI sequences

Sequence	Advantages/utility	Disadvantages
Spin echo	Higher signal-to-noise ratio Less susceptibility	Longer scan times (much improved with fast spin echo)
Gradient echo	Faster image acquisition More and thinner slices (allows multiplanar reconstructions) More readily reveals blood, calcium, and other metallic deposits (increased susceptibility) Allows flow-related enhancement (MRA and MRV)	Poorer T2 contrast Increased susceptibility to perturbations in the magnetic field also gives more artefact
Echo planar imaging	Rapid image acquisition for uncooperative patients and for fetal or paediatric scanning	Marked susceptibility distorts anatomy at tissue interfaces Much poorer image quality
FLAIR	Suppresses CSF signal Allows detection of more subtle T2 abnormalities (particularly periventricular MS lesions) Incomplete CSF suppression can suggest subarachnoid blood, pus, or malignant meningitis Distinguishes perivascular spaces (black) from ischaemic foci (white)	Flow-related artefact and incomplete CSF suppression (notably in the posterior fossa) can confuse Inferior to fast spin echo for detecting ischaemic lesions in the posterior fossa Old, fluid-filled ischaemic foci will also suppress
STIR	Suppresses fat signal, including water content Allows detection of pathology in areas of high fat content (orbits and brachial plexus especially)	Fat suppression not absolutely specific, as blood, mucus, and protein-rich fluid may also suppress; fat-saturation techniques are better in this regard
DWI/ADC	DWI is highly sensitive in detection of acute infarction ADC differentiates old (high signal) and new (low signal) ischaemic stroke DWI is sensitive and specific for CJD	DWI high signal is not completely specific to infarction; it is also seen with, for example, acute MS demyelination May not be positive with reversible ischaemia (i.e. TIA) Relatively poor delineation of anatomy

Abbreviations: ADC, apparent diffusion coefficient; CJD, Creutzfeldt–Jakob disease; CSF, cerebrospinal fluid; DWI, diffusion-weighted imaging; FLAIR, fluid attenuated inversion recovery; MRA, magnetic resonance angiography; MRV, magnetic resonance venography; MS, multiple sclerosis; STIR, short T1 inversion recovery; TIA, transient ischaemic attack.

Angiography

Radiological visualization of the vasculature can be carried out as part of a CT or an MRI study (see Figure 221.7C). In addition, it can also be carried out by catheter (femoral artery puncture) study under X-ray, whereby it can be analysed on sequential films or by digital subtraction techniques. Over the last few years, catheter angiography has expanded to encompass endovascular treatment of cerebral aneurysms and vascular malformations.

Myelography

MRI is the most commonly used technique for imaging of the spinal cord/column. However, when MRI is contraindicated, then CT or X-ray myelograms can be produced following injection of an iodinated contrast material into the subarachnoid space.

Lumbar puncture

Lumbar puncture is the removal of fluid from around the spinal cord, usually by inserting a needle between two of the higher lumbar

vertebrae, through the ligamentum flavum, and into the subarachnoid space, allowing the removal of CSF.

Indications for lumbar puncture

The indications for lumbar puncture are both diagnostic and therapeutic. Table 221.2 highlights typical test results in the following conditions:

- acute:
 - diagnostic: possible meningitis, encephalitis, or subarachnoid haemorrhage
 - therapeutic: to relieve sight- or life-threatening raised intracranial pressure
- chronic:
 - diagnostic: MS, other CNS inflammatory conditions, chronic meningitis, Guillain–Barré syndrome, CNS lymphoma, and dementia, especially Creutzfeldt–Jakob disease (neuronal and glial proteins; e.g. 14-3-3 and S100)
 - therapeutic: idiopathic intracranial hypertension, chronic cryptococcal meningitis, intrathecal chemotherapy delivery

Table 221.2 Cerebrospinal fluid results in common neurological conditions

Neurological condition	WCC	RBCs	Protein	Glucose*	Other tests
Bacterial meningitis	Neutrophilia	Absent	Raised	Reduced	Gram stain and culture
Viral meningitis/encephalitis	Lymphocytosis	Absent	Mildly raised/normal	Mildly reduced/normal	Viral PCR
Subarachnoid haemorrhage	Mildly raised/normal	Remains raised in sequential bottles [†]	Normal	Normal	Xanthochromia test
Multiple sclerosis	Mildly raised/normal	Absent	Normal	Normal	Oligoclonal banding*
Chronic infective meningitis	Lymphocytosis	Absent	Raised	Reduced	AAFB; tests for ACE, CMV, cryptococcus, and Whipple's disease
Guillain–Barré syndrome	Normal	Absent	Raised	Normal	
CNS lymphoma	Lymphocytosis	Absent	Normal	Normal	Cytology

Abbreviations: AAFB, acid- and alcohol-fast bacteria; ACE, angiotensin-converting enzyme; CMV, cytomegalovirus; CNS, central nervous system; CSF, cerebrospinal fluid; PCR, polymerase chain reaction; RBC, red blood cell; WCC, white-cell count.

*Always send a paired serum sample. Oligoclonal bands can be present in serum and CSF (matched), CSF only, or serum only. Bands which are present in CSF but not in serum (unmatched) are considered helpful in the diagnostic algorithm for CNS inflammatory conditions, particularly multiple sclerosis.

[†]Unlike the results from a traumatic tap.

Contraindications for lumbar puncture

Raised intracranial pressure is a relative contraindication for lumbar puncture, but is considered more absolute where non-communicating hydrocephalus is present. In addition, significant coagulopathy, depending on its importance/urgency, is a contraindication. Local cutaneous infection is another contraindication.

Procedure for lumbar puncture

The procedure for lumbar puncture is as follows:

1. Knowing that the iliac crests are at L4 means you can avoid the spinal cord, which ends at L1. Using this knowledge, you can plan to go in at an interspace from L2/3 to L4/5.
2. Make sure the spine of the patient is symmetrical about the midline in the left lateral position. This may require pillows between knees and under the neck.
3. Prepare the site using an aseptic technique and infiltrate 5 ml of 1%–2% lignocaine. Be generous and cover more than one interspace in the event of a failed first attempt.
4. Insert the spinal needle bevel up until you feel a 'give' as you leave the ligamentum flavum and enter the dura. We would estimate this sensation in around 50% of cases. Feel happy to remove the stylet to observe CSF flow if you have not felt a clear 'give'.
5. Measure the opening pressure with a manometer and collect CSF in four bottles for appropriate investigations (as under 'indications').

Complications/consent issues for lumbar puncture

Complications/consent issues for lumbar puncture are as follows:

- low-pressure headache (better when lying flat):
 - studies suggest rates between 20% and 40%
 - the incidence can be reduced by using atraumatic needles but there is limited evidence for bedrest or fluid intake
 - patients may require analgesia and caffeine
 - in severe cases, a blood patch may be necessary
- haemorrhage and infection are rare (<1%), but may lead to an epidural haematoma /abscess which can be surgically evacuated
- failure of procedure: not common in a thin, cognitively intact patient

Biochemistry

Serum electrolyte levels may be an important part of the diagnostic workup in a number of acute neurological settings. Specifically, serum sodium levels may be of importance in assessment of confusion and seizures, while potassium levels can be helpful in determining the cause of generalized muscle weakness or when diagnosing the periodic paralyses. The actual levels at which electrolyte disturbances cause neurological problems vary and, particularly in the case of sodium, the rate of change of serum concentration is an important factor.

Vitamin deficiencies/toxicity are associated with a variety of neurological disorders. Laboratory diagnosis may not rest on measurement of vitamin levels alone, but assays of active metabolites (e.g. pyridoxal phosphate for vitamin B₆) or specific enzymes (e.g. red cell transketolase for vitamin B₁).

Identification of porphyrins in urine or faeces in an acute attack can lead to a diagnosis of porphyria. Assays of the underlying defective enzyme are more helpful in defining the precise syndrome, particularly in the clinically quiescent state.

Serum ammonia levels may be helpful in investigating encephalopathy.

Immunology

Serum (and CSF) antibodies directed against certain neuronal proteins are of diagnostic importance in neurology. Most conditions associated with the following antibodies are immunotherapy responsive.

Skeletal muscle nicotinic acetylcholine receptor (AChR) antibodies are found in around 80% of cases of myasthenia gravis (MG). Lower rates of AChR-antibody positivity are seen in cases with pure ocular MG. These antibodies have been shown to be

directly pathogenic, and titres correlate reasonably closely with clinical measures in an individual patient.

MuSK (for muscle-specific kinase) antibodies are found in 5%–10% of MG cases. This leaves around 10% of generalized MG cases without positive serology, but most of these antibodies are thought to be directed against the AChR and can be detected by using more sensitive assay techniques.

Ganglioside antibodies are associated with peripheral nerve inflammatory diseases within the Guillain-Barré syndrome spectrum. GM1 IgG antibodies are associated with *Campylobacter jejuni* infection and a motor syndrome. Also, GM1 IgM antibodies are found in around half of multifocal motor neuropathy patients. GQ1b antibodies strongly associate with the Miller-Fisher variant of Guillain-Barré syndrome (characterized by the triad of ataxia, ophthalmoplegia, and areflexia), being positive in 90%–95% of such cases.

Voltage-gated calcium channel (P/Q type) antibodies are seen in around 90% of cases of Lambert-Eaton myasthenic syndrome (LEMS). Like AChR antibodies, these are thought to be pathogenic. There is a low rate of positivity in patients with small cell lung cancer, which has a strong association with LEMS.

LG11 (leucine-rich, glioma inactivated 1) and CASPR2 (contactin associated protein like-2) antibodies are tested for in patients with a variety of neurological syndromes. Testing for these directly offers improved sensitivity and specificity over testing for VGKC-complex antibodies, as VGKCs are – surprisingly – only rarely the direct target of these autoantibodies. LG11 antibodies are known to associate with a predominantly non-paraneoplastic limbic encephalitis and a form of epilepsy known as 'faciobrachial dystonic seizures'. CASPR2 anti-bodies are more commonly seen in neuromyotonia (peripheral nerve hyperexcitability), and in the rare Morvan's syndrome, which combines features of neuromyotonia and limbic encephalitis, also often with LG11 antibodies. The latter two conditions are associated with a malignancy (commonly a thymoma) in around 25% of cases. CSF and serum should be sent to optimize assay sensitivity.

Table 221.3 Paraneoplastic antibodies and their associated clinical features and tumours

Antibody	Associated clinical syndrome (s)	Commonly associated tumours
Anti-Hu	Limbic encephalomyelitis Sensory neuronopathy Cerebellar degeneration Dysautonomia	SCLC Neuroblastoma Prostate
Anti-Ma2	Limbic brainstem encephalitis	Testicular (germ cell) Non-SCLC
Anti-CV2/CRMP5	Limbic encephalomyelitis Cerebellar degeneration Sensory neuronopathy Chorea Optic neuritis	SCLC Thymoma
Anti-Ma	Limbic brainstem encephalitis	SCLC Breast Others
Anti-amphiphysin	Encephalomyelitis Stiff person syndrome	Breast SCLC
Anti-Tr	Cerebellar degeneration	Hodgkin's disease
Anti-Ri	Ataxia +/- opsoclonus-myoclonus Brainstem encephalitis	Breast SCLC Bladder Gynaecological
Anti-Yo	Cerebellar degeneration	Breast Ovarian Uterine SCLC

Abbreviations: SCLC, small cell lung cancer.

Table 221.4 Common neurogenetic conditions, with their clinical features, diagnostic tests, chromosome affected, protein affected, and mode of inheritance

Condition	Clinical features	Diagnostic tests	Chromosome affected	Protein affected	Mode of inheritance
<i>Muscle related</i>					
Duchenne muscular dystrophy, or Becker's muscular dystrophy	Proximal weakness	Creatine kinase (raised) EMG (myopathic)	21 (X)	Dystrophin	X linked
Myotonic dystrophy type 1	Distal weakness and myotonia	EMG (myotonia ('dive bombing'))	19	Myotonic dystrophy protein kinase	Autosomal dominant (CTG repeat)
Mitochondrial	Ophthalmoplegia Retinopathy Diabetes Deafness	Many	Mitochondrial genome, or nuclear genes encoding mitochondrial proteins	Many	Autosomal dominant, or maternal
<i>Peripheral nerve related</i>					
Charcot–Marie–Tooth disease type 1A*	Peripheral motor and sensory loss	NCS (demyelination)	17	Peripheral myelin protein 22	Autosomal dominant (gene duplication)
Charcot–Marie–Tooth disease type 2A2	Peripheral motor and sensory loss +/- optic atrophy, tremor, and hearing loss	NCS (axonal pattern)	1	Mitofusin 2	Autosomal dominant or recessive
HNPP	Recurrent pressure palsies	NCS (generalized mild demyelination and focal slowing)	17	Peripheral myelin protein 22	Autosomal dominant (deletion)
Fabry's disease	Rash, renal dysfunction	Alpha-galactosidase activity	21 (X)	Alpha-galactosidase A	X linked
<i>Ataxias</i>					
Friedreich's ataxia	Ataxia Neuropathy Cardiomyopathy	NCS	9	Frxataxin	Autosomal recessive (GAA repeat)
Spinocerebellar ataxia	Retinopathy Other neurology	Many	Many	Many	Autosomal dominant (triple repeats)
Fragile X-associated tremor/ataxia syndrome	Tremor Cognitive impairment Neuropathy	Many	21 (X)	Fragile X mental retardation protein 1	X linked (CGG repeat)
Episodic ataxia type 1	Brief attacks of ataxia +/- myokymia		12	Kv1.1 potassium channel	Autosomal dominant
Episodic ataxia type 12	Prolonged attacks of ataxia and nystagmus		19	P/Q-type calcium channel	Autosomal dominant
<i>Dementia</i>					
Huntington's disease	Choreiform and other involuntary movements Cognitive decline		4	Huntingtin	Autosomal dominant (CAG repeat)
CADASIL	Strokes Migraine with aura Cognitive decline	Skin biopsy (small vessel changes) MRI (subcortical infarcts)	19	Notch 3	Autosomal dominant
Prion disease	Ataxia Cognitive decline		20	Prion protein	Autosomal dominant
<i>Motor nerve related</i>					
Familial motor neuron disease	Global motor neuron dysfunction		21 (X)	Superoxide dismutase 1†	X linked
Kennedy's disease	Lower motor neuron dysfunction Gynaecomastia	Endocrine	21 (X)	Androgen receptor	X linked (CAG repeat)
<i>Phakomatoses</i>					
Neurofibromatosis type 1	Café au lait spots Lisch nodules Axillary freckling	MRI brain/plexus/cord for neurofibromas	17	Neurofibromin	Autosomal dominant
Neurofibromatosis type 2	Bilateral acoustic neuromas		22	Merlin	Autosomal dominant

Abbreviations: CADASIL, cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy; EMG, electromyography; HNPP, hereditary neuropathy with liability to pressure palsy; MRI, magnetic resonance imaging; NCS, nerve conduction study.

*The commonest form of Charcot–Marie–Tooth disease is the 1A subtype; other forms have alternative modes of inheritance, and mutations in different genes.

†The mutation affecting this protein is the commonest known mutation in familial motor neuron disease.

Glutamic acid decarboxylase antibody levels are mildly raised in diabetics, but are very high in cases with stiff person syndrome and in some cases of epilepsy and cerebellar ataxia.

Some of the aforementioned antibodies can be measured via a radioimmunoassay technique where a specific radioactively labelled ligand determines the antibody that can be detected (e.g. alpha-bungarotoxin, for AChR). ELISAs are used to detect ganglioside antibodies. In this assay, the gangliosides themselves are bound to the well of a polystyrene plate and probed with serum; binding is detected by way of an enzyme-linked secondary antibody and a colour change reaction. In contrast, LGI1, CASPR2 and the following antibodies are measured using a cell-based assay where the antigen of interest is expressed on the cell surface, and patient antibodies bind this exposed antigen.

NMDA-receptor antibodies target an excitatory receptor in the CNS and are increasingly recognized in an encephalopathy affecting young patients, often with a characteristic choreoathetoid movement disorder. A minority of cases have an underlying ovarian teratoma, and in some patients the syndrome arises after HSV encephalitis. Patients respond to (often prolonged) courses of immunotherapy. CSF and serum should be sent to optimize assay sensitivity.

Aquaporin-4 antibodies have been recently described in neuromyelitis optica (NMO; also known as Devic's disease), but not in MS. NMO produces severe optic neuritis and longitudinally extensive transverse myelitis. Hence, traditionally, there has been some confusion between this condition and MS. Differentiation between these conditions is of great importance, given the clear differential immunotherapy response seen in NMO. The importance of early immunotherapy in patients with faciobrachial dystonic seizures (Makuch et al. 2017).

The targets of the antibodies listed in Table 221.3 are all intracellular, so the antibodies are unlikely to be directly pathogenic. Furthermore, conditions associated with these antibodies are commonly associated with characteristic distant tumours (paraneoplastic) and often have a poor prognosis. The antibodies are typically detected by indirect immunohistochemistry (on rodent brain sections) followed by Western blotting for the specific antigen.

Genetics

Genetic testing and discussions with family members are often only performed with the help of a trained geneticist or genetic counsellor. A clear family history of neurological disease is often the most helpful pointer in assessment of an individual case, but awareness and recognition of the phenotype of neurological conditions with a strong

genetic component is important when the family history is unhelpful. Genetic neurological diseases may affect any part of the nervous system. The majority of laboratory genetic testing is carried out on blood samples; however, supportive evidence from muscle and skin biopsies is important in certain diseases.

