The incidence of meningoencephalitis due to TB infection appears to be rising in the UK. It most often occurs in those exposed to the infection in Africa or India, or in the context of coexistent HIV infection. The clinical presentation is usually more subacute than for other CNS infections, and a longer prodrome of weight loss, malaise, and night sweats is typical. The CSF findings can be highly suggestive (Table 229.2), but the glucose is not *always* low, and the organism itself may be difficult to isolate.

Typical symptoms of the disease, and less common symptoms

Typical presenting symptoms include fever or an antecedent febrile illness, meningism (neck stiffness, nausea, and vomiting), headache, reduced or altered consciousness, seizures, and focal neurological signs. In encephalitis, there may be a reduced level of consciousness. However, the alteration in consciousness is often a more subtle neuropsychiatric presentation of altered behaviour and cognition. Therefore, a collateral history is crucial. Evidence of focal neurological motor or sensory disturbance, including dysphasia or seizures, suggests brain parenchymal inflammation such as encephalitis, cerebral abscesses, or antibody-mediated encephalitides.

Effort should be undertaken to look for symptoms or signs which may suggest a particular pathogen. These include:

- a non-blanching purpuric rash in meningococcal septicaemia
- dermatomal vesicular rash in varicella zoster infection
- stigmata of HIV infection (e.g. oral hairy leukoplakia and Kaposi's sarcoma)
- orchitis or pancreatitis in mumps virus infection
- lower cranial neuropathies and myoclonus suggesting a rhombencephalitis often due to listeria or some enteroviruses
- a longer prodrome including weight loss and night sweats; this suggests TB, and there may be multiple cranial nerve palsies and pyramidal signs in the meningitic phase
- movement disorders and extrapyramidal features, as seen in flavivirus infection such as West Nile or Japanese encephalitis virus infection

However, no clinical symptoms and signs, or combinations thereof, have been identified which can accurately diagnose or exclude CNS infection or accurately determine the aetiology. For example, the classical triad in meningitis of fever, meningism, and altered mental status is only present in 44% of cases. Even a rash which looks 'meningococcal' can be caused by other bacteria. Additionally, fever may be absent at presentation in up to 24% of patients with proven HSV encephalitis. Therefore, when the diagnosis of CNS infection is suggested by the presence of some, if not all, of the associated clinical features, further investigation is vital.

Demographics of the disease

The annual incidence is approximately 2.9–10.0 in 100 000 for viral encephalitis, 0.6–4.0 in 100 000 for purulent meningitis, and 5.2–7.6 in 100 000 for aseptic meningitis, although these are thought to be underestimates.

Acute CNS infections can occur at any age, but the young and the elderly are particularly at risk. While CNS infections often occur in the immunocompetent, individuals with immune compromise, such as patients with HIV infection or iatrogenic immune suppression, are at increased risk. Additionally, people with any chronic disease are

Table 229.1 A staged approach to pathogen identification in patients with suspected CNS infection