Modes of inheritance may be autosomal dominant, recessive, or X linked. Mitochondrial DNA is maternally inherited. Triplet repeat diseases are common causes of neurogenetic disorders and show anticipation: a lengthening of the triplet repeat through generations, and a more severe disease with earlier onset (see Table 221.4).

Polygenic inheritance

Many common CNS issues have a known genetic association which only accounts for a minority of cases of the disease. Such complex polygenic traits include Alzheimer's disease, where an association with the E4 allele of the APOE gene has been established; Parkinson's disease, where variants in the LRRK2 gene are present in a small proportion of sporadic cases; and MS, which has an established association with the HLA locus.

222 Demographics of neurological disease

Sarah Cader

Introduction

This chapter reviews the epidemiology of common neurological disorders. While neurological symptoms can potentially appear confusing, understanding which diseases affect particular groups can provide diagnostic guidance.

Epilepsy

Between 0.4% and 1% of the UK population have epilepsy, with an incidence of about 50 per 100 000 per year, affecting males slightly more than females. With treatment, most patients become seizure-free, but a poor prognosis is associated with epilepsy syndromes, early onset, or underlying cerebral disorder. Two-thirds of cases of epilepsy, which is defined as the occurrence more than one unprovoked seizure, have no identifiable cause.

There are different types of seizures that present at different ages, and this helps with classification of the epilepsy. The genetic epilepsy syndromes present in children, but secondary epilepsy will affect adults, especially in those suffering cerebrovascular disease.

Juvenile myoclonic epilepsy, characterized by myoclonus, tonic-clonic seizures, and absences, start around puberty. This has a strong genetic basis and is idiopathic.

Absence seizures tend to present before the age of 10, rather than in adults. Many of these children (about half) will go on to develop tonic-clonic seizures as adults.

Complex partial seizures usually arise from the mesial temporal lobe, and may indicate underlying sclerosis or other structural anomaly. They may present in early adult life, if not earlier.

Parkinson's disease and other movement disorders

Affecting approximately 70 000 patients in the UK, Parkinson's disease is a condition that leads to progressive disability due to a triad of bradykinesia, rigidity, and tremor. It is more common in men, and about 10% of patients have a relative with the condition. It has been reported to have a higher incidence in rural areas, and a reduced risk for smokers.

Parkinson's tends to affect individuals over the age of 55, with the prevalence increasing with age. However, in autosomal recessive juvenile parkinsonism, the onset is before the age of 40 years. This is caused by a mutation in the PRKN gene (Chromosome 6). While Parkinson's can lead to significant disability, average life expectancy is not significantly affected, and response to treatment with dopamine (L-DOPA) is usually good.

The other hypokinetic movement disorders, such as multisystem atrophy, progressive supranuclear palsy, and corticobasal degeneration, also usually begin in older adults. However, they are generally resistant to treatment, and prognosis is poor.

Huntington's disease is a genetic disorder causing writhing movements (chorea), ataxia, and dementia. It is a trinucleotide repeat disorder causing gene instability on Chromosome 4. Typically the onset is in the third decade, but 10% of those affected may not get symptoms until after 60 years old. The phenomenon of anticipation is seen, usually via paternal transmission, and can cause earlier onset and more fulminant course. These patients will have a particular large trinucleotide repeat. There is no currently available treatment.

Wilson's disease is an autosomal condition that presents in childhood, leading to copper deposition and causing a variety of

movement disorders. It can present in adults with neurological or psychiatric features, but seldom beyond 40 years of age. Its importance, despite the rarity, is due to the potential for reversibility with chelating agents (penicillamine) if caught early.

Multiple sclerosis

Multiple sclerosis (MS) is a condition that is common in more northerly and southerly latitudes, but very rare in equatorial regions. Notable exceptions are the high prevalence in Italy, and the north-west to south-east gradient in the USA. This may reflect environmental factors that are still to be determined fully, but may be due to timing of exposure to viral insult.

Characterized by neurological disturbance anywhere in the CNS, it can present in discrete reversible episodes (relapsing–remitting) or progressive disability from onset (primary progressive) in 25% of patients. The peak incidence is at the age of 30, but MS does, rarely, affect children and those over 60 years. Women are twice as likely to be affected as men, and about 1 in 1000 people in the UK are affected.

One-third of patients will have a benign course, and about 20% of patients have marked disability within 20 years of onset. A poor prognosis is associated with older age of onset, in men, cerebellar symptoms at onset, and early progression.

There are some conditions that mimic MS. Devic's disease or neuromyelitis optica presents with optic neuritis or transverse myelitis. The age of onset is similar, but has less geographical variation. In most patients, antibodies to aquaporin-4 can be found, and the disease is characterized by frequent relapses that may respond to strong immunosuppression.

If the symptoms present in childhood or adolescence, then the demyelination may be due to a leukodystrophy, leading to a relentless progression in neurological disability with prominent dementia.

Motor neuron disease

Motor neuron disease is a degenerative condition causing progressive weakness and usually presents in the sixth decade. Men are slightly more affected than women. The incidence is around 1–2 per 100 000.

It is mostly a sporadic condition, but in a small proportion it is familial, although not all the mutations have been determined. In three-quarters of cases, the patients present with limb symptoms; the rest present with bulbar symptoms. Prognosis is usually poor, with median survival less than 5 years. Riluzole, the only licensed treatment, has a modest effect on life expectancy. However, in a small proportion with no bulbar involvement, the survival may be considerably longer.

Peripheral nerve disorders

Peripheral nerves disease can follow one of several patterns including mononeuropathies, radiculopathies, and polyneuropathies. Mononeuropathies are often caused by compression, and are most frequently seen in young adults. The most common is carpal tunnel syndrome, which predominates in women.

Guillain-Barré syndrome (GBS), an acute neuropathy, occurs at any age but is more common in the elderly and men. Two-thirds of patients will have onset within 6 weeks of an infection. It has a worse prognosis in older patients but, with good support and early treatment, there is usually a good recovery. The annual incidence is about 1–2 per 100 000.

There are number of conditions that are similar to GBS. Miller Fisher syndrome causes ataxia, ophthalmoplegia, and areflexia, and is also often preceded by a viral-like illness. Patients often have antibodies to GQ1b ganglioside. In acute axonal motor neuropathy, there can be antibodies to GM1 ganglioside, but the disease does not lead to the demyelinating neuropathy of GBS. The chronic relapsing variant of GBS, known as chronic inflammatory demyelinating polyneuropathy, may also have identifiable antibodies. Progression may occur, but usually responds to immunosuppressive treatment.

There are hereditary neuropathies that typically affect younger patients than the inflammatory and metabolic neuropathies do. Onset is usually before the age of 20, but the most severe types start in infancy, and some may present in later life. The progression is variable depending on the variant.

Myasthenia gravis, and related conditions

Myasthenia affects approximately 4 per 100 000. The distribution of myasthenia is bimodal, affecting young adults (20–25) and older individuals (over 40 years). It is a condition associated with antibodies to acetylcholine receptors, although it is more frequently seen in younger patients.

Myasthenia usually causes generalized weakness characterized by fatigability. However, in ocular myasthenia, there is isolated ptosis and ophthalmoplegia. This can occur at any age. Some patients with ocular myasthenia may progress to develop generalized symptoms. In those patients that are seronegative for receptor antibodies, a significant proportion are positive for the MuSK antibody. This can also present at any age, often with a different pattern of weakness that is predominantly ocular, facial, and bulbar.

In patients with late-onset myasthenia and ocular myasthenia, the ratio of men affected to women is 3:2. Otherwise, women tend to be affected more than men. There is an association with HLA A1, B8, and DR3, and other autoimmune conditions. There is a congenital form of myasthenia, which is autosomal recessive, and presents within the first 2 years of life.

Lambert–Eaton myasthenic syndrome is far less common than myasthenia gravis. Antibodies are found to presynaptic calcium channels that cause augmentation of motor contraction after sustained contraction or repetitive stimulation. In about half of patients, there is an underlying small cell lung cancer.

Dystrophies and other primary muscle diseases

Comprising a diverse range of acquired and genetic conditions, primary muscle disease affects about 50 000 people in the UK.

The age range can be wide but, broadly speaking, the genetic dystrophic conditions present early in childhood. The underlying defect in the muscle is present from birth, leading to muscle destruction, and so the less severe conditions may present in adolescence or early adult life. Other genetic muscle disorders with less deleterious effects may, therefore, also present in early adult life. Life expectancy depends on the phenotypic presentation, but is typically reduced due to problems with breathing or cardiac conduction defects.

Mitochondrial diseases can present at any age with most patients only suffering mild weakness, although they can suffer other problems such as deafness, visual loss, stroke-like episodes, and cardiac difficulties.

Inflammatory myopathies present later in life, although dermatomyositis does affect children also. Polymyositis and dermatomyositis affect women more than men. Immunosuppressive treatment is usually effective, but investigations should consider the possibility of associated underlying malignancies. Inclusion body myositis is more common in older men and tends to be progressively disabling, however.

Migraine and other headache disorders

Headache is a very common neurological presentation, representing at least 20% of neurology outpatient referrals. These are mostly due to migraine or tension headache.

The lifetime prevalence of migraine is about 15% ; over a 1-year period, it is approximately 10%. Migraine with aura is less common, affecting 4% in a 1-year period. Women are 2–3 times more likely to suffer with either form of migraine. There is a genetic predisposition, which has been demonstrated in twin studies, and there is a rarer familial form associated with hemiplegia. It commonly presents in the second or third decade, and is unusual over the age of 50. However, there is a variant of migraine accompaniment that occurs in late life without headache. Ophthalmoplegic migraine generally begins before the age of 10 years. It is more common in males and not usually familial.

Tension headache affects up to 3% of the population, and is also more common in women, most often presenting in the second decade. The prevalence declines with age.

Cluster headache is more often found in men (about 80%) but is far less common than migraine. In 2% there is a family history, and is sometimes associated with a structural brain lesion. It usually has onset in the late twenties.

Temporal arteritis presents with headache due to inflammation in arteries, almost invariably in Caucasians. Loss of vision may occur due to involvement of the posterior ciliary artery. It is usually seen in patients in their seventies, and is rare under the age of 50. It affects slightly more women than men.

Alzheimer's disease and other dementias

Alzheimer's is a neurodegenerative condition that causes progressive cognitive decline. Initially causing poor recollection of recent events, over time, it leads to wandering, irritability, worsening language skills, confusion, and, eventually, total dependence. There is an accumulation of characteristic amyloid plaques and neurofibrillary tangles, and gradual loss of neurons. It is not surprising that this is a disease that typically affects people over the age of 65. The incidence roughly doubles every 5 years after the age of 65, from about 1% to about 20% in those over the age of 85 years. Women are more likely to be affected than men. In a small number, there is onset before the age of 65 years; this is indicative of a genetic mutation.

Half of all dementias are due to Alzheimer's. Vascular dementia comprises the next largest proportion, affecting about 15% of all dementias. It is a rather heterogeneous group of patients, and the incidence does not increase with age, although doesn't usually present until after the age of 65.

Lewy body dementia presents at about the same age as Alzheimer's and Parkinson's. It shares features with both, and there is typically fluctuating cognition with vivid visual hallucinations.

Frontotemporal dementia may have an onset at an earlier age, but again tends to present at the age of 60 years. It is a rare form of dementia, and about a quarter of cases are familial.

Neurological infections

Meningitis can be caused by a variety of organisms and, as such, can affect a wide range of ages. However *Haemophilus influenzae* predominantly affects children under 5 years and *Neisseria meningitidis* is also common in children, but also affects adults. *Streptococcus pneumoniae* particularly affects the very young and very old, and the mortality can be as high as 20%. Other bacterial organisms, such as *Listeria monocytogenes*, are uncommon, and their presence raises the possibility of immunocompromise. Cryptococcus, tuberculosis, and fungal infections similarly tend to occur in those with predisposing conditions. However, tuberculous meningitis remains common in some developing countries, and may be present in immigrants from these regions.

Encephalitis is also caused by a large variety of organisms that vary according to geography, and there are some areas where rabies is a common cause of both encephalitis and paralysis. In the UK, herpes simplex is commonly seen. Following a measles infection, some individuals may develop subacute sclerosing panencephalitis. This affects about 1–3 per million, and does not occur after the age of 25 years.

Syphilis is still an important condition that is re-emerging in those not treated in the primary stage. It might present months to years later and so is more likely in older individuals. Similarly, Creutzfeldt–Jakob disease (CJD), a spongiform encephalopathy, also has a long latency, presenting in older adults, with dementia, involuntary movements, and seizures. There are about 50–100 cases a year of sporadic CJD. There are also familial forms that evolve slower, also presenting in older adults.

Many of the neurological infections tend to follow a pattern of exposure, and so may occur in travellers and those with bites. A detailed history is therefore important.

Further Reading

There is no one review that will cover all of the conditions discussed.

223 Neurogenetic disease

Tracey Graves

Introduction

There are many genetic diseases which affect the nervous system. Although some of these are extremely rare, several are quite common and, as a group, they comprise a significant proportion of neurological disease. Almost all clinical neurological syndromes can have a genetic cause. Not all of these have been genetically elucidated, but some have been extensively characterized in terms of clinical phenotype, molecular genetics, and cellular pathophysiology. Given the improvement in laboratory techniques and subsequent reduction in the cost of direct DNA sequencing, there is likely to be a rapid expansion over the next decade in the identification of causative genes and hence the availability of genetic tests. Thus, all clinicians should have a basic understanding about genetic disease; inheritance patterns; availability of genetic tests; genetic counselling; and ethics. Particular subspecialty areas where neurogenetic disease is common include neuromuscular disease and movement disorders.

The neurogenetic diseases have been categorized in Table 223.1. The four commonest conditions are discussed in detail in this chapter.

Huntington's disease

Definition of Huntington's disease

Huntington's disease (HD) is a neurodegenerative condition and is the archetypal polyglutamine expansion disorder.

Aetiology of HD

HD is due to a trinucleotide (CAG) expansion in the HTT gene and is inherited in an autosomal dominant manner.

Typical symptoms of HD, and less common symptoms

HD is characterized by a movement disorder, psychiatric features, and dementia. The movement disorder is usually choreiform; however, the juvenile onset form produces parkinsonism, and ataxia is also seen. The classical triad may not be present at presentation, but may develop during the course of the illness.

Demographics of HD

HD is globally distributed and there is no particular ethnic predilection.

Natural history of HD, and complications of the disease

HD is relentlessly progressive. The combination of dysphagia and catabolism lead to dramatic weight loss. Death is usually by progressive bulbar dysfunction and aspiration pneumonia or by suicide.

Approach to diagnosing HD

Those with the classical triad of HD symptoms should cause no diagnostic difficulty; however, monosymptomatic cases may be overlooked without a high index of clinical suspicion. A detailed family history including age and cause of death over two or three generations may show relatives with psychiatric disease, suicide, and institutionalization. Those with a known family history are now increasingly common, especially with the widespread availability of genetic testing.

Other diagnoses that should be considered aside from HD

There are HD mimics but, in practice, these are rare.

'Gold-standard' diagnostic test for HD

A clinical suspicion of HD can be readily confirmed by molecular genetic testing. The test is simple and inexpensive. However, the test should not be performed without adequate genetic counselling of the patient; this should include discussing the risk of diagnosing presymptomatic obligate carriers (i.e. the patient's parents) and the identification of at-risk individuals (siblings and offspring). Presymptomatic testing should only be carried out in a specialist genetics clinic with clinical expertise in counselling and after a cooling-off period, where the individual has had adequate time to contemplate the consequences of a positive test, with respect to life insurance, reproductive plans, and dealing with a positive test.

Acceptable diagnostic alternatives to the gold-standard test for HD

For HD, there are no acceptable diagnostic alternatives to genetic testing.

Other relevant investigations

There are no relevant investigations for HD, other than genetic testing.

Prognosis of HD, and how to estimate it

In general, the severity of HD and its age of onset are inversely proportional to CAG repeat length. However, this can be difficult to estimate in an individual. Lifespan is significantly reduced in younger onset cases.

Treatment of HD, and its effectiveness

For the treatment of HD, a multidisciplinary approach is required, with input from a physiotherapist, an occupational therapist, a dietician, a speech and language therapist, and, importantly, a clinical psychologist or psychiatrist. Chorea, although dramatic, often disturbs other family members more than it does the patient. It can be treated with tetrabenazine; however, this drug is contraindicated in those with psychiatric disease. Psychiatric complications should be treated in a standard manner.

Myotonic dystrophy type 1

Definition of myotonic dystrophy type 1

Myotonic dystrophy type 1 (DM1) is the commonest muscular dystrophy in adults. Although its clinical manifestations are largely in skeletal and cardiac muscle, it is a multisystem disease.

Aetiology of DM1

Like HD, DM1 is an autosomal dominant trinucleotide expansion disorder, but one where the CTG repeat is in the 3' untranslated region of the DMPK gene, leading to aberrant RNA processing. This affects various gene products and is thought to underlie the multisystem nature of the condition. For example, abnormal RNA processing of the chloride channel protein CLC1 causes myotonia.

Typical symptoms of DM1, and less common symptoms

The classical phenotype of DM1 includes facial myopathic features (temporalis wasting, facial weakness), neck flexion, and finger extension weakness, with myotonia (delayed muscle relaxation after contraction). Cardiac involvement manifests as conduction abnormalities. Cataracts,

Table 223.1 Neurogenetic conditions				
Disorder	Type	Examples	Genes	
Nervous system disorders	Charcot–Marie–Tooth disease	Charcot–Marie–Tooth disease type 1 (autosomal dominant, demyelinating)	MPZ PNP22

	Leukodystrophies	Canavan disease	ASPA
		Alexander disease	GFAP

diabetes mellitus, premature balding, subfertility, and cognitive impairment may all occur. Congenital DM1 usually occurs when the repeat is inherited from the mother, with massive expansion occurring during meiosis. It is characterized by severe generalized weakness, hypotonia, and respiratory compromise, which may lead to death. Surviving infants have a gradual improvement in motor function and swallowing and can independently ventilate but develop learning difficulties.

Demographics of DM1

DM1 is globally distributed and there is no particular ethnic predilection.

Natural history of DM1, and complications of the disease

In DM1, the myopathy is slowly progressive and, as weakness ensues, myotonia becomes less prominent. Patients usually maintain ambulation, but have increasing problems with facial and hand weakness. A significant proportion of patients will develop cardiac conduction defects requiring placement of a permanent pacemaker. Cardiomyopathy is rare. Obstructive sleep apnoea or excessive daytime somnolence may also occur.

Approach to diagnosing DM1

The diagnosis of DM1 is clinical in those with a classic myopathic facies, frontal balding, and distal myotonia. The vast majority of adults who are found to have clinical or electrical myotonia will have DM1. Where this is not evident, the diagnosis may be delayed while other causes of myopathy are excluded.

Other diagnoses that should be considered aside from DM1

There are other causes of myotonia aside from DM1, but these do not lead to dystrophic features or multisystem involvement.

‘Gold-standard’ diagnostic test for DM1

A clinical suspicion of DM1 can be readily confirmed by molecular genetic testing. The test is simple and inexpensive. However, this should not be undertaken without adequate genetic counselling of the patient, including the risk of diagnosing presymptomatic obligate carriers (i.e. the patient’s parents) and the identification of at-risk individuals (siblings and offspring).

Acceptable diagnostic alternatives to the gold-standard test for DM1

For DM1, there are no acceptable diagnostic alternatives to genetic testing.

Other relevant investigations for DM1

DM1 patients should have an annual ECG and referral to a cardiologist should conduction abnormalities appear. Blood or urine glucose should also be tested on an annual basis. Sleep studies can help elucidate the cause of excessive daytime somnolence.

Prognosis of DM1, and how to estimate it

In patients with DM1, lifespan is shortened by cardiac and respiratory involvement. A milder late-onset form with partial clinical manifestation is correlated with shorter CTG repeat length. However, in general, repeat length cannot be used to predict phenotype.

Treatment of DM1, and its effectiveness

There are no treatments to reverse muscle wasting and weakness in DM1. Myotonia is rarely disabling for patients. If prominent, it can be treated effectively with mexiletine (with regular ECG monitoring); phenytoin is less effective. Excessive daytime somnolence can be treated with modafinil or overnight continuous positive airway pressure, if there is a significant respiratory contribution. Conduction defects can be treated with permanent pacemaker implantation. Multidisciplinary involvement is useful in the later stages with input from a physiotherapist, an occupational therapist, a dietician, and a speech and language therapist.

Charcot–Marie–Tooth disease type 1a

Definition of Charcot–Marie–Tooth disease type 1a

Charcot–Marie–Tooth disease type 1a (CMT1a) is the commonest genetic neuropathy in adults.

Aetiology of CMT1a

CMT1a is an autosomal dominant demyelinating neuropathy due to a chromosomal duplication leading to duplication of PMP22.

Typical symptoms of CMT1a, and less common symptoms

The classical phenotype of CMT1a is of a slowly progressive sensory and motor neuropathy with onset in adulthood. This presents as foot weakness and deformity and leads to pes cavus, distal muscle wasting, and sensory loss.

Demographics of CMT1a

CMT1a is the commonest genetic neuropathy in Europe.

Natural history of CMT1a, and complications of the disease

The neuropathy in CMT1a is slowly progressive with weakness and sensory loss. Complications are usually of joint destruction (Charcot's joints) and subsequent loss of mobility. Pressure ulcers may also occur. There is no effect on lifespan.

Approach to diagnosing CMT1a

The diagnosis of Charcot–Marie–Tooth disease is clinical in those with the classic inverted-champagne-bottle legs, pes cavus, and stocking sensory loss. However, this does not elucidate what type of Charcot–Marie–Tooth disease a patient has. EMG and nerve conduction studies are required to determine whether the neuropathy is axonal or demyelinating. The genotype–phenotype correlation in this condition is poor.

Other diagnoses that should be considered aside from CMT1a

Other diagnoses that should be considered aside from CMT1a are other types of Charcot–Marie–Tooth disease.

'Gold-standard' diagnostic test for CMT1a

A clinical suspicion of CMT1a can be readily confirmed by molecular genetic testing. The test is simple and inexpensive. Over 98% of patients with CMT1a have a duplication of PMP22, and this can be detected using dosage techniques. However, around 2% have point mutations in PMP22, and this requires direct DNA sequencing to detect.

Acceptable diagnostic alternatives to the gold-standard test for CMT1a

For CMT1a, there are no acceptable diagnostic alternatives to genetic testing.

Other relevant investigations for CMT1a

For CMT1a, there are no relevant investigations other than genetic testing.

Prognosis of CMT1a, and how to estimate it

The lifespan of patients with CMT1a is not significantly reduced.

Treatment of CMT1a, and its effectiveness

There are no treatments to reverse muscle wasting and weakness in CMT1a. Multidisciplinary involvement is useful with input from physiotherapy, occupational therapy, and, in particular, the use of orthotics. Painful dysaesthesias are rare, but can be treated with amitriptyline, gabapentin, pregabalin, or duloxetine. Treatment trials are ongoing. Genetic counselling should be offered.

Friedreich's ataxia

Definition of Friedreich's ataxia

Friedreich's ataxia (FRDA) is the commonest autosomal recessive ataxia.

Aetiology of FRDA

FRDA is an autosomal recessive ataxia due to a trinucleotide repeat (GAA) expansion in the first intron of the FXN gene.

Typical symptoms of FRDA, and less common symptoms

FRDA begins in the first or second decade and is relentlessly progressive. It is characterized by ataxia, pyramidal signs, large fibre axonal neuropathy, skeletal abnormalities (pes cavus and scoliosis), cardiomyopathy, and, more rarely, optic atrophy, deafness, and diabetes mellitus. Patients are usually wheelchair bound by their twenties, and lifespan is considerably reduced, largely by the cardiomyopathy.

Demographics of FRDA

FRDA is the commonest hereditary ataxia amongst Caucasian populations and does not occur in non-Caucasians.

Natural history of FRDA, and complications of the disease

Most patients with FRDA will lose the ability to walk, stand, or sit unaided within 10–15 years of disease onset. The neuropathy is often subclinical. Hypertrophic cardiomyopathy occurs in around 10% of patients and may be asymptomatic. Diabetes mellitus occurs in about 10% of patients.

Approach to diagnosing FRDA

The diagnosis of FRDA is clinical in those with ataxia, scoliosis, pes cavus, absent reflexes, and pyramidal signs. Those who are less symptomatic may be harder to diagnose. With the advent of genetic testing, phenotypic variation has been noted, in particular, with later onset cases.

Other diagnoses that should be considered aside from FRDA

FRDA mimics include ataxia with oculomotor apraxia types 1 and 2, and ataxia–telangiectasia.

'Gold-standard' diagnostic test for FRDA

A clinical suspicion of FRDA can be readily confirmed by molecular genetic testing. The test is simple and inexpensive. Over 99% of patients with FRDA have two copies of the GAA expansion, and this can be detected using Southern blotting. However, around 1% have one GAA expansion and one point mutation in FXN, and this requires direct DNA sequencing to detect.

Acceptable diagnostic alternatives to the gold-standard test for FRDA

Other relevant investigations for FRDA

Patients with FRDA should have an annual ECG and echocardiography, and referral to a cardiologist should abnormalities occur. Blood or urine glucose should also be tested on an annual basis.

Prognosis of FRDA, and how to estimate it

The lifespan of patients with FRDA is significantly reduced. The GAA repeat size is inversely correlated with age of onset and age of confinement to wheelchair, and directly correlated with the incidence of cardiomyopathy.

Treatment of FRDA and its effectiveness

There are no treatments to reverse ataxia, muscle wasting, and weakness in FRDA. Multidisciplinary involvement is useful with input from physiotherapy, occupational therapy, and, in particular, the use of orthotics when patients are still mobile. When mobility is lost, wheelchair services are essential to prevent further complications from ill-fitting seats, arms, or foot rests. Dysarthria may be severe, and speech and language therapy can be extremely valuable. Orthopaedic intervention for scoliosis can reduce pain and disability. Treatment trials of idebenone (a coenzyme Q10 analogue) are ongoing.

224 Neurocutaneous syndromes

Nerissa Jordan

Definition of the disease

The neurocutaneous syndromes are a diverse group of rare genetic disorders with both neurological and cutaneous manifestations. Each syndrome has a distinct phenotype. See Box 224.1 for a list of neurocutaneous syndromes.

Symptoms

Symptoms are variable and depend on the syndrome. See Table 224.1 for a summary of typical clinical and radiological features.

Demographics and aetiology

Neurocutaneous syndromes often present in childhood or adolescence; for example, tuberous sclerosis typically presents in early childhood. The age range of presentation is broad, depending on the specific condition and severity of expression. The majority are autosomally inherited conditions. De novo mutations can occur.

Natural history of the disease

Most are progressive conditions, such as tuberous sclerosis and neurofibromatosis. Others, such as Ehlers–Danlos, have milder phenotypes, with most symptoms due to intermittent complications, particularly haemorrhage.

Box 224.1 Neurocutaneous syndromes

- tuberous sclerosis
- neurofibromatosis type 1 and 2
- Ehlers–Danlos syndrome
- hereditary haemorrhagic telangiectasia
- Sturge–Weber syndrome
- ataxia–telangiectasia
- Fabry’s disease
- von-Hippel–Lindau disease
- progressive facial hemiatrophy
- pseudoxanthoma elasticum
- kinky hair syndrome
- cerebrotendinous xanthomatosis
- epidermal naevus syndrome
- hypomelanosis of Ito
- neurocutaneous melanosis
- Wyburn–Mason syndrome
- xeroderma pigmentosum

Complications

There are two main groups of complications:

- complications of tumours, including local pressure effects and seizures
- vascular events, including stroke and haemorrhage

Approach to diagnosing the disease (including diagnostic pitfalls)

Most of these diseases may be diagnosed clinically, with characteristic skin lesions. Imaging may be helpful, for example, in identifying the typical cerebral lesions in tuberous sclerosis. The diagnosis may be clear at an early age. In other cases, the cutaneous lesions may be missed and diagnosed only when vascular lesions become symptomatic. For example, hereditary haemorrhagic telangiectasia may only be recognized following a cerebral haemorrhage in an individual with cutaneous telangiectasia. Genetic testing is available for confirmation for many of the disorders.

‘Gold-standard’ diagnostic test

Molecular genetic testing is the gold-standard test for diagnosing neurocutaneous syndromes (see Table 224.1 for known mutations).

Acceptable diagnostic alternatives to the gold standard

Clinical and radiological features can be highly suggestive.

Other relevant investigations

Other relevant investigations include MRI of the brain, with or without MRI of the spinal cord; angiography; EEG, for seizures; EMG, for peripheral neuropathy; an ophthalmology review, if relevant (e.g. cataracts); and audiometry, in neurofibromatosis type 2.

Prognosis, and how to estimate it

Severity of presentation and presence of complications will largely determine the prognosis.

Treatment and its effectiveness

Most neurocutaneous syndromes do not have a specific treatment, and management is predominantly supportive and aimed at symptom reduction and appropriate monitoring. This includes surgical excision of compressive tumours, radiation therapy, management of epilepsy, and surveillance for tumours. A multidisciplinary approach

Syndrome	Genetics	Cutaneous features	Neurological features	Systemic features	Imaging features
Tuberous sclerosis	TSC1/TSC2 gene Chromosome 9q34 Autosomal dominant Disorder of cellular differentiation/proliferation	Hypomelanotic macules Shagreen patch* Ungual fibromas Facial angiofibromas	Seizures (80%–90%) Mental retardation Behavioural disorders (autism, aggressiveness, psychosis)	Retinal hamartomas Cardiac rhabdomyoma Renal angiomyolipomas Lymphangiomyomatosis	Calcified subependymal nodules Abnormal neural migration
Neurofibromatosis type 1	NF1 gene Chromosome 17q Autosomal dominant Cytoplasmic regulatory molecule	Café au lait spots Subcutaneous neurofibromas Axillary freckling	Peripheral neurofibromas Optic nerve gliomas Other CNS tumours	Pigmented iris hamartomas (Lisch nodules) Dysplasia of renal or carotid arteries Short stature Macrocephaly	Increased signal in basal ganglia, cerebellum, or brainstem
Neurofibromatosis type 2	NF2 gene Chromosome 22 Autosomal dominant Usually suppresses tumour function	Café au lait spots Peripheral neurofibromas	Bilateral vestibular schwannomas (deafness, brainstem compressive symptoms) Meningiomas, ependymomas		CNS tumours
Hereditary haemorrhagic telangiectasia	HHT1 gene/HHT2 Chromosome 9q34 Chromosome 12q13 Autosomal dominant TGF-beta receptor component	Telangiectasias of skin and mucous membranes	Arteriovenous malformations: CNS haemorrhage Pulmonary arteriovenous malformations: paradoxical embolism Cerebral abscess or meningitis from septic emboli	Organ telangiectasia: epistaxis Organ-related haemorrhage	Arteriovenous malformations Aneurysms
Ataxia–telangiectasia	ATM gene Chromosome 11q22–23 Autosomal recessive DNA repair	Telangiectasias of skin, especially of earlobes, sclera, and nasal bridge	Progressive ataxia followed by tremor, segmental myoclonus, and choreoathetosis	Sinopulmonary infections Increased risk of malignancy	Non-progressive cerebellar atrophy
Ehlers–Danlos syndrome	Multiple different defects of collagen subtypes	Hyperelastic or fragile skin Easy bruising	Intracranial aneurysms, particularly in the carotid artery Carotid–cavernous fistula	Hyperextensible joints	
Fabry's disease	Chromosome X q21.33–q22 X-linked recessive Alpha-galactosidase A deficiency	Punctate angiectatic lesions on trunk, buttocks, and legs	Peripheral neuropathy Severe limb pain Ischaemic or haemorrhagic strokes	Corneal opacification Cardiac and renal lesions	Left ventricular hypertrophy on echocardiography (may simulate hypertrophic cardiomyopathy)

*An area of yellowed, elevated, roughened skin with a texture of orange peel, often on the lower back.

is necessary. There are several new molecularly based treatments under investigation for conditions such as neurofibromatosis type 2; however, the role for these therapies is still being defined. Enzyme replacement is possible to treat Fabry's disease.

225 Congenital neurological disorders

Simon Rinaldi

Introduction

This chapter covers four congenital neurological disorders which may be encountered in adult medicine: cerebral palsy, Chiari malformations, spina bifida, and tethered cord syndromes.

Cerebral palsy

Cerebral palsy is a disturbance of motor function arising from damage to the developing fetal or infant brain. It usually refers to a disorder resulting from a non-progressive insult which occurred at less than 3 years of age. The term lacks specificity, and encompasses a wide range of clinical presentations and differing pathological processes.

In the developed world, cerebral palsy has a prevalence of around 2 per 1000 live births. It is substantially more common in premature births. The immature cerebral vasculature is at increased risk of failing to adequately perfuse certain areas of the brain, most notably the deep-lying periventricular white matter. This can result in periventricular leukomalacia and/or germinal matrix haemorrhage. In severe cases, the haemorrhage extends into the lateral ventricles or brain parenchyma. In contrast, vascular injuries in term infants more often affect the territory of the middle cerebral artery.

There is a widespread belief that cerebral palsy is solely a result of hypoxic–ischaemic birth injury. This is incorrect. In less than 10% of cases can ‘birth asphyxia’ be conclusively identified as the cause. In around 80%, the pathological process appears to have occurred prenatally. Congenital malformations, growth retardation, maternal hypotension, infection, thyroid disease, and exposure to toxins are part of a long list of prenatal, gestational risk factors. Even in these cases, the clinical deficit may not become apparent until much later in development.

Overall, around 30%–50% of cerebral palsy cases are associated with learning disability, and a similar proportion with epilepsy. The different clinical syndromes—spastic (80%), dyskinetic (10%–15%), or ataxic (<5%)—result from predominant damage to pyramidal, extrapyramidal, or cerebellar structures. Spastic cerebral palsy is further subdivided on the basis of the affected body regions into diplegic (affecting both legs, usually with lesser involvement of the arms), hemiplegic, and quadriplegic types. In premature infants, spastic diplegia is often a result of periventricular leukomalacia or haemorrhage. Pathological–clinical associations in term infants and for the other types of spastic cerebral palsy are less consistent.