Diagnostic suspicion	Investigation	Indication	Items to test for
Suspected encephalitis	CSF PCR	All patients	HSV-1 HSV-2 VZV Enterovirus Parechovirus
		Immunocompromised patients	EBV CMV HHV6 HHV7 Adenovirus Influenza A Influenza B Parvovirus B19
		If clinically indicated	Measles Mumps Chlamydia
		If indicated by the travel history	Rabies West Nile virus and other flaviviruses Tick-borne encephalitis
	CSF and serum IgM and IgG antibody testing in acute and convalescent samples	If CSF PCR is negative	HSV-1 HSV-2 VZV CMV HHV6 HHV7 Enterovirus Parvovirus Adenovirus Influenza A and B
		If the patient is immune-suppressed	Cryptococcus Toxoplasma
	Serum antibody and antigen	Advised in all patients	HIV
	Serum antibody for autoimmunity	If psychiatric symptoms, seizures, movement disorder, subacute presentation, or known/suspected malignancy is present	Voltage-gated potassium channel complex antibodies Anti-NMDA receptor antibodies Further intra- or extra-cellular antibodies guided by clinical phenotype
		If associated with an atypical pneumonia	Mycoplasma serology Cold agglutinins Chlamydia serology
	Ancillary investigations: PCR and/or culture (these establish systemic infection, but not necessarily the cause of the CNS disease)	Respiratory tract symptoms: throat swab, nasopharyngeal aspirate Gastrointestinal symptoms: rectal swab Vesicular rash: vesicle swab	Enterovirus Mycoplasma Chlamydia Influenza Adenovirus HSV VZV
Brain biopsy	Above investigations are negative and patient is deteriorating despite empirical treatment	Microscopy and immunohistochemistry Bacterial culture Extended fungal and mycobacterial culture Viral PCR (as above)	
	Above investigations are negative and patient is deteriorating despite empirical treatment and is immune-suppressed	India ink stain for cryptococcus Ziehl–Neelsen stain for TB	
Suspected meningitis	CSF culture	All patients	Microscopy, culture, and sensitivity for all pathogens
		Immune-suppressed patients	Extended culture for mycoplasma and fungi
	CSF PCR	If suspected viral meningitis	As for encephalitis
		If suspected bacterial meningitis and culture is negative	<i>Neisseria meningitidis</i> <i>Streptococcus pneumoniae</i> Listeria
CSF cytological examination	Known or suspected systemic or CNS malignancy	Malignant cells Sample also for flow cytometry if haematological malignancy known/suspected	

Abbreviations: CNS, central nervous system; CSF, cerebrospinal fluid; EBV, Epstein–Barr virus; HHV6, human herpes virus 6; HHV7, human herpes virus 7; HIV: human immunodeficiency virus; HSV, herpes simplex virus; PCR, polymerase chain reaction; TB, tuberculosis; VZV, varicella zoster virus.

Table 229.2 Cerebrospinal fluid analysis interpretation in patients with suspected CNS infection

Investigation	Normal	Purulent Meningitis	Aseptic Meningitis or Encephalitis	Tuberculous Meningitis	Fungal
Opening Pressure	10–20 cm*	High	Normal/High	High	High/Very High
Colour	Clear	Cloudy	'Gin' Clear	Cloudy/Yellow	Clear/Cloudy
Cells/mm ³	<5**	High/Very High 100–50 000	Slightly Increased 5–1000	Slightly Increased 25–500	Normal–High 0–1000
Differential	Lymphocytes	Neutrophils	Lymphocytes	Lymphocytes	Lymphocytes
CSF/Plasma Glucose	66%***	Normal	Low	Low–Very Low (<30%)	Normal–Low
Protein (g/L)	<0.45	High >1	Normal–High 0.5–1	High–Very High 1.0–5.0	Normal–High 0.2–5.0

Abbreviations: CNS, central nervous system; CSF, cerebrospinal fluid; LP, lumbar puncture.

*Normal CSF opening pressure approximately <20 cm in adults and <10 cm in children under 8 years, but may be 'normal' at up to 25 cm.

**A bloody tap will falsely elevate both the CSF white-cell count and protein. To correct for a bloody tap; subtract 1 white cell/mm³ for every 700 red blood cells/mm³ and 0.1 g/dl of protein for every 1000 red blood cells/mm³.

***'Normal' CSF glucose ratio is typically quoted as 66%, although, in practice, only values below 50% are likely to be significant. Absolute CSF glucose levels can be misleading—a paired plasma glucose level is always required.