Dyskinetic cerebral palsy is characterized by choreoathetoid movements, but combinations of dystonia, myoclonus, tremor, and hemiballismus can also be seen. Historically, kernicterus (neonatal hyperbilirubinaemia) was the most frequent cause. Current cases are usually attributed to hypoxic–ischaemic damage of the basal ganglia and/or thalamus.

The adult physician most usually encounters cerebral palsy in the context of an acute or subacute deterioration in functioning on the background of prior clinical stability. The challenge is then to identify and appropriately treat the cause of this deterioration. There are four broad possibilities.

First, intercurrent infections or metabolic disturbances can more profoundly affect patients with preexisting brain pathology than might otherwise be the case and, in this context, apparent new focal deficits can sometimes be seen. Second, like the wider population, cerebral palsy patients remain at risk of developing further neurological disease such as strokes, infective encephalitis, or even neurodegenerative pathology, and are at an increased risk of seizures.

Third, static pathological insults can cause clinical progression due to the additional effects of development (dyskinetic cerebral palsy especially can progress or even appear in adolescence) or normal ageing (‘pseudodegeneration’). Finally, the label of cerebral palsy may be erroneous, and the patient instead suffers from a different, progressive pathology. Nevertheless, the priority of the acute medical team lies with assessing the first and second possibilities. Missed diagnoses of, for example, adrenoleucodystrophy, Wilson’s disease, or metachromatic leucodystrophy, are uncommon but may need to be considered at a later time.

Chiari malformations

Chiari malformations are congenital abnormalities of the anatomy and structural relationships of the cerebellum, brainstem, and foramen magnum. They are numbered I to IV. Type III and IV malformations are rare, severe, well outside the domain of the adult physician, and are not further discussed.

In contrast, Chiari I malformations are by far the most common and least severe defects, and are often diagnosed in adult life. The key abnormality here is displacement of the cerebellar tonsils below the level of the foramen magnum. With the increasingly widespread availability of MRI, the diagnosis is made more frequently. Indeed, this often asymptomatic anomaly is found on up to 1 in every 200 MRI brain scans performed. Commonly, this is an incidental and unexpected finding but, on other occasions, symptomatic Chiari I malformations require surgical treatment. The adult physician therefore needs to be familiar with the neurological signs and symptoms which may result from a Chiari I malformation.

Herniation of the tonsils can compress the cerebellar structures themselves (resulting in dysmetria, ataxia, and other cerebellar signs and symptoms). In this context, the nystagmus is downbeating. The tonsils can additionally compress the cervicomedullary junction in the foramen magnum (giving lower cranial nerve dysfunction and/or upper cervical myelopathy). The disruption of CSF flow through the foramen can result in hydrocephalus, but much more commonly induces a syrinx in the cervical cord. This leads to a suspended sensory level and motor weakness in the arms. CSF flow abnormalities are also the likely pathological mechanism for the cough-impulse headache which can be associated with Chiari I malformations. Here, a short-lived, severe, cervico-occipital headache occurs a fraction of a second or so after coughing or straining—the delay presumably reflecting the time taken for the CSF pressure wave to be transmitted to pain-sensitive structures.

When these symptoms can be correlated with the imaging abnormalities, surgical decompression is indicated, and can result in resolution of any associated syrinx. Surgical intervention is not warranted outright with this context or for the treatment of non-cough-impulse headaches or neck pain.

Type II malformations involve additional displacement of the lower brainstem structures through the foramen magnum, resulting in a more severe abnormality. As such, the diagnosis is usually made in infants who have signs and symptoms of brainstem dysfunction. Unlike type I malformations, type II malformations are frequently associated with hydrocephalus, and treatment of this with shunting is the surgical priority.

Dysraphism (spina bifida)

Dysraphism is a failure of opposition of anatomical structures which are normally fused. Spinal dysraphism is synonymous with spina bifida, a failure of embryological fusion of the neural tube. In all types,

the vertebral arch fails to completely form. There is an association with maternal folate deficiency, pregestational diabetes, antiepileptic drug exposure (particularly sodium valproate), and certain chromosomal abnormalities.

Spina bifida occulta

Spina bifida occulta is usually an incidental and asymptomatic finding, and is likely to be very common. Although there is a defect in the vertebral arch, the meninges and neural tissue remain in the spinal canal. Progressive neurological symptoms can be seen, however, if there is an associated tethered cord (see 'Tethered cord syndromes') or other distortion of the cord and roots.

Spina bifida cystica

Spina bifida cystica involves protrusion of the meningeal sac through the vertebral defect. If the sac contains part of the spinal cord or roots it is termed a **myelomeningocele**. If these elements are absent, the term **meningocele** is used. Discounting spina bifida occulta, myelomeningocele is by far the most common type of spina bifida and, indeed, the most common major birth defect. Most often, lower lumbar segments are involved. With neurological involvement, the level of the defect generally relates to the resultant level of impairment. However, there may be additional contributions from coexistent syringomyelia, cerebral polymicrogyria, and/or hydrocephalus (sometimes with cerebellar herniation producing a Chiari II malformation).

Spina bifida cystica is treated with early neurosurgical closure to prevent infection and significantly improve survival. Existing myelopathic and radiculopathic symptoms are likely to persist, with varying degrees of lower limb paralysis and sensory loss. Incontinence is very common. If hydrocephalus is present, shunting allows the development of normal intelligence.

Complications arise from shunt obstruction, shunt infection, renal impairment, and urinary tract infections secondary to the neurogenic bladder, and from the long-term effects of reduced lower limb function, such as contractures and pressure sores.

Tethered cord syndromes

The tethered cord syndromes involve a restriction of the normal cephalad migration of the conus during life. This can occur both with and without spina bifida. On occasions, the cauda appears 'stuck' to an associated lipoma or dermoid. Combinations of upper and lower motor neuron signs, sensory disturbance in the legs, sphincter dysfunction, and scoliosis are found. Evolution of the symptoms in adulthood can be seen. Neurosurgical release of the cord is undertaken for progressive symptoms. A tethered cord is a contraindication to lumbar puncture, while spina bifida occulta itself is not, and may make the procedure easier.

226 Epilepsy

Yvonne Hart

Definition of the disease

Epilepsy is defined as the occurrence of at least two unprovoked or reflex seizures occurring more than 24 hours apart, an epilepsy syndrome, or a single unprovoked or reflex seizure where the chance of recurrence is at least 60%. A seizure can be defined as a transient excessive discharge of nerve cells within the brain, causing an event which is discernible to the person experiencing the seizure or to an observer. The term 'epilepsy' excludes provoked seizures, such as febrile seizures.

Symptoms

The symptoms of epilepsy vary according to the extent of the seizure activity, and the site of onset of the seizure. The 1981 classification of seizures developed by the International League Against Epilepsy (ILAE), shown in Box 226.1, is commonly used, but the ILAE has now published suggestions for a new 'organization' of seizures and epilepsies. Generalized seizures involve the rapid engagement of bilaterally distributed networks of seizure activity.

Generalized seizures

Generalized tonic-clonic seizures involve an initial tonic phase, usually lasting about 20 seconds, in which the patient becomes stiff, stops breathing and may cry out as air is forced out of the lungs, and tongue biting may occur. This is followed by a clonic phase often lasting 2–3 minutes, with jerking of the limbs and which is sometimes followed by incontinence of urine. A postictal phase follows, with headache, drowsiness, and confusion being common symptoms.

Absence ('petit mal') seizures usually develop in childhood or adolescence. The patient abruptly appears blank, as if in a trance, usually for around 10 seconds. Fluttering of the eyelids and swallowing may also occur.

Myoclonic jerks are brief muscle jerks involving part or all of the body, similar to the jerks sometimes seen as people are dropping off

to sleep. They may occur in association with absence seizures and generalized tonic-clonic seizures in people with presumed genetic (idiopathic) generalized epilepsy.

Tonic seizures, in which patients develop a sudden generalized increase in muscle tone causing falling, and atonic seizures, in which the patient falls limply, are other forms of generalized seizures usually occurring in the context of severe childhood-onset epilepsy, such as Lennox-Gastaut syndrome. The seizures are usually brief but frequently cause injury due to the sudden falls. Clonic seizures are another form of generalized seizure.

Focal (partial) seizures

Focal (partial) seizures have their onset in a localized area of cerebral cortex, although they may spread to involve the rest of the cerebral cortex.

Focal seizures are described according to the symptoms experienced. Focal seizures without loss of awareness were previously termed simple partial seizures. They generally reflect the function of the area in which they arise; thus, occipital seizures commonly take the form of visual hallucinations (e.g. patients may complain of seeing coloured lights), frontal lobe seizures often take the form of motor seizures, and temporal lobe seizures may cause gustatory or auditory hallucinations, dysphasia, fear, and déjà vu or jamais vu.

Focal dyscognitive (complex partial) seizures occur when the seizure discharge spreads further such that loss of awareness occurs. They commonly (but not exclusively) arise in the temporal lobes, and may be characterized by a motionless stare, lip smacking or chewing, fiddling, rubbing, and undressing or wandering.

Focal seizures may progress further to become bilateral convulsive (secondarily generalized) seizures. These may appear identical to generalized tonic-clonic seizures, but symptoms occurring in the course of the preceding focal seizure may act as a warning or 'aura' to the attack.

Demographics and aetiology of epilepsy

Epilepsy occurs in all races and may develop at any time of life: it is most common in the elderly, probably due to the occurrence of cerebrovascular disease, with the second highest incidence being in childhood, where the most common causes are birth injury, developmental abnormalities, infection, and presumed genetic (idiopathic) epilepsy. Epilepsy is marginally more common in males than females. Overall, the incidence in the developed world is about 50–60 in 100 000 per annum; it is rather more common in the developing world, where it may exceed 100 in 100 000 per annum. The prevalence of active epilepsy is 0.5%–1.0%.

Other causes of epilepsy in adults include alcohol abuse, tumour, head trauma, infection, and, particularly in developing countries, parasitic infection.

Natural history of the disease

Approximately 50% of people experiencing a seizure do not have any recurrence, and it is therefore usual not to start treatment after a single seizure, unless there is an underlying condition (such as tumour) likely to significantly increase the risk of recurrence. Of those patients who do have a recurrence and are started on treatment, it will be possible to completely control the seizures in approximately 70%, while 20%–30% will be expected to have

Box 226.1 Classification of epileptic seizures (simplified)

1 Focal seizures (partial seizures)

- Without impairment of consciousness (e.g. focal motor) (simple partial seizures)
- Focal dyscognitive seizures (complex partial seizures)
- Bilateral convulsive seizures (secondarily generalised seizures)

2 Generalised seizures

- Absence seizures
- Myoclonic seizures
- Clonic seizures
- Tonic seizures
- Tonic clonic seizures
- Atonic seizures

3 Unclassified epileptic seizures

seizures which are resistant to medication. Patients whose seizures fail to respond to the first two or three antiepileptic drugs often fail to respond to the addition of other antiepileptic drugs, although a small proportion (perhaps 4%) will find that a new antiepileptic drug will be effective. Approximately 50% of patients will eventually be able to discontinue medication without recurrence of seizures.

Epilepsy surgery may be feasible for patients with epilepsy which is refractory to medical treatment, where it is possible to identify the epileptic focus, and where the likely benefits of surgery outweigh the risks (e.g. of functional deficit as a result of surgery). In appropriately selected patients, the chance of becoming seizure-free may be of the order of 70%–80%.

Complications of epilepsy

Epileptic seizures, particularly where they cause falls without warning, are common causes of injury, with burns or scalds, dental injuries, head injuries, and fractures being particularly common. In one survey, a quarter of people having at least one seizure during the previous year had had such an injury. Dislocated shoulders and wedge fractures of the vertebrae may occur as a result of tonic–clonic seizures, as may aspiration pneumonia. Epilepsy is also associated with excess mortality, the standardized mortality ratio being of the order of 2–3, with the main causes of death being accidental death or drowning due to seizures, the underlying cause of the epilepsy, suicide, status epilepticus, and sudden unexpected death in epilepsy, the risk of which has been estimated at between 1 in 500 to 1 in 1000 (more for those with very severe epilepsy). Epilepsy is also responsible for considerable psychosocial morbidity.

Approach to diagnosing epilepsy

The diagnosis of epilepsy is essentially clinical, relying on the description of an eyewitness and of the patient himself.

Other diagnoses that should be considered

The most common conditions to be considered in the differential diagnosis of seizures are syncope (either vasovagal syncope or secondary to cardiac disorders), and psychogenic non-epileptic (dissociative or functional) seizures (formerly known as pseudoseizures). Hypoglycaemia, convulsive seizures (seizures occurring within 2 seconds of a head injury and not causing long-term damage or predisposing to the development of epilepsy), and breath-holding attacks in children may also be confused with seizures causing loss of awareness. Focal seizures need to be distinguished from such conditions as migraine, transient global amnesia, panic attacks, and transient ischaemic attacks.

'Gold-standard' diagnostic test

The gold-standard diagnostic test is EEG videotelemetry, in which EEG and simultaneous video monitoring are carried out to record a seizure and confirm that the typical symptoms and signs of a seizure are accompanied by epileptic activity at the appropriate time on the EEG. In practice, this test is usually only helpful in people whose seizures are occurring so frequently that they can reliably be recorded in a reasonable period of EEG videotelemetry recording (up to a week in most centres).

Acceptable diagnostic alternatives to the gold standard

As noted in 'Approach to diagnosing epilepsy', a clinical diagnosis of epilepsy frequently rests solely on the description of the event by the patient and an eyewitness, since it is often not possible to record a seizure, and investigations may be normal in between attacks.

Other relevant investigations

Diagnosis involves not only establishing that the patient is having epileptic seizures, but also diagnosis of the epilepsy syndrome, if possible, and of the underlying cause. Although the history is the most important factor in establishing the diagnosis of seizures, ECG is important in all patients to rule out cardiac causes of loss of consciousness, and a cardiology opinion may be appropriate. Interictal EEG only consistently shows epileptic abnormalities in 35% of patients with epilepsy while, in another 50% of patients, epileptic abnormalities will be present in some, but not all, interictal EEGs. On the other hand, only 0.5% of patients without epilepsy have interictal epileptic abnormalities on their EEG. Non-specific abnormalities (such as focal or diffuse slow waves) may be seen in 15%–25% of the normal population. The EEG may be helpful in classifying the type of epilepsy.

Blood tests are usually normal in people presenting with their first seizure, but may be helpful in ruling out infection or metabolic disorder. Liver function tests are useful in cases of suspected alcohol abuse, and should be checked as a baseline prior to starting antiepileptic drugs, many of which can have an effect on them. Neuroimaging should be carried out in all adults developing epilepsy, and in most children (except where the idiopathic nature of the epilepsy can be clearly established on EEG), to help establish the underlying aetiology.

Prognosis, and how to estimate it?

Approximately 50% of people having a single seizure will have a further seizure in the next 2 years, most commonly soon after the first. As noted in 'Natural history of the disease', epilepsy eventually becomes inactive in many patients, with up to 70% of all people developing epilepsy becoming seizure-free, and about half being able to successfully withdraw their medication. However, in about 30% of people developing epilepsy, the condition will become chronic and resistant to antiepileptic drugs. Most patients will have their seizures controlled by the first or second antiepileptic drug. However, if they fail to respond to the first three antiepileptic drugs, the chance of becoming seizure-free with any new drug is of the order of 4%. Therefore, the possibility of using other methods of treatment such as epilepsy surgery should be considered in any person with epilepsy whose seizures persist despite medication.

In the UK, people having a single seizure are permitted to resume driving a car after 6 months in the absence of such factors as MRI or EEG abnormalities which might increase the risk of recurrence. People with epilepsy must be seizure-free for a year to be eligible to drive a car: special rules apply to those only having seizures which do not involve loss of consciousness or with seizures occurring in sleep.

Treatment and its effectiveness

In the UK, antiepileptic drugs are not usually prescribed after a single seizure in the absence of factors increasing the risk of recurrence (e.g. the presence of an underlying tumour). Prophylactic measures which may reduce the risk of recurrent seizures include avoiding sleep deprivation and excesses of alcohol. Those patients with epilepsy who are photosensitive (about 5% of the total) should avoid flashing lights.

The SANAD (**S**tandard **A**nd **N**ew **A**ntiepileptic **D**rugs) study compared valproate with topiramate and lamotrigine, and suggested that valproate was the most effective and best-tolerated drug in patients with genetic generalized epilepsy. However, it carries a relatively high risk of teratogenicity (of the order of 6%), and should preferably be avoided in women of childbearing age, in whom lamotrigine or levetiracetam may be a more appropriate choice. For patients with partial onset seizures, the SANAD study compared carbamazepine with lamotrigine, topiramate, gabapentin, and oxcarbazepine. While carbamazepine and lamotrigine appeared to be equally effective in controlling seizures, lamotrigine was better tolerated. However, response to antiepileptic drugs varies from person to person, and antiepileptic drug treatment should be tailored to the individual according to efficacy and adverse effects. At present,

carbamazepine, lamotrigine, and levetiracetam appear to be the safest choices with respect to teratogenicity for women of childbearing age. Any woman taking antiepileptic drugs and planning a pregnancy should take folic acid 5 mg daily prior to conception and for the first trimester. Certain drugs, particularly enzyme-inducing drugs, can affect the efficacy of the oral contraceptive pill, and necessitate the use of an increased dose of the oral contraceptive or an alternative method such as a barrier method, intramuscular medroxyprogesterone, or the levonorgestrel-releasing intrauterine coil.