Some important exceptions

- In viral CNS infections, an early LP may show predominantly neutrophils, or there may be no cells in early or late LPs.
- If acute bacterial meningitis is partially treated with antibiotics (or patient <1 year old) the CSF cell count may not be very high and may be mostly lymphocytic.
- Tuberculous CSF may have predominant polymorphs early on.
- Listeria can give a similar CSF picture to tuberculous meningitis, although the history is shorter.
- CSF findings in cases of a bacterial abscess range from near normal to purulent depending on location and whether there is associated meningitis or rupture.
- A cryptococcal antigen test and India ink stain should be performed on all CSF samples of patients in whom cryptococcus is possible.

Solomon, Management of suspected viral encephalitis in children – Association of British Neurologists and British Paediatric Allergy, Immunology and Infection Group National Guidelines, pp. 449–477, Copyright (2012), with permission from Elsevier.

at increased risk, particularly if they have diabetes mellitus, chronic kidney disease, or a history of alcohol excess.

In the UK, bacterial infection is more common in the winter, respiratory viruses are more common in the winter and spring, and enteroviral infection is more common in the summer.

Natural history, and complications of the disease

Acute CNS infections have a mortality rate of 10%–28% in encephalitis and 3%–37% in bacterial meningitis, despite treatment. The national cost for patients hospitalized with encephalitis in the USA is estimated to be \$630 million. Neurological and neuropsychiatric sequelae are common, particularly following encephalitis; they include seizures, focal neurological weakness, and cognitive and behavioural problems. Deafness is a common complication following bacterial meningitis.

If a patient with an acute CNS infection deteriorates despite treatment, look for complications, including:

- cerebral infarction
- cerebral oedema, brain shift, and herniation
- seizures, especially subtle motor status epilepticus
- venous sinus thrombosis
- subdural empyemas
- systemic shock
- aspiration pneumonia
- hyponatraemia or if delayed consider infection relapse or post-infectious autoimmunity

Hydrocephalus, vasculitis, tuberculomas, and radiculomyelopathy may additionally complicate TB infection.

Approach to diagnosing the disease

An approach to diagnosis is outlined in Figure 229.1.

All patients should undergo a lumbar puncture (LP), providing there are no clinical contraindications (Table 229.3). This can quickly confirm or refute the diagnosis and direct treatment towards a viral, bacterial, or mycobacterial pathogen. Additionally, the CSF culture can identify the pathogen and determine antibiotic sensitivities, which is of particular importance given the concerns of growing antibiotic resistance. Additionally, PCR allows for the rapid amplification of viral

nucleic acid and should also be requested in bacterial meningitis if the CSF culture is negative.

However, if clinical contraindications to an immediate LP are present urgent neuroimaging should be undertaken. While MRI is more sensitive for the identification of parenchymal lesions, CT is often more easily available urgently. As it is sufficient to identify significant brain shift precluding a LP, it is often the most pragmatic approach.

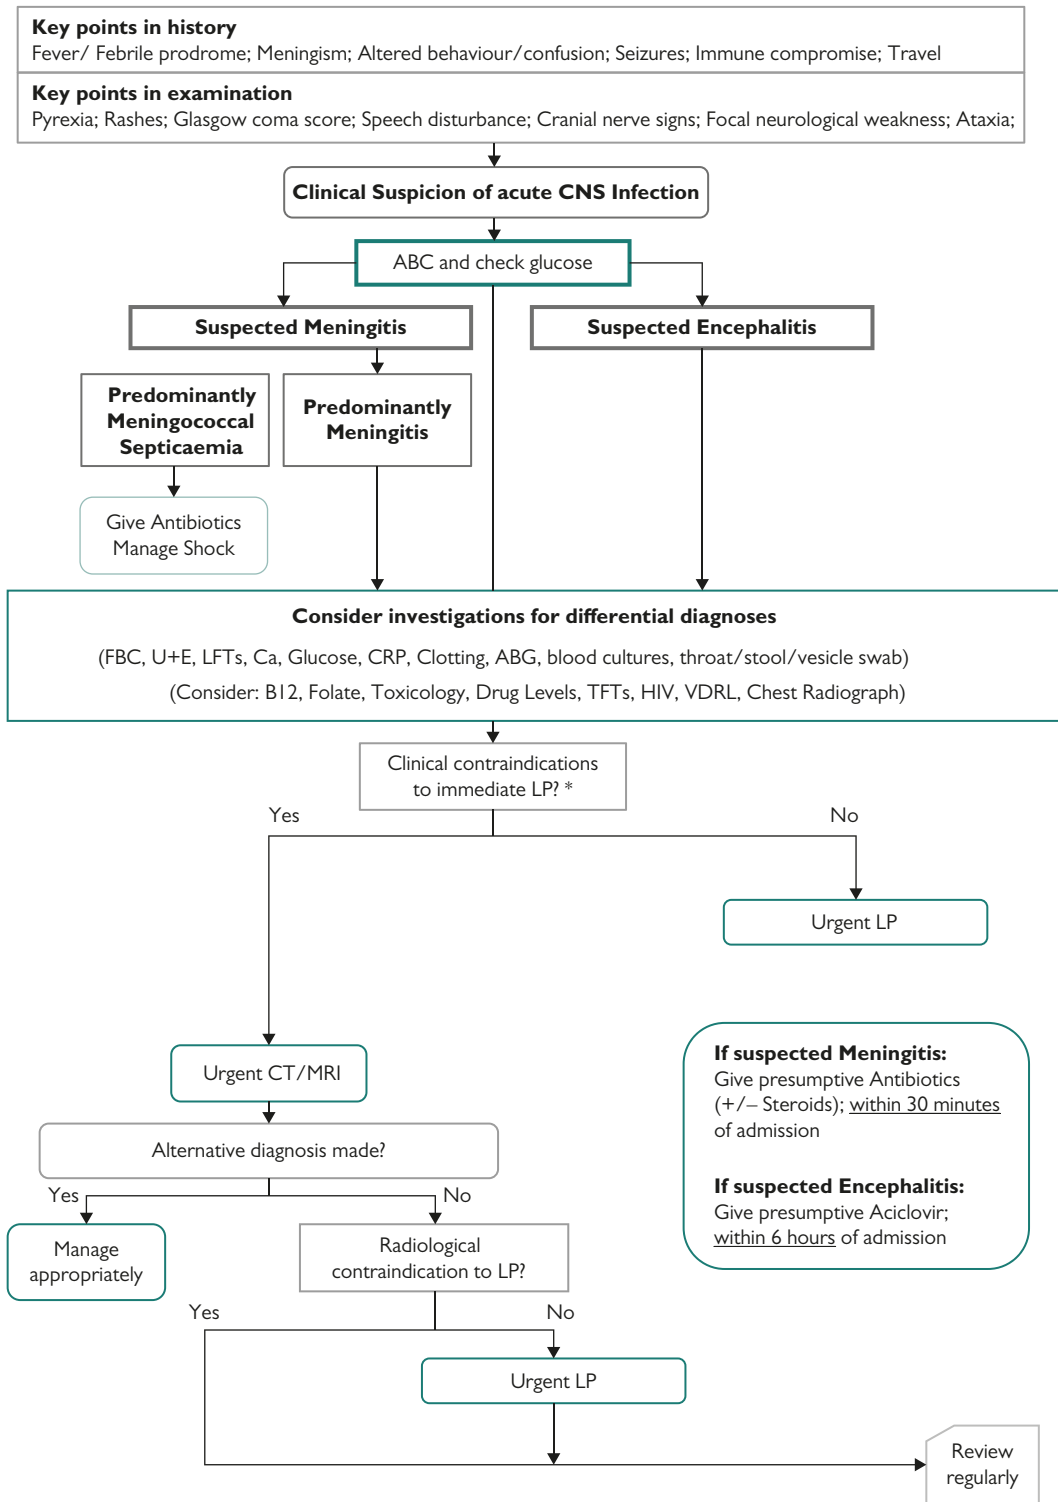

The initial CSF findings may be normal, for example in approximately 11% of patients who ultimately have proven HSV encephalitis. If clinical suspicion of CNS infection remains, the patient should be started on the appropriate antimicrobial regimen and the LP repeated 24–48 hours later.