227 Stroke

Victoria Haunton, Aung Sett, Amit Mistri, and Martin Fotherby

Definition of stroke

The World Health Organization defines stroke as 'a clinical syndrome consisting of rapidly developing clinical signs of focal (at times global) disturbance of cerebral function lasting greater than 24 hours (or leading to death) with no apparent cause other than that of vascular origin'.

Transient ischaemic attack (TIA) is defined as a rapid presentation of neurological deficit with complete recovery within 24 hours of the onset of symptoms. However, the 24-hour cut-off is arbitrary, has no biological basis, and is of limited use clinically. A shorter duration is now regarded as more appropriate, although it has yet to be universally accepted. In clinical practice, stroke and TIA are best thought of as comprising a continuum, as they have similar pathological mechanisms, etiologies, and management strategies.

While subarachnoid haemorrhage is a type of stroke, based on the above definition, it is not covered in this chapter, as its pathophysiology, clinical manifestations, and management are distinct from those of ischaemic stroke and haemorrhagic stroke.

Demographics of stroke

Stroke is a common medical emergency with an annual incidence of between 130 and 200 per 100 000. At least 46 000 people in the UK each year have a first TIA, and approximately 152 000 had a first or recurrent stroke in 2014. Stroke is the fourth-largest cause of death in the UK after cancer, heart disease, and respiratory disease, and is responsible for approximately 50 000 deaths per annum. At any one time, there are likely to be 25–35 patients with stroke as their primary diagnosis in an average UK general hospital and, at present, there are approximately 1.2 million stroke survivors in England, with around half being dependent on others for everyday activities. The costs of stroke are estimated to be between £3.7 billion and £8 billion, or 5% of the total NHS annual budget. If post-stroke-care community costs are taken into account, this figure rises to nearly 12%.

Although stroke was previously regarded as a disease of the developed world, its incidence in the developing world is rising because of the adoption there of healthier lifestyles. WHO data indicate that, globally, stroke is the second-commonest cause of death, being responsible for 6.7 million deaths worldwide every year. Of these, two-thirds are in the developing world.

While stroke can occur at any age, it is predominantly a disease of older people. Over two-thirds of cases occur in those over 65, and less than 15% occur in those under 45. The incidence of stroke increases progressively with each successive decade of life over the age of 55, with an overall rate of 0.2/1000 in those aged 45–54, and 10/1000 in those aged over 85. While stroke risk is higher in men, more women die from stroke, due to their overall greater life expectancy.

The incidence of stroke and the relative distribution of stroke subtypes vary amongst ethnic groups. African-Caribbean, Africans, and African descendants have a higher incidence of stroke, compared to Caucasians. Stroke incidence also appears to be higher in Chinese populations.

Ischaemic stroke

Aetiology of ischaemic stroke

Ischaemic stroke can be classified as being due to:

- large artery atherosclerosis
- cardioembolism

- small blood vessel occlusion (lacunar stroke)
- other determined etiologies, including arterial dissection, hereditary factors, vasculitis, haematological disorders, coagulopathies, moyamoya disease, and drugs
- undetermined aetiology

Atherosclerosis

Atherosclerosis is a well-recognized risk factor for ischaemic stroke and involves large and medium-sized arteries, most commonly, the aorta, the coronary arteries, the carotid artery at its bifurcation, and the basilar artery. Its prevalence increases with age, and hypertension, hyperlipidaemia, and diabetes mellitus are all predisposing risk factors for its development. Atherosclerotic plaques develop as a result of vessel wall injury and the deposition of lipids. Stroke occurs as these plaques rupture, promoting thrombus formation and subsequent occlusion of the cerebral arterial circulation.

Cardioembolism

Cardioembolism accounts for approximately 25% of all ischaemic strokes, and 36% of ischaemic stroke in young patients. Atrial fibrillation is the commonest cause of cardioembolic stroke and is usually associated with more severe stroke and higher mortality rates. Other causes of cardioembolic strokes are listed in Box 227.1.

Small blood vessel occlusion

Small vessel disease usually affects the arterioles and is associated with hypertension. It is caused by fibrosis and the sub-endothelial accumulation of a pathological protein, hyaline, which lead to narrowing and occlusion of these vessels.

Other determined etiologies

Arterial dissection

Arterial dissection is a common cause of stroke in younger patients, accounting for 20% of strokes in patients under the age of 45. It may be spontaneous or precipitated by neck trauma, which may be mild. A tear in the media or intima of the carotid or vertebral artery lumen leads to bleeding in the arterial wall. This may then track, creating

Box 227.1 Cardioembolic causes of stroke

High risk

- atrial fibrillation
- sick sinus syndrome
- mechanical prosthetic heart valve replacement
- mitral stenosis
- infective endocarditis
- myocardial infarction
- dilated cardiomyopathy
- atrial flutter
- left atrial thrombus
- left atrial appendage thrombus
- left ventricular myxoma

Low/uncertain risk

- subaortic hypertrophic cardiomyopathy
- aortic valve calcification
- patent foramen ovale
- mitral valve prolapse
- atrial septal aneurysm
- congestive cardiac failure

Box 227.2 Connective tissue disorders associated with carotid artery dissection

- Marfan syndrome
- collagen disorders
- Ehlers–Danlos syndrome type IV (vascular)
- osteogenesis imperfecta
- polycystic kidney disease
- fibromuscular dysplasia
- pseudoxanthoma elasticum

a false lumen, which may occlude the artery or predispose to the development of a thrombus which then embolizes.

Spontaneous arterial dissections are associated with a variety of connective tissue diseases, which are listed in Box 227.2.

Hereditary disorders

Several hereditary disorders have been implicated in stroke, including CADASIL (for **c**erebral **a**utosomal **d**ominant **a**rteriopathy with **s**ubcortical **i**nfarcts and **l**eukoencephalopathy) syndrome, Fabry's disease, homocystinuria, MELAS (for **m**itochondrial **e**ncephalopathy with **l**actic **a**cidosis and **s**troke) syndrome, and HERNs (for **h**ereditary **e**ndotheliopathy with **r**etinopathy and **s**troke) syndrome.

Vasculitis

Cerebral vasculitides may be primary or secondary, as outlined in Table 227.1.

Haematological disorders and coagulopathies

Various haematological disorders are associated with stroke, as outlined in Box 227.3

Moyamoya disease

Moyamoya disease is a progressive intracranial vasculopathy that usually becomes symptomatic in children or young adults. Angiographic studies reveal a tight stenosis or occlusion of the intracranial carotid arteries.

Drugs

Illicit drugs, including cocaine, amphetamines, ephedrine, and MDMA (ecstasy) have all been implicated in stroke. Of the prescribed drugs, antipsychotics (particularly atypical antipsychotics in elderly patients

Box 227.3 Haematological disorders associated with stroke

- thrombotic thrombocytopenic purpura
- haemoglobinopathies
- paroxysmal nocturnal haemoglobinuria
- protein C deficiency
- protein S deficiency
- antithrombin III deficiency
- activated protein C resistance
- factor V Leiden mutation
- prothrombin gene mutation
- antiphospholipid antibody syndrome
- polycythaemia
- anaemia
- leukaemia
- essential thrombocytosis
- lymphoma
- disseminated intravascular coagulation

with dementia) have been implicated, as has the oral combined or oestrogen contraceptive pill and oestrogen-containing hormonal replacement therapy.

Undetermined aetiology

The term 'undetermined aetiology' refers to strokes where the likely aetiology could not be determined despite an extensive evaluation, or where the treating physician felt that not all necessary investigations had been performed. As many as one-third of strokes may fall into this category.

Risk factors for ischaemic stroke

Multiple risk factors contribute to ischaemic stroke; these can be divided into modifiable and non-modifiable factors (see Box 227.4).

Signs and symptoms of ischaemic stroke

The typical presentations of anterior circulation and posterior circulation strokes are detailed in Box 227.5. However, the exact clinical presentation and stroke syndrome will depend upon which arterial territory is involved and the size and type of the lesion. These are explored in detail in this section. It should be noted that confusion and memory disturbance alone and syncope are rarely attributable to stroke, and their presence should prompt the clinician to consider alternative diagnoses.

Signs and symptoms of anterior circulation strokes

The anterior circulation refers to the area of the brain supplied by the carotid arteries. There are five main branches (see Figure 227.1): the ophthalmic artery, the posterior communicating artery, the anterior choroidal artery, the anterior cerebral artery, and the middle cerebral artery (MCA), which is further divided into the M1, M2, M3, and M4 segments.

Anterior choroidal strokes typically cause a lacunar-type syndrome with pure motor or sensorimotor hemiparesis. However, they may also give rise to the triad of contralateral hemiparesis, hyperaesthesia, and upper quadrantanopia.

Anterior cerebral artery infarcts usually lead to weakness and sensory loss of the contralateral lower limb but other presentations include urinary incontinence, mutism, anterograde amnesia, and behavioural disturbance secondary to frontal lobe dysfunction. Primitive reflexes may be elicited on clinical examination.

The MCA territory is the one most frequently affected by acute strokes. Complete MCA strokes give rise to contralateral hemiplegia, hemisensory loss, and homonymous hemianopia with a head and gaze preference away from the side of the hemiplegia (i.e. towards the lesion). Cognitive signs are usually present with dominant hemisphere infarcts, which result in a global aphasia and ideomotor apraxia, and non-dominant hemisphere infarcts, which result in a multimodal neglect and anosognosia (denial of illness). Segmental infarctions will give rise to some, but not all, of these features. A rare complication

Table 227.1 Cerebral vasculitides

Primary vasculitis	Granulomatous, inflammatory, non-sarcoidotic, non-infectious vasculitis with giant cells
Secondary vasculitis in systemic disorders	Polyarteritis nodosa Churg–Strauss syndrome SLE Sjögren's syndrome Behçet's syndrome Sarcoidosis Inflammatory bowel disease Takayasu's arteritis Buerger's disease Eales disease Acute multifocal placoid pigment endotheliopathy Köhlmeier–Degos disease
Secondary vasculitis in infectious disorders	Tuberculosis HIV Syphilis Ophthalmic herpes zoster Lyme disease Malaria Cysticercosis Aspergillosis Cryptococcosis

Box 227.4 Ischaemic stroke risk factors

Non-modifiable risk factors

Age

- most potent risk factor
- risk of stroke doubles with each decade of life after 55 years of age

Gender

- incidence higher in men
- prevalence higher in women, due to lower mortality

Ethnicity

- incidence higher in African-Caribbeans, Africans, African descendants, and Asian and Chinese populations

Hereditary disorders

- first-degree family history of premature atherosclerosis
- CADASIL syndrome
- HERN syndrome
- MELAS syndrome
- Fabry's disease
- homocystinuria

Socio-economic status

- stroke risk is 60% higher for the lowest socio-economic class than for the highest social class

History of coronary heart disease or stroke

- prior history of coronary heart disease is a potent risk factor, indicating the need for better primary prevention

Modifiable risk factors

Hypertension

- most controllable risk factor
- risk doubles with each 5–7 mm Hg increase in systolic blood pressure

Diabetes

- diabetic patients have a 1.5- to 4-fold increased risk of stroke

High total cholesterol/LDL and low HDL

- high risk of atherosclerosis and ischaemic stroke
- greater risk in smokers and those with inactive lifestyles

Atrial fibrillation

- commonest cardioembolic cause

Smoking

- twofold increased risk of stroke
- risk diminishes 5 years after stopping

Alcohol consumption

- minimal alcohol consumption has some protective effect but heavy alcohol intake confers an increased risk of stroke

Obesity

- BMI ≥ 25 confers increased risk of stroke

Hyperhomocysteinaemia

- recognized risk factor
- no clear evidence of benefit from intervention

of large MCA infarction is the malignant MCA syndrome. This occurs in younger patients without brain atrophy and is caused by the development of life-threatening space-occupying oedema, which leads to raised intracranial pressure with subsequent subfalcine, uncal, and transtentorial herniation.

Signs and symptoms of posterior circulation strokes

The posterior circulation consists of the vertebral arteries, the basilar artery, and the posterior cerebral arteries with their branches. These arteries typically supply the brainstem (medulla, pons, and midbrain), the thalamus, the hippocampus, the cerebellum, and parts of the occipital and temporal lobes, including the

Box 227.5 Typical stroke presentations

anterior circulation

- cerebellar signs
- nystagmus
- bilateral or crossed signs

visual cortex. However, there is marked individual variability in the exact arterial anatomy of the posterior circulation, and persisting fetal circulations are not uncommon. Clinical features that suggest a posterior circulation stroke rather than an anterior circulation event include preceding TIAs in the days and hours prior to the event, and headache, which is typically ipsilateral to the side of the lesion. The most common symptoms are dizziness, diplopia, dysarthria, dysphagia, and ataxia, but the hallmark of a posterior circulation event is crossed signs with cranial nerve findings ipsilaterally and sensorimotor findings on the opposite side. However, patients may present with a wide variety of other

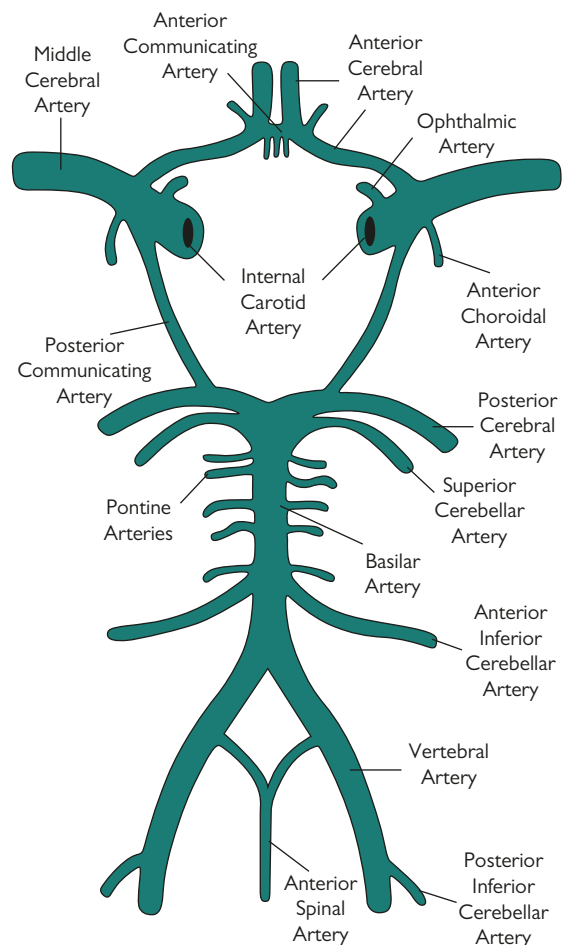

Figure 227.1 Cerebral circulation.

This article was published in *Gray's Anatomy*, Susan Standing, *The Arteries of the Brain*, p. 574, Copyright Elsevier (2008)

symptoms, including vertigo, fluctuating episodes of drowsiness, cranial nerve palsies, disorders of conjugate gaze, Horner's syndrome, and acute unilateral deafness.

Specifically, cerebellar strokes usually present with headache, vertigo, vomiting, nystagmus, and ataxia.

Lateral medullary syndrome, caused by sudden occlusion of the posterior inferior cerebellar artery, results in vertigo and vomiting with ipsilateral cranial nerve palsies, Horner's syndrome, and contralateral pain and temperature deficits.

Midbrain injury may produce coma, oculomotor nerve palsy, dilated pupils, and hemi- or quadriplegia.

Basilar artery occlusion is usually devastating, giving rise to massive brainstem dysfunction and death. However, if the medulla is spared, a significant number of syndromes can occur, including the 'locked-in' syndrome, in which patients are quadriplegic and communicate only by means of vertical eye movements.

Signs and symptoms of lacunar strokes

A lacunar infarct is a small, subcortical infarct of a perforating branch of a large cerebral artery. The most common clinical presentation of a lacunar stroke is a pure motor hemiparesis but they may also give rise to a pure sensory stroke, a sensorimotor stroke, dysarthria-clumsy hand syndrome, or an ataxic hemiparesis.

Haemorrhagic strokes

Aetiology of haemorrhage strokes

The causes of spontaneous intra-cerebral haemorrhage are listed in Box 227.6.

Signs and symptoms of haemorrhage strokes

Haemorrhagic strokes often have an apoplectic onset. Seizures, bilateral extensor plantars, and marked hypertension are common. However, these features are not specific and may also be seen with large infarcts. Furthermore, as with ischaemic strokes, the exact clinical presentation of a spontaneous intra-cerebral haemorrhage will depend on its site and size. The most common sites of haemorrhage, in order of frequency, are putaminal, thalamic, lobar, caudate, pontine, and cerebellar. The deep grey matter of the brain, including the basal ganglia and the thalamus, is the most common site for hypertensive haemorrhagic stroke, with cerebral amyloid intra-cerebral bleeds usually occurring in the white matter of brain parenchyma.

Putaminal haemorrhages typically give rise to contralateral limb weakness and hemisensory loss. Extension of the bleeding into the frontal lobe will cause conjugate eye deviation. Thalamic bleeding causes total hemisensory loss and dense hemiplegia. There may also be convergent downward gaze (the patient looks at the tip of their nose).

Progressive deterioration of the conscious level points to a growing haematoma, and sudden posturing and coma indicate bleeding into the lateral or third ventricle.