The investigation and management of meningoencephalitis due to *Mycobacterium tuberculosis* infection is well described in the National Institute for Health and Clinical Excellence guideline and is beyond the scope of this chapter.

Other diagnoses that should be considered

Other causes of encephalopathy (altered consciousness) should be considered, including systemic sepsis, metabolic derangement, or toxemia. However, be cautious of ascribing a previously healthy patient's altered mental state to an extra-CNS infection, such as a urinary infection, unless there is strong evidence for it. Additionally, hyponatraemia may often occur in CNS infection due to the syndrome of inappropriate antidiuretic hormone secretion and, when identified, may be a result of CNS infection rather than the cause of encephalopathy.

Two important diagnoses not to miss are venous sinus thrombosis and subtle convulsive status epilepticus. Venous sinus thrombosis should be considered, as it typically presents with headache, altered consciousness, and seizures, often in the context of a febrile illness such as sinusitis/otitis as the precipitant of the thrombosis. The diagnosis is confirmed by imaging of the venous system of the CNS. Subtle convulsive status epilepticus should be suspected in those with fluctuating levels of consciousness, particularly if there is evidence of subtle motor signs or a history suggestive of previous seizures. In this instance an EEG can be invaluable.

Table 229.3 Clinical contraindications to an immediate lumbar puncture in patients with suspected CNS infections*

Contraindication	Notes
Seizure(s)	New or persistent
Focal neurological signs	Hemiparesis Monoparesis Extensor plantar response Ocular palsies
Reduced level of consciousness	Glasgow Coma Scale score of <13 or a deterioration of >2
Signs of brain shift	Cushing's reflex Papilloedema Abnormal respiratory pattern Decorticate/decerebrate posturing Altered pupillary response Absent doll's eye reflex
Local superficial infection	At potential lumbar puncture site
Coagulation disorder	Including iatrogenic anticoagulation or platelets <40 × 10 ⁹ /l
Known immune compromise	
Strong suspicion of meningococcal septicaemia	In a patient with sepsis, meningism, and a typical purpuric rash, a lumbar puncture is not needed, as the diagnosis may be made from blood cultures

* Clinical contraindications to lumbar puncture without neuroimaging.

'Gold-standard' diagnostic test

Traditionally, the gold-standard diagnostic investigation in encephalitis is histopathological examination of brain biopsy tissue demonstrating brain parenchymal inflammation with evidence of direct infection by a causal pathogen. However, due to the risks associated with brain biopsy and newer molecular diagnostic techniques, it is performed less often. Therefore, microbiological investigations identify the cause. In bacterial meningitis CSF culture and/or CSF PCR are used. As CSF viral culture has a lower sensitivity, PCR analysis of the CSF are used is the gold standard and has a high sensitivity (>95%) and specificity (>99%). Identification of viral nucleic acid in the CSF is diagnostic of active infection in the case of HSV-1, HSV-2, VZV, enterovirus, and parechovirus. However, ubiquitous lymphotropic viruses such as EBV and human herpes viruses 6 and 7 may be identified due to latent infection or, in the case of human herpes virus 6, inherited viral DNA inclusions. Viral load determined by quantitative PCR may be useful.

Further investigation should be guided by the clinical, CSF, and neuroimaging features and by close collaboration between the attending clinicians, virologists, and infectious disease specialists.

Acceptable diagnostic alternatives to the gold standard

In the presence of the clinical features described in 'Approach to diagnosing the disease', identification of CNS inflammation on CSF findings and/or neuroimaging, if the features are classical, may be sufficient to establish the diagnosis of a CNS infection.