Classification of stroke

Several additional classification systems exist for stroke, including the Oxfordshire Community Stroke Project (OCSP) classification, which is often referred to as the Bamford classification, and the ICD-10 system.

Box 227.6 Causes of spontaneous intra-cerebral haemorrhage

- hypertension
- amyloid angiopathy
- arteriovenous malformation
- bleeding diatheses
- drugs (amphetamines, cocaine, anticoagulants, thrombolytics)
- tumours

Table 227.2 The Oxfordshire Community Stroke Project classification of stroke

FEATURES	CLASSIFICATION
All 3 present (see OCSP classification paragraph below)	TACS
2 out of 3 present	PACS
Drowsy + unilateral weakness (visual + higher cerebral involvement assumed)	TACS
Motor/Sensory/sensori-motor involvement affecting ≥ 2 of 3 body areas (arm/face/leg)	LACS
Cerebellar syndrome or brainstem involvement	POCS
Isolated speech or visual involvement	PACS
Restricted motor or sensory involvement—affecting only one body area (arm or face or leg)	PACS

Reprinted from *The Lancet*, Volume 337, J. Bamford, P. Sandercock, M. Dennis, C. Warlow, J. Burn, Classification and natural history of clinically identifiable subtypes of cerebral infarction, pp. 1521–1526, Copyright (1991), with permission from Elsevier

OCSP classification

In the OCSP classification system (see Table 227.2), strokes are classified according to their constellation of symptoms and signs into four groups. These are:

- total anterior circulation stroke (TACS)
- partial anterior circulation stroke (PACS)
- lacunar stroke (LACS)
- posterior circulation stroke (POCS)

A stroke episode occurring in a patient with a current neurological deficit should never be labelled a 'TIA'. Classification depends on three main features:

- unilateral motor or sensory involvement (arm/face/leg)
- visual involvement (hemianopia, quadrantanopia, or visual neglect)
- higher cerebral dysfunction (dysphasia, dyscalculia, visuospatial disorder/inattention/neglect)

This is a clinical classification prior to any investigations. Once haemorrhage is excluded, the 'S' can be replaced by an 'I' (i.e. TACI, LACI, etc.), or 'H' indicating haemorrhage; however, the prognostic value of OCSP in PICH is uncertain.

Examples of OCSP classifications

The following are examples of OCSP classifications:

- weakness of left face, arm, and leg, expressive dysphasia, and left homonymous hemianopia: right TACS
- weakness of right face and arm, and right-sided sensory inattention: left PACS
- sensory loss in left arm and leg: right LACS
- sensory loss in left arm only: right PACS
- ataxic hemiparesis: LACS (contralateral to affected side)
- Horner's syndrome: POCS
- cerebellar syndrome: POCS

The four classical lacunar syndromes are: isolated hemimotor dysfunction, hemisensory dysfunction, hemi-sensori-motor dysfunction, and ataxic hemiparesis.

ICD-10 classification

The ICD-10 classification is outlined in Box 227.7.

Stroke prevention

Stroke prevention strategies can be classified as primary prevention, where there is no prior history of TIA or stroke, and secondary prevention, where there is such a history.

Primary prevention

All patients should have their cardiovascular risk assessed on a regular basis. In the UK, the National Institute for Health and Care Excellence

Box 227.7 ICD-10 classification of stroke

Acute stroke

- I60 Non-traumatic subarachnoid haemorrhage
- I61 Non-traumatic intracerebral haemorrhage
- I63 Cerebral infarction
- I64 Stroke, not specified as haemorrhage or infarction

Consistent with WHO definition of stroke, but considered distinct from a clinical viewpoint

- I62 Other and unspecified non-traumatic intracranial haemorrhage (includes subdural, extradural and unspecified intracranial haemorrhages)

Other relevant codes

- G45 Transient ischaemic attack, including transient global amnesia
- I69 Sequelae of cerebrovascular disease
- Z82.3 Family history of stroke

(NICE) recommends assessing a patient's 10-year cardiovascular risk with the Joint British Societies JBS3 Risk Calculator. Following this, lifestyle modifications and medical therapies should be instigated as appropriate.

Lifestyle modifications

All patients should be encouraged to stop smoking, maintain an appropriate weight (BMI between 20 and 25), and eat healthily. Dietary measures associated with stroke risk reduction include reduced total fat and cholesterol intake; increased consumption of fruits, vegetables, and fish oils; and reduced salt intake. Alcohol should be taken in moderation, with the weekly intake not exceeding 14 units per week. Exercise has a significant association with reduction in relative stroke risk, and the effect is even greater with strenuous activity. Patients should therefore be encouraged to take at least 30 minutes of exercise at least five times per week, or whatever they can achieve if they have limited mobility.

Hypertension

This is the most common risk factor for stroke, and is extremely treatable. Adults over 40, and those with other vascular risk factors, should therefore be screened regularly for raised blood pressure. Current British Hypertension Society and NICE guidelines classify hypertension as being Stage 1, Stage 2, or severe. Stage 1 hypertension refers to a clinic blood pressure of $\geq 140/90$ mm Hg, and subsequent ambulatory blood-pressure monitoring (ABPM) daytime average or home blood-pressure monitoring (HBPM) average blood pressure of $\geq 135/85$ mm Hg. Stage 2 hypertension is defined as a clinic blood pressure of $\geq 160/100$ mm Hg, and subsequent ABPM daytime average or HBPM average blood pressure of $\geq 150/95$ mm Hg. A clinic systolic blood pressure of >180 mm Hg or higher or clinic diastolic blood pressure of >110 mm Hg indicates severe hypertension. Antihypertensive drug treatment should be offered to all people aged under 80 who have Stage 1 hypertension and target organ damage, established cardiovascular disease, renal disease, diabetes, or a 10-year cardiovascular risk equivalent to 20% or greater and to people of any age with Stage 2 or severe hypertension. Current treatment targets are a clinic blood pressure $<140/90$ mm Hg in people aged under 80, and $<150/90$ mm Hg in people aged 80 and over.

Blood-pressure variability may be as important as average levels in predisposing to stroke risk, and further research is needed in this area.

Dyslipidaemia

Although hypercholesterolaemia is a weaker risk factor for stroke than for heart disease, trials have shown a clear positive effect of cholesterol-lowering therapy on the incidence of ischaemic stroke. The NICE guideline recommends pharmacological lipid modification in individuals with $>20\%$ 10-year risk of cardiovascular disease; lipid reduction is targeted at a total cholesterol level of <4 mmol/l, and

an LDL cholesterol level of <2 mmol/l. Dietary measures should be used for all patients, and pharmacological therapies added as needed. Niacin, fibrates, and statins can all be used, although statins have been shown to be most effective.

Diabetes

High-vascular-risk individuals should be screened for diabetes, and treatment instigated accordingly.

Atrial fibrillation

Atrial fibrillation is a strong independent risk factor for stroke; when atrial fibrillation is detected, serious consideration should be given to anticoagulant therapy. Various risk stratification tools are in use to guide such therapy, including the CHA₂DS₂-VASc score, which gives an estimate of embolic stroke risk, and the HASBLED score, which estimates bleeding risk. Antiplatelets are no longer considered adequate for prevention of cardioembolic stroke. There is strong evidence that dose-adjusted warfarin reduces the risk of stroke occurrence by approximately two-thirds, with only a slight increase in bleeding risk. The most common reasons for not prescribing warfarin are a high perceived risk of bleeding, and difficulties maintaining an international normalized ratio in the therapeutic range. Newer anticoagulants in the form of oral direct inhibitors have recently been evaluated by NICE and are available as alternatives to warfarin. These include Factor II inhibitors (dabigatran) and Factor X inhibitors (rivaroxaban, apixaban, edoxaban). Large clinical trials have demonstrated that these agents have effects that are broadly similar to those of warfarin, with a consistent reduction in intracranial haemorrhage risk. Their key advantage is their fixed dosing regimen with no requirement for anticoagulation monitoring. However, they are contraindicated in patients with a creatinine clearance less than 15 ml/min, and the current absence of an established antidote or rapid-reversal agent is considered a disadvantage.

Anticoagulant therapy

Outside the context of atrial fibrillation, anticoagulation is also recommended as primary prevention for various other patients who are at high risk of cardioembolic stroke. This includes patients who are at high risk of thromboembolism following acute myocardial infarction, particularly a large anterior myocardial infarction; patients with left ventricular aneurysm or thrombus; and patients with paroxysmal tachyarrhythmias, chronic heart failure, or a history of thromboembolic events. Anticoagulation is also indicated for patients with mechanical prosthetic heart valves or rheumatic mitral valve disease.

Antiplatelet agents

Antiplatelet agents provide no net benefit in the primary prevention of stroke, although they are widely accepted for secondary prevention.

Secondary prevention

While primary prevention of stroke is essential, it can be difficult to apply, as the population at risk is ill defined. Conversely, patients who have a history of stroke or TIA are a well-defined target population for secondary prevention, and come into contact with specialists as a result of the index event. Effective secondary prevention has the potential to reduce stroke risk by a half to two-thirds. The preventative strategies for long-term stroke prevention can be classified into three main categories: lifestyle modifications, medical therapies, and surgical intervention for carotid disease.

Lifestyle modifications

All patients should be educated regarding the same lifestyle modifications as recommended for primary prevention.

Medical therapies

Antithrombotic therapy

Overall, antiplatelet therapy reduces the risk of a recurrent vascular event by a fifth in people with a history of TIA or stroke. In the UK, aspirin, modified-release dipyridamole, and clopidogrel are the three drugs almost exclusively used in secondary prevention following TIA or ischaemic stroke. The recent Royal College of Physicians guideline

recommends that clopidogrel 75 mg daily should be used first line and, if this is not tolerated, then aspirin 75 mg daily in combination with modified-release dipyridamole 200 mg twice daily should be offered.

Long-term dual antiplatelet therapy with aspirin and clopidogrel is not routinely used for stroke prevention. While prolonged use is associated with a reduction in ischaemic stroke, this is offset by an increased risk of major bleeding. There is some evidence for short-term use in those with significant symptomatic carotid atherosclerotic disease which is not amenable to surgery, and those at high risk of subsequent stroke (e.g. an ABCD₂ Score ≥ 4).

Anticoagulation should be initiated unless contraindicated in patients with cardioembolic stroke, after a suitable interval to avoid increasing the risk of early haemorrhagic transformation of cerebral infarcts.

Antihypertensives

The target blood pressure for stroke patients, as guided by the fifth edition of the *National Clinical Guideline for Stroke* (Royal College of Physicians London) and the American Stroke Association is <130/80 mm Hg, except for patients with severe bilateral carotid stenosis, for whom a systolic blood-pressure target of 130–150 mm Hg is appropriate. For patients aged 55 or over, and African or Caribbean patients of any age, antihypertensive treatment should typically be initiated with a long-acting dihydropyridine calcium channel blocker or a thiazide-like diuretic. If the target blood pressure is not achieved, an angiotensin-converting enzyme inhibitor or an angiotensin-II receptor blocker should be added.

For patients not of African or Caribbean origin, or younger than 55 years, the first choice for initial antihypertensive therapy should be an angiotensin-converting enzyme inhibitor or a low-cost angiotensin-II receptor blocker. Beta blockers are not routinely recommended as a first line antihypertensive therapy for stroke prevention unless there are associated comorbidities (e.g. ischaemic heart disease, heart failure, and atrial fibrillation). Blood-pressure-lowering treatment should be initiated after stroke or TIA. Thereafter, treatment should be monitored frequently and increased as necessary to achieve the target blood pressure as quickly as is tolerated and safe in primary care. Patients who do not achieve the target blood pressure should be referred for a specialist opinion.

Lipid-modifying agents Statin therapy should be initiated in almost everyone with a history of ischaemic stroke or TIA, unless the total cholesterol is <3.5 mmol/l. If statins are contraindicated or not tolerated, other agents such as fibrates (for elevated total cholesterol or high LDL) or niacin (for low HDL) should be used.

Glycaemic control

The general recommendation for the Hb A1c target level after a stroke is <7%, although a more stringent target of <6% may be considered in the early management of diabetes. More aggressive Hb A1c targets are not advised in the long-term management of glycaemic control, particularly in patients with high cardiovascular risk, as such targets are associated with increased mortality.

Surgical intervention for carotid artery disease

Early carotid ultrasound or angiogram is recommended for anterior circulation stroke and TIA patients with no significant dependency, either before or after the event. If an ipsilateral carotid artery stenosis of 50%–99% is detected, carotid artery revascularization (usually with endarterectomy) should be performed as soon as possible, but certainly within 2 weeks.

Approach to diagnosing stroke

Prompt diagnosis of stroke is crucial in order to commence appropriate treatment as quickly as possible. Several stroke screening tools are now in widespread use to help improve time to diagnosis, including FAST (for **F**ace **A**rm **S**peech **T**est; see Box 227.8), which is predominantly used outside hospitals, and the ROSIER (**R**ecognition of **S**troke **I**n the **E**mergency **R**oom) scale (see Table 227.3).

The diagnosis of stroke is predominantly clinical and, once stroke is suspected, the initial assessment should first to seek to establish

Box 227.8 FAST test

Facial weakness: Can the person smile? Has their mouth or eye drooped?

Arm weakness: Can the person raise both arms?

Speech problems: Can the person speak clearly and understand what you say?

Time to call '999'

that there is indeed a clear history of **rapid** onset of **focal** neurological deficit. If these criteria are satisfied, the diagnosis of stroke will be correct in 95% of cases. Clinical assessment should then seek to establish what the mechanism of stroke is and where the lesion is, with a focused history and examination. As part of the clinical examination, a National Institutes of Health Stroke Scale (NIHSS) should be performed. This is a clinical evaluation instrument, with documented validity and reliability, and is used to assess the severity of a stroke and its likely prognosis. The NIHSS grades the following areas: conscious level, orientation, gaze, visual fields, facial weakness, limb weakness, ataxia, sensation, language, dysarthria, and inattention.

All patients should then undergo prompt brain imaging. The indications for immediate brain imaging are given in Box 227.9.

'Gold-standard' diagnostic test for stroke

CT perfusion scanning is the most sensitive for the detection of acute ischaemic stroke with a sensitivity of approximately 75% for ischaemic strokes and above 85% for non-lacunar supratentorial infarcts. In CT perfusion scanning, a baseline CT is followed by CT angiography of the head and neck and a contrast-enhanced CT of the brain using iodinated contrast. The perfusion CT images and their data are then used to create a map of the ischaemic area (infarct and penumbra).

Acceptable diagnostic alternatives to the gold-standard test for stroke

Despite the sensitivity of CT perfusion scanning in detecting early ischaemia, it is not yet widely enough available to be practicable. As prompt scanning is crucial for guiding emergency management in acute stroke, plain CT is currently the most practical and widely available modality available for imaging. A non-contrast CT brain scan can be performed in less than a minute with a helical CT scanner and is considered sufficient to select patients for IV thrombolysis. It is highly accurate for identifying acute intra-cerebral haemorrhage, which is present within minutes of onset and seen as hyperattenuation, but

Table 227.3 The ROSIER score

Symptoms	Points
New onset of asymmetric facial weakness	1
New onset of asymmetric arm weakness	1
New onset of asymmetric leg weakness	1
Speech disturbance	1
Visual field defect	1
Loss of consciousness or syncope	-1
Any seizure activity	-1
Total	

If score totals >0, assume diagnosis of stroke. If score totals 0, -1, or -2, stroke diagnosis is unlikely but not excluded.

Box 227.9 Indications for immediate brain imaging

- indications for thrombolysis or early anticoagulation treatment
- on anticoagulant treatment
- a known bleeding tendency
- a depressed level of consciousness (Glasgow Coma Score <13)
- unexplained progressive or fluctuating symptoms
- papilloedema, neck stiffness, or fever
- severe headache at onset of stroke symptoms

only 5% of acute infarcts will be visible within the first 12 hours. Changes indicative of acute ischaemia include focal hypoattenuation, which is very specific and predictive for irreversible ischaemia, and oedema without hypoattenuation, in which case the tissue is potentially salvageable. The typical CT scan appearances of haemorrhage and ischaemia are shown in Figures 227.2 and 227.3, respectively.

MRI scanning is now being used in some centres as the sole modality for the emergency imaging of stroke, as it has been shown to be more effective than plain CT in the detection of acute ischaemia and can detect both acute and chronic haemorrhage. Typically, multiparametric sequences are obtained, including diffusion-weighted imaging, T1- and T2-weighted sequences, angiography, and fluid-attenuated inversion recovery. The advantage of this is that the extent of the lesion and the stroke mechanism can be clarified very early on.

It is likely that, with time, access to both immediate CT perfusion scanning and MRI will become more widely available.

Other investigations required following a stroke or a TIA

Other investigations required following a stroke or a TIA are outlined in Table 227.4.

Other diagnoses that should be considered aside from stroke

While the diagnosis of acute ischaemic stroke is often straightforward, there are several important stroke mimics (see Box 227.10). These should be considered in the differential diagnosis, and care taken to exclude them as appropriate.

Treatment for stroke

Stroke requires a multifaceted treatment approach, consisting of general measures including homeostatic control, drug therapies, prevention and

Figure 227.3 Acute right middle cerebral artery territory infarct; note the typical wedge shape.

Anonymised image obtained from University Hospitals of Leicester NHS Trust

management of complications, and rehabilitation. Occasionally, neurosurgical intervention forms part of stroke treatment.

Stroke units

A stroke unit is defined as ‘a geographically defined unit staffed by a coordinated multidisciplinary team with expertise in stroke’. All stroke patients should be treated in a stroke unit, as there is strong evidence that this significantly reduces death, dependency, and the need for institutional care. The gold standard is to admit patients with stroke directly to a stroke unit and continue care there until discharge.

Homeostasis

Oxygen

Patients should receive oxygen therapy if they are hypoxaemic (oxygen saturations <95%), as hypoxaemia can worsen cerebral ischaemia. However, the routine use of supplemental oxygen in patients who are not hypoxaemic is not currently recommended.

Blood pressure

Blood pressure is often elevated in acute stroke but usually returns to the patient’s normal level within the first few days. Blood pressure

- subdural haematoma

should not be lowered routinely in acute ischaemic stroke, as this may decrease cerebral perfusion and increase the infarct size. Current evidence suggests that it is probably safe to continue with antihypertensives that patients are already taking, but additional or new treatments should only be given if the blood pressure is persistently elevated above 200 mm Hg systolic or 120 mm Hg diastolic, or there are signs of cardiac failure, hypertensive encephalopathy, hypertensive nephropathy, aortic dissection, pre-eclampsia, or eclampsia.

In patients who are candidates for thrombolysis, the blood pressure should be lowered to $\leq 185/110$ mm Hg.

In haemorrhagic stroke, however, intensively lowering systolic blood pressure to ≤ 140 mm Hg leads to reduced morbidity and increased quality of life at 90 days, although mortality rates are unchanged.

Temperature

Raised temperature is associated with a poorer outcome after stroke, as it may increase infarct volume. Pyrexial patients should be treated with paracetamol and cooling fans, and the cause of the pyrexia should be sought and appropriately treated.

Hyperglycaemia

Hyperglycaemia also appears to be associated with a poorer outcome, and blood glucose levels ≥ 11.1 should be treated with insulin. However, care should be taken to avoid overtreatment and hypoglycaemia.

Drug treatments**Thrombolysis**

Thrombolysis with alteplase has been shown to improve outcomes in carefully selected patients. The main inclusion and exclusion criteria for its use are given in Table 227.5. It should only be used by trained, experienced physicians in centres which have immediate access to brain imaging and nursing staff who are trained in monitoring for complications. Although alteplase is currently only licensed for the thrombolysis of strokes in patients aged 80 or less, with a definite time of onset within 3 hours, there is growing evidence that it is safe both in older patients and in selected patients up to 4.5 hours after stroke onset. More recently, thrombectomy has been shown to dramatically improve outcomes in selected patients.

Antiplatelet therapy

Aspirin is safe, simple, and usually well tolerated and has been shown to improve long-term outcome. Indeed, treating 1000 patients for 2 weeks prevents 13 being dead or dependent at 6 months. All patients presenting with acute stroke who have had haemorrhage excluded with brain imaging should therefore be given aspirin 300 mg, either orally or rectally if they are unable to swallow.

Aspirin should be continued at this dose for 2 weeks and then patients should be switched to clopidogrel 75 mg daily, which they should remain on for the long term for secondary prevention.

Anticoagulants

There is no net benefit to be gained in the routine use of anticoagulants after acute stroke, except in the presence of venous thromboembolism and cardioembolic stroke (chiefly, atrial fibrillation). For patients with ischaemic stroke in atrial fibrillation, anticoagulation should be the standard treatment. However, it should not be commenced in patients with uncontrolled hypertension and, in patients with disabling ischaemic stroke, it should be deferred for at least 14 days, with aspirin 300 mg daily used in its place. In the case of

Table 227.5 Inclusion and exclusion criteria for thrombolysis with alteplase*

Inclusion criteria	Exclusion criteria
CT scan appearances consistent with acute ischaemic stroke	Symptom onset greater than 4.5 hours before National Institutes of Health Stroke Scale ≤ 4 or ≥ 25
Onset of symptoms within 4.5 hours	Recent (less than 10 days) traumatic external cardiac massage, puncture of a non-compressible blood vessel, or lumbar puncture
Clinical diagnosis of ischaemic stroke causing a measurable neurological deficit	Fixed head or eye deviation Seizure at onset Pre-stroke Rankin score >3 Blood pressure ≥ 185 mm Hg systolic or ≥ 110 mm Hg diastolic
Risks and benefits explained to patient or relative	Trauma with internal injuries, or visceral biopsy, within previous 4 weeks Serious head trauma or CNS surgery within 3 months Colitis, oesophageal varices, active peptic ulcer disease, aortic aneurysm, severe liver disease, or acute pancreatitis Proliferative diabetic retinopathy Blood glucose <3 or >22 Hereditary or acquired bleeding disorder Recent severe or dangerous bleeding Platelet count <100 or haematocrit $<25\%$ Current anticoagulation therapy (unless patient's international normalized ratio <1.7 while on warfarin)

*Relative contraindications: pregnancy or childbirth within the last 4 weeks, or stroke within 3 months.

minor, non-disabling stroke, anticoagulation could be started sooner at the discretion of the treating clinician. In the case of TIA, once brain imaging has ruled out haemorrhage, an agent with a rapid onset, such as low-molecular-weight heparin or an oral direct thrombin or Factor Xa inhibitor, should be commenced.

In patients with proximal deep vein thrombosis or pulmonary embolus, anticoagulants should be given in preference to aspirin.

Patients who are taking anticoagulants for prosthetic heart valves and develop stroke require special consideration. In the case of ischaemic stroke, anticoagulation therapy can usually be continued unless there is a significant risk of haemorrhagic transformation. Patients who develop haemorrhagic stroke while taking anticoagulants for prosthetic heart valves may have their anticoagulation therapy temporarily withheld for a short period, with low risk of systemic embolism.

Stroke clinicians should weigh up the benefit and risk of initiating anticoagulation in patients who present with ischaemic stroke with haemorrhagic transformation, or those with mixed haemorrhagic and ischaemic strokes and atrial fibrillation, or those who have concurrent venous thromboembolism.

Statin therapy

As stated in 'Lipid-modifying agents', statin therapy should be initiated in almost everyone with a history of stroke or TIA, unless total cholesterol is < 3.5 mmol/l. Although there is evidence that statins are anti-inflammatory and may have beneficial effects on neuroprotection, endothelial function, and homeostasis, there is also a concern that they may increase the risk of haemorrhagic transformation. Statins should therefore only be considered 48 hours after the onset of an acute stroke if there is a high risk of haemorrhagic transformation (depending on the size of the infarct and the severity of stroke) and need not be given to patients with acute haemorrhagic stroke alone.

Prevention and management of complications**Prevention of venous thromboembolism**

Despite traditionally held beliefs, there is no evidence to indicate any net benefit from the use of heparin or antiembolic stockings

in preventing venous thromboembolism in acute ischaemic stroke. Indeed, these measures may be harmful. Evidence indicates that intermittent pneumatic compression significantly reduces major venous thromboembolism in patients with acute stroke, but robust health economics data have yet to be established. Simple measures including avoidance of dehydration and early mobilization should be encouraged for all stroke patients.

Pressure areas

Pressure areas should be checked regularly and care should be taken to reduce the risk of bedsores. This can be done by treating infections, maintaining nutrition, providing pressure-relieving mattresses, and turning immobile patients regularly.

Fluids and nutrition

Care must be taken to avoid dehydration as it can lead to electrolyte abnormalities, further vascular events, and urinary tract infection. If necessary, supplementary fluids should be given parenterally. Patients' swallowing should be screened at admission, by an appropriately trained professional person. If screening reveals a problem with swallowing, the patient should have a specialist assessment by a speech and language therapist. This should ideally be done within 24 hours. If swallowing is impaired, it may be possible for the patient to have food and fluids which have been modified in consistency (e.g. with thickener). However, if there is marked dysphagia, and the recovery of swallow is likely to be delayed, feeding should be commenced via a nasogastric tube. In the longer term, PEG tube insertion provides an easier route of feeding.

All patients with impaired swallow should be referred to the dietetics team, in addition to the speech and language team.

Continence

Urinary retention and constipation are relatively common in acute stroke and should be treated promptly. Care should, however, be given to ensuring that catheters are removed in a timely fashion, as they may lead to the development of urinary tract infection.

Early mobilization

Patients with acute stroke should be mobilized and helped to sit out of bed as soon as possible, as this helps to decrease the risk of complications, namely venous thromboembolism, orthostatic hypotension, infection, contractures, and subluxations.

Depression

The prevalence of post-stroke depression has been estimated to be as high as 61%. Stroke patients should therefore be screened carefully for depression via a validated method such as the Geriatric Depression Score, or the Aphasia Depression Rating Scale. Antidepressant therapy should then be initiated accordingly, as untreated depression may hinder rehabilitation and is associated with adverse outcomes.

Neurosurgery in acute stroke

Discussion with the neurosurgical team should be considered for most patients with intracerebral haemorrhage. However, patients with small, deep haemorrhages, lobar haemorrhages, multiple comorbidities, or a Glasgow Coma Score of ≤ 8 rarely benefit from surgical intervention and are usually managed medically.

Neurosurgical intervention should also be considered in patients with the malignant MCA syndrome in ischaemic stroke. It may be possible to treat such patients with decompressive hemicraniectomy, although there are strict selection criteria for the procedure (see Box 227.11).

Rehabilitation

Once the acute phase of their treatment is complete, and they are medically stable, stroke patients should receive ongoing neurorehabilitation. Such neurorehabilitation remains one of the key components

Box 227.11 Selection criteria for decompressive hemicraniectomy

- age ≤ 60
- National Institutes of Health Stroke Scale ≥ 15
- score of ≥ 1 or 1a on the National Institutes of Health Stroke Scale
- infarct size $>50\%$ of the middle cerebral artery territory on CT scan, or $>145 \text{ cm}^3$ on diffusion-weighted MRI

Data from National Institute for Health and Care Excellence 2007 Diagnosis and initial management of acute stroke and transient ischaemic attack (TIA). CG68. London: National Institute for Health and Care Excellence. Available at: <http://www.nice.org.uk/nicemedia/live/12018/41363/41363.pdf>

of stroke care today and is vital in decreasing the odds of death, institutionalization, and dependency. Specific neurorehabilitation allows patients to benefit from the skills and knowledge of a dedicated multidisciplinary team and, in much the same way that patients benefit from early specialized care on an acute stroke unit, they also benefit from specialized rehabilitation. Indeed, for every 100 patients treated by organized multidisciplinary neurorehabilitation, as compared to those treated on a general ward and in other non-specific rehabilitation facilities, an extra 5 will return home in an independent state.

The key aims of rehabilitation are to restore the individual to his or her fullest physical, mental, and social capability. This is achieved through:

- input from a multidisciplinary team consisting of medical, nursing, and therapy staff with expertise in stroke and rehabilitation, with the team's work coordinated through regular weekly meetings
- interdisciplinary goal setting
- involvement of patients and their families in the rehabilitation process

We shall now examine these key approaches in more detail.

A crucial aspect of successful rehabilitation is close multidisciplinary team working. For the team to be successful, the individuals must be motivated by a shared philosophy and goals and be prepared to coordinate their work. They must also recognize their complementary skills and have mutual respect for one another.

Typically, in stroke rehabilitation, the team comprises doctors, nurses, physiotherapists, occupational therapists, and speech and language therapists but it may also include neuropsychologists, social workers, and dietitians. Occasionally, lay people, such as previous stroke survivors or representatives from stroke charities and patient support groups, also form part of the team. The role of each team member is detailed in Box 227.12.

For this team to be effective, the team members must meet regularly. This helps to generate cohesion and allows careful coordination of patient care. Each team member may carry out different assessments and identify different problems. Multidisciplinary team meetings are therefore vital in ensuring that all members of staff have compatible goals and objectives and are providing a standard message to patients and carers. These meetings are also important to allow team members to get to know each other and discuss proposed practice changes. The meetings also provide a helpful forum for feedback and education.

Goal setting is crucial in rehabilitation. Goals are highly focused statements of intent that should be generated from the assessment processes. They may be physical, functional, psychological, or social but should be SMART (**S**pecific, **M**easurable, **A**chievable, **R**ealistic, and **T**imed). In ensuring that goals are measurable, a variety of assessment scales are used. These include the Rivermead Mobility Index, the Motor Assessment Scale, the Nine Hole Peg Test, and the Barthel index.

The Rivermead Mobility Index, a clinically relevant measure of disability, concentrates on body mobility. It consists of a series of 14 questions and one direct observation and covers a range of activities from turning over in bed to running. A modified version with a reduced number of test items has been developed specifically for use in stroke.

Box 227.12 Stroke multidisciplinary team members**Doctors**

- provide medical care as appropriate for each patient
- need a good working knowledge of patients' diagnosis, prognosis, complications, and comorbidities
- it is often assumed that they are responsible for leading the multidisciplinary team but, in reality, this role should rotate

Nurses

- have a central role in stroke care, assisting with the daily care needs of patients
- help to prevent complications
- help to provide support for patients and their families

Physiotherapists

- largely responsible for the recovery of movement
- advise on positioning and handling issues
- provide mobility aids
- help prevent complications (particularly respiratory)

Occupational therapists

- dedicated to the recovery of functional tasks
- help patients gain independence with activities of daily living
- assess visuospatial function
- provide aids and appliances
- assess patients' abilities within the home

Speech and language therapists

- aid the recovery of function and speech
- provide detailed assessment of patients' swallow

Social workers

- help access and coordinate services and facilities within the community when patients are ready to leave hospital

Clinical psychologists

- help in the management of psychological and behavioural complications of stroke

Dietitians

- help to manage nutritional problems, dietary modification, and artificial feeding

Box 227.13

- dense weakn
- cardiac com
- urinary incor
- pupillary abn
- poor sitting b

The Motor Assessment Scale is a brief assessment of eight areas of motor function, and one area related to muscle tone. It is aimed at the functional capabilities of stroke patients.

The Nine Hole Peg Test is aimed at measuring manual dexterity and comprises a square board with nine pegs. The patient is instructed to take pegs from a container and place them into the holes on the board as quickly as possible.

The Barthel index is one of the numerous scales used to assess functional ability in activities of daily living. The activities assessed include feeding, bathing, grooming, toilet use, transfers, and mobility. While all these generic scales can be useful in helping to standardize rehabilitation, it is paramount that rehabilitation is ultimately tailored to each individual patient.

Rehabilitation is not passively 'done' to a patient, and there is no generic process that a patient goes through. Goals should be highly specific to each patient. Patients and their families should be fully informed about what the rehabilitation process entails and, while the multidisciplinary team should be optimistic and positive about rehabilitation, they should also be realistic, as false hope can be potentially devastating. The predictors for poor outcomes with

stroke rehabilitation include poor postural control and sitting balance, advanced age, persistent bowel and bladder incontinence, prolonged hyporeflexia, prior stroke, visuospatial deficits, pre-stroke dependency, and initially decreased conscious level. Other barriers to rehabilitation include intercurrent medical illness, depression, and cultural reluctance to accept disability.

While the majority of stroke rehabilitation is provided in organized inpatient units, there is growing evidence that early supported discharge schemes are not only equally as effective but may actually improve physical function and decrease the economic burden of stroke care. In early supported discharge schemes, a qualified multidisciplinary team of healthcare professionals provides specialist stroke rehabilitation in the patients' home, with care initiated as soon as the patient is medically stable enough to leave hospital. This has several benefits. First, stroke patients undergoing rehabilitation at home have been shown to take the initiative more and express their desired goals more frequently than those undergoing hospital rehabilitation do. Second, therapists are able to observe the patient in a wider variety of roles and, consequently, identification of problem areas becomes more readily apparent both to the patient and

228 Dementia

Richard Armstrong

Definition of the disease

Dementia is a syndrome defined by a persistent, progressive decline in multiple cognitive functions to a degree sufficient to detrimentally impact activities of daily living and social function. The syndromic diagnosis of dementia remains useful, since the general management and economic burden of these patients remains similar, irrespective of aetiology. However, a more precise etiological diagnosis must be sought, since disease-specific treatment is increasingly likely to be appropriate.

The term 'mild cognitive impairment' (MCI) refers to objective impairment in a cognitive function (usually memory) which does not impair activities of daily living. The aim underlying the use of this term is to identify those with the early pathophysiological changes of neurodegenerative disease. Nonetheless, 'MCI' is not synonymous with 'early dementia', as a significant proportion of those with MCI will not worsen. The term should therefore be used cautiously.

Aetiology of the disease

Dementia results from progressive dysfunction of the cerebral cortex or its connections and may emerge from diverse disease processes. Most commonly implicated are the neurodegenerative diseases of ageing, but the relative importance of other causes is greater in the younger population (see Figure 228.1).

Molecular aetiology

Many neurodegenerative diseases share characteristic molecular pathological signatures. Insoluble, misfolded, aggregated proteins are found and they are of probable etiopathogenic importance. Multiple cellular processes may be affected but, ultimately, neuronal dysfunction and death ensues. Aggregates can be extracellular or intracellular, and the predominant protein component varies, although there is a considerable degree of overlap.

Genetic factors

Genotype is critical in determining the risk of developing a dementia. Classical genetic approaches in rare families with Mendelian inheritance of dementia have found that certain mutations confer very high risk, for example mutations in APP, PS-1, and PS-2 in Alzheimer's disease. These account for few (<5%) cases overall, but are instructive in disease neurobiology. Similar monogenic forms of other dementias exist.

Having two or more first-degree relatives with Alzheimer's disease confers around an 8× increased risk of developing the disease, attesting to the role of genetic factors in apparently sporadic cases. Modern genetic approaches, such as population-based genome-wide association studies, have identified frequently occurring low-risk polymorphisms that account for around 60% of the population-attributable risk of developing Alzheimer's disease. Similar studies are underway for other diseases. Soon, genetic tests will be available that give an individualized risk for developing a dementia.

Figure 228.1 The causes of dementia. Common cause of dementia in (A) those under 65 and (B) those over 65. Causes are listed in (C); this is not an exhaustive list of causes of global cognitive decline, but includes causes which are encountered on clinical practice; AD, Alzheimer's disease; DLB, dementia with Lewy bodies; FTLT, frontal temporal lobe dementia; HD, Huntington's disease; NMDA-R, NMDA receptor; PD, Parkinson's disease dementia; PML, progressive multifocal leukoencephalopathy; VaD, vascular dementia; VGKC, voltage-gated potassium channel.

Environmental factors

Not all of the risk of dementia is currently explained by genetic factors. Other factors associated with an increased risk of developing dementia include diabetes, smoking, hypertension, hypercholesterolaemia, depression, and low social support. Conversely, high fruit and vegetable consumption, use of statins, low alcohol consumption, educational attainment, and physical activity have all been suggested to be protective. Overall, however, the quality of the scientific evidence is low for these factors, and interventional studies are lacking.

Typical symptoms of the disease, and less common symptoms

The end stage of most dementias is characterized by profound global impairment in all cognitive domains; behavioural disturbance; and functional dependence. The earliest symptoms and signs, however, reflect dysfunction in specific brain regions. These patterns are often characteristic and suggest the underlying cause of the dementia.

Memory

Memory is broadly represented in the brain, although deficits in the medial temporal lobes produce the well-recognized deficits in episodic memory in Alzheimer's disease. Episodic memory is the memory for autobiographical information (e.g. times, places, experiences, and contextual knowledge). Symptoms will include forgetting names, places, and facts about events that have occurred. Characteristically, there is a temporal gradient, with more recently experienced information being most vulnerable. Patients may therefore refer to such problems as 'poor short-term memory'. Such difficulties may lead to patients becoming repetitive. Difficulties in route finding reflect difficulties with topographical memory, a form of episodic memory. There is often difficulty in learning new tasks.

Semantic memory refers to concept-based knowledge ('general knowledge') unrelayed on specific experiences, for example the knowledge that an elephant is an animal, not a plant. It is distinctively impaired in a form of frontotemporal dementia (FTD) termed semantic dementia. Patients will complain of 'word-finding difficulties', since they fail to link concepts of items to words.

Speech and language

Speech and language are subserved by distributed networks mainly located in the dominant frontal and temporal lobes. Language problems are a common symptom in many dementias. Difficulties in naming objects, comprehension of spoken or written language, misuse of grammar, word retrieval pauses, and circumlocutions are seen. Where speech dysfunction is early, isolated, or prominent, the syndrome is characterized as a primary progressive aphasia, in which case the underlying disease is usually FTD but occasionally is Alzheimer's disease.

Praxis and visuospatial function

Praxis and visuospatial function are prominently affected in conditions which have a posterior predominance and affect the parietal and occipital lobe. Posterior cortical atrophy refers to an early, isolated, or predominant posterior syndrome. Such posterior functions are commonly involved in Alzheimer's disease and Lewy body dementia (LBD) but spared in FTD and vascular dementia (VaD). Dyspraxia refers to the inability to execute complex motor programmes, for example being unable to work out how to dress or unlock a door. On examination, there are deficits in copying intersecting pentagons, mimicking meaningless hand gestures, and pantomiming actions. When visuospatial function is affected, patients may fail to recognize objects or even people, and there may be difficulty distinguishing objects such as coins, banknotes, or keys. On examination, there are difficulties in recognizing abstract representations such as fragmented letters/pictures. Calculation ability is susceptible to impairments in dominant parietal function, and these are often associated.

Executive function

Executive function refers to the ability to coordinate and sequence multiple cognitive functions and adapt them to the behavioural

context. It is particularly susceptible to disease processes which affect the frontal lobe or its subcortical connections and thus deficits are prominently seen in behavioural variant FTD, Parkinson's disease, Huntington's disease, and VaD. There may be a slowing of thought and difficulty with tasks that require planning or flexibility. Examination tests which involve following simple rules or planning strategies are impaired.

Behavioural and psychiatric problems

Behavioural and psychiatric problems are common in advanced disease, irrespective of aetiology. Aggression, restlessness, and wandering can be troublesome. Psychotic features are seen.

In addition, symptoms often considered 'psychiatric' can be prominent early in certain circumstances. Hallucinations are a characteristic early feature of LBD and take a characteristic form of well-formed, silent, and usually non-threatening visual hallucinations. Visual misperceptions are also common.

When the pathological burden of disease falls mainly on frontal lobe circuits (e.g. in FTD, subcortical dementias, and VaD), behavioural disturbance may be an early problem: personality changes, emotional lability, apathy, and a loss of empathy are characteristic. Patients may lose the ability to modulate their behaviour appropriately in the social context ('disinhibition'). Depression also frequently complicates dementia.

Demographics of the disease

Dementia becomes more common with age. In the developed world, the prevalence below age 65 is around 1%, but increases exponentially to over 25% in those over 85, and data suggest little ethnic and geographical variation.

Natural history, and complications of the disease

There has been considerable emphasis on characterizing the natural history of MCI, giving hope that early disease-modifying therapy may soon be available. The risk of developing dementia in those with MCI is increased, but 20%–40% will never develop the full syndrome. Those with MCI have, on average, a 10%–15% annual risk of developing dementia, compared with a 1%–2% risk in the non-MCI population. Better objective markers of early disease and disease progression are therefore required. These 'biomarkers' will be of use in tracking the response to therapeutic interventions.

Practically, from clinical diagnosis, the decline in cognitive function is progressive and the tempo varies by aetiology. There is an average interval of 7 years between diagnosis and death in typical Alzheimer's disease, with the last couple of years characterized by dependency. LBD and VaD tend to progress faster, and FTD more slowly. A very rapidly progressive syndrome, over months, is not seen in the common neurodegenerative dementias and should lead one to consider non-degenerative (e.g. inflammatory) conditions or prion disease.

Late-stage disease is characterized by complications associated with frailty. Falls, fractures, malnutrition, and respiratory infections are common and usually contribute to death.

Approach to diagnosing the disease

The diagnosis of dementia and its cause currently remains largely clinical and criterion based and is made from the history obtained from the patient and an informant; this history should focus on symptoms from all domains specified in 'Natural history, and complications of the disease', together with an objective cognitive assessment. Further investigations (see 'Gold-standard' diagnostic test, alternatives, and other relevant investigations) provide support for underlying aetiology and serve to rule out reversible conditions that can produce a syndrome of global cognitive impairment.

Other diagnoses that should be considered

Cognitive impairment may result from non-neurodegenerative conditions which may be reversible. These conditions should be actively

sought and excluded. Depression can result in complaints of subjective memory impairment and result in a 'pseudodementia'; cognitive testing may reveal inconsistencies but, occasionally, it can be very difficult to distinguish pseudodementia from early cognitive impairment and so longitudinal assessment will be required. Mass lesions rarely result in progressive global cognitive impairment in the absence of other neurological features, but tumours and subdural haematomas should be considered. Infective (e.g. HIV, syphilis), metabolic (e.g. hypothyroidism, B₁₂ deficiency), and inflammatory (e.g. immune-mediated encephalitis, multiple sclerosis) conditions can all result in cognitive impairment but other symptoms usually suggest these diagnoses.

'Gold-standard' diagnostic test, alternatives, and other relevant investigations

As mentioned in 'Approach to diagnosing the disease', the diagnosis of dementia and its cause is criterion based, with most weight based on aspects of clinical history and objective cognitive assessment. Adjunctive investigations may allow more certainty, but currently established criteria allow a 'definite' (or gold-standard) disease-specific diagnosis only after pathological examination. Therefore, the choice of investigations must be tailored to the clinical scenario. All of the following investigations may be indicated in certain circumstances:

- objective cognitive assessment
- structural brain imaging
- nuclear/functional imaging
- CSF examination
- EEG
- blood work

Objective cognitive assessment

Objective cognitive assessment may take the form of 'bedside' cognitive tests or may involve detailed neuropsychological testing. Numerous validated cognitive tests are available for use in a clinic. The aim is to examine cognitive function across a number of domains. A given score can diagnose cognitive impairment with a given sensitivity and specificity. The Mini-Mental State Examination (MMSE) is widely used, with scores of $\leq 25/30$ indicating impairment. Cognitive domains other than memory receive rather limited testing, however, and MMSE is less sensitive for the diagnosis of diseases other than Alzheimer's disease. The Montreal Cognitive Assessment is broader in scope and takes a similar amount of time to administer. It provides assessment of a number of domains, and is freely available for clinical use. The revised Addenbrooke's Cognitive Examination takes longer to administer but provides a fuller assessment. Multiple other assessments are available. Additional neuropsychological tests may be selected depending on dominant problems suggested in history taking.

Structural brain imaging

Structural brain imaging is mandatory in all cases. MRI is the most informative. While important to exclude alternative pathology, regional patterns of atrophy can suggest the underlying disease. The vascular burden can be estimated and diseases such as Creutzfeldt-Jakob disease have characteristic signal abnormalities. Serial volumetric imaging may be of use as a biomarker.

Nuclear/functional imaging

Nuclear/functional imaging may be used in specialist practice to reveal regional hypometabolism in the parietal and medial temporal lobes in Alzheimer's disease, and in the frontotemporal regions in FTD. Dopamine transporter imaging can reveal deficits in dopamine metabolism, suggesting LBD. It is likely that, in the near future, direct imaging of pathological proteins (e.g. amyloid beta 42) will become widely available.

CSF examination

CSF examination can be useful in restricted circumstances. Standard tests (e.g. cell count, protein, glucose) are normal in the common neurodegenerative dementias, and any abnormalities should suggest

an alternative diagnosis. The 14-3-3 protein and S100 tests are sensitive for CJD but are non-specific, as these markers are raised in other circumstances where rapid cell death occurs, such as stroke. Specific assays are now available for amyloid beta 42 and tau in CSF. Amyloid beta 42 is reduced and tau is increased in Alzheimer's disease, and a significantly increased ratio of amyloid beta 42 to tau is specific for Alzheimer's disease pathology. Guidelines recommend these assays in young-onset cases.

EEG

EEG has restricted use but CJD gives a characteristic pattern of biphasic or triphasic spike discharges, although these can also be seen in metabolic encephalopathies. The common neurodegenerative dementias often show generalized slowing with a loss of alpha rhythm.

Blood work

Blood work has a role in excluding metabolic comorbidities which can, rarely, contribute to cognitive difficulty. A full blood count and renal, liver, calcium, and thyroid tests should be routinely performed. There may occasionally be cause to check HIV, syphilis serology, and vitamin B₁₂ levels, but the yield from testing unselected patients is low.

Prognosis, and how to estimate it

A clearer understanding of the natural history of the individual diseases and the validation of biomarkers (see 'Natural history, and complications of the disease') will allow more accurate prognostication. Comorbidities such as diabetes mellitus and vascular disease worsen survival. In addition, for most acute medical conditions, the survival of those with advanced dementia is diminished with respect to unaffected individuals.

Treatment and its effectiveness

No proven treatments retard neurodegeneration or significantly alter the natural history of the neurodegenerative dementias, and all current treatments are considered symptomatic. Nonetheless, active management of symptoms can significantly improve quality of life and temporarily ameliorate cognitive function to some degree.

General and non-pharmacological measures

A multidisciplinary approach to care is requisite. The benefit of community specialist nurses, therapists, support groups, and social care workers to patients and their carers should not be underestimated. Caregiver stress must not be overlooked. There is some data to support a specific benefit of cognitive rehabilitation techniques and in improving cognitive function but standardized approaches need to be tested and validated.

Symptomatic treatment

Cognitive enhancers

A deficit in cholinergic neurotransmission is seen in Alzheimer's disease, and cholinesterase inhibitors (e.g. donepezil, rivastigmine, galantamine) are of clear (but temporary and modest) benefit on measures of cognitive function and activities of daily living. Adverse effects are relatively common and are largely gastrointestinal, but serious adverse events like heart block and seizures are well recognized. Meta-analyses suggest improvement on activities of daily living scales in mild-moderate dementia (an MMSE score of 10–26). This practically equates to preventing 2 months per year decline in typical Alzheimer's disease patients. It is doubtful whether there is any effect on long-term outcomes such as entry into institutionalized care. The benefit in advanced dementia (an MMSE score <10) is questionable, and standard practice is to withdraw treatment at this stage. A few patients will decline significantly when this is done. Practically, guidelines support consideration of individualized trials of these drugs in mild-moderate Alzheimer's disease, with objective regular assessment of benefit. In LBD and Parkinson's disease dementia, cholinesterase inhibitors are helpful in the treatment of hallucinations, and there is evidence for some benefit in VaD. They are of no proven benefit in any other

condition. NMDA antagonists (e.g. memantine) may be of some modest benefit in moderate–advanced Alzheimer's disease, and some data suggest an additive benefit to cholinesterase inhibitors. Individualized trials may be considered in specialist practice.

Behavioural and psychiatric symptoms

If behavioural disturbance or psychotic features continue to present significant clinical risk despite sustained attempts at non-pharmacological solutions, then drug treatment should be carefully considered. There is evidence for a modest benefit of newer atypical antipsychotic drugs, but their use has recently been discouraged, since they are associated with a small increase in all-cause mortality when used in advanced dementia. Despite this, they retain some role after careful consideration and discussion of relative risks. Antipsychotic drugs can produce very significant worsening in patients with LBD and must be avoided. Benzodiazepines can provoke delirium or a worsening of cognitive function but are occasionally helpful to manage agitation. Comorbid depression should be treated with serotonin-specific reuptake inhibitors.

Disease-modifying treatment

A vast number of compounds proposed to modify pathways of neurodegeneration have been unsuccessfully trialled. Nonetheless, considerable optimism exists that more specific agents currently being developed and trialled will produce a more positive outcome.

229 Neurological infection

Tom Solomon and Benedict Michael

Definition of the disease

Neurological infections, affecting the central nervous system (CNS), can be broadly subdivided into chronic/subacute and acute. Chronic/subacute infection usually presents with global cognitive decline, with the prototypical disease being progressive multifocal leucoencephalopathy due to infection with the JC virus in immunocompromised patients. Acute neurological infections can be defined microbiologically, by the nature of the pathogen, clinically, by the presenting signs and symptoms and initial CSF findings, or anatomically. The anatomical definitions are those occurring intracranially ('meningitis', where infection involves the meninges overlying the brain; 'encephalitis', where the brain parenchyma is involved; or 'cerebral abscesses') and those affecting the spinal cord ('myelitis'). However, there is often both clinical and histological overlap between these syndromes; consequently, the terms 'meningoencephalitis' and 'encephalomyelitis' are often used.

Patients with acute intracranial CNS infections provide the greatest challenge to general physicians, because urgent investigation and appropriate treatment can save lives; they therefore form the focus of this chapter.

Aetiology of the disease

Acute CNS infections can be caused by a wide range of pathogens in the immunocompetent, and an even wider variety in the immunocompromised. There is significant global variation in the incidence of causal pathogens, reflecting endemic rates of HIV infection, TB infection, and malnutrition; viral vector prevalence; and vaccination programmes. Despite current diagnostic techniques, the causal pathogen is often not identified; for example, the causal pathogen in approximately 40% cases of encephalitis is not identified. A staged approach to the identification of the causal pathogen is outlined in Table 229.1.

Meningeal infection is subdivided into aseptic and purulent meningitis on the basis of the clinical presenting features and initial CSF findings (Table 229.2). Aseptic meningitis is typically caused by viruses, with enteroviruses, accounting for >90% of cases. Although accounting for fewer cases of aseptic meningitis, herpes simplex virus (HSV) 2 (HSV-2) is of particular importance as it can result in a recurrent meningitis (previously termed 'Mollaret's') and should direct investigation towards genital infection. Purulent meningitis is usually due to bacterial infection, with *Streptococcus pneumoniae* and *Neisseria meningitidis* making up >90% of cases in adults in the developed world. Since the introduction of the *Haemophilus influenzae* and the measles, mumps, and rubella (MMR) vaccines, there has been a dramatic decline in the incidence of these pathogens, although they remain important in resource-poor countries. In addition, the recent decline in vaccination uptake in some developed countries has been accompanied by a rise in the incidence of these infections.

The most common infectious cause of encephalitis is viral, most commonly due to HSV-1 and varicella zoster virus (VZV) (approximately 19% and 5% of viral cases, respectively). A recent cohort study in the UK identified that HSV was the most common cause of acute CNS infections overall. However, in approximately 11% of cases, encephalitis follows infection or vaccination, causing an 'acute disseminated encephalomyelitis (ADEM)'. Additionally, antibody-mediated forms of encephalitis have been identified which often respond to immunomodulatory therapy; these are most commonly caused by the presence of anti-NMDA antibodies (accounting for 4% of cases) or antibodies against the voltage-gated potassium channel complex (accounting for 3% of cases).