Other relevant investigations

All adults and teenage children with a CNS infection should have an HIV test. HIV seroconversion is a common cause of aseptic meningitis; alternatively, a CNS infection may be a clue that a patient is HIV positive.

Box 229.1 Risk factors for a poor prognosis

- age >60 years
- seizures
- immunocompromised patients
- abnormal brain imaging
- delays in treatment (e.g. due to inappropriate neuroimaging):
 - >6 hours from admission to starting treatment with antibiotics (in bacterial meningitis)
 - >1-2 day from admission to starting treatment with aciclovir (in viral encephalitis)

Young people and children should be tested for complement deficiency if they have any one of the following:

- more than one episode of meningococcal disease
- one episode of meningococcal disease caused by a serogroup other than B
- one episode of meningococcal disease, and a history of other recurrent bacterial infections

Patients with recurrent bacterial meningitis should undergo CT of the head, to look for dural defects, and an ear, nose, and throat specialist review. Patients with recurrent aseptic meningitis should be screened for systemic disease such as systemic lupus erythematosus.

Encephalitis, meningitis, and meningococcal septicaemia are notifiable conditions.

Prognosis and how to estimate it

There are no validated prognostic tools for clinical use for cases of CNS infection. However, cohort studies and case series have identified the risk factors for a poor prognosis (see Box 229.1).

Treatment and its effectiveness

In primary care, a single dose of IV or intramuscular third-generation cephalosporin should be given to patients in whom meningococcal infection is suspected and also in any patient with signs of severe sepsis or in whom there will be a delay of >1 hr before arriving in hospital. Guidelines recommend that this therapy be started within 30 minutes of hospital admission and as guided by local microbiology policy for suspected meningitis. There is slightly less time pressure when treating encephalitis because patients with encephalitis do not appear to deteriorate as rapidly as those with bacterial meningitis. However, UK guidelines recommend aciclovir within 6 hours of admission and there is evidence of a worse prognosis in those in whom treatment is delayed beyond 1-2 days of admission. As it is often not possible to determine whether the infection is due to a virus or bacteria in the acute phase, it is reasonable to commence treatments for both. Nevertheless, due to the risks of opportunistic infection, antibiotic resistance, and nephrotoxicity, the prescription of antimicrobials should be regularly reviewed in light of test results.

Ideally, an LP should be undertaken prior to commencing treatment, to maximize the chance of establishing the diagnosis and identifying the pathogen. For example, in a recent study of 92 patients with suspected bacterial meningitis, a delay of 4 hours resulted in a significant decline in the detection rate; beyond 8 hours, no CSF culture was positive. Similar studies have identified CSF sterility between 2 and 10 hours following commencement of antibiotics. However, antibiotics should be commenced prior to the LP in two scenarios: first, if there is a strong clinical suspicion of meningococcal septicaemia, such as a septic patient with a widespread purpuric rash (blood cultures taken at the time of venous cannulation can often establish the diagnosis); second, in cases where there are clinical contraindications to an LP. In the latter case, antibiotics should not be delayed until neuroimaging and subsequent LP, as this is associated with increased morbidity and mortality. However, the time period during which it may be possible to detect infection following the commencement of antimicrobials is longer for PCR tests than for CSF culture, so the LP should still be performed urgently to maximize diagnostic sensitivity.

IV dexamethasone should be given immediately prior to the first antibiotic dose in patients with suspected streptococcal meningitis. Patients aged over 60yrs should also be given ampicillin or amoxicillin, to cover listeria infection.

230 Disorders of movement

Cris S. Constantinescu and Fahd Baig

Introduction

The neural pathways that control movement involve several structures, from the cerebral cortex through to the muscle. This allows for the maintenance of tone, posture, and volitional movement. Disruption of subcortical structures which modulate these pathways (such as the basal ganglia) can cause a variety of clinical presentations collectively termed movement disorders. They can be simply divided into hypokinetic disorders (e.g. parkinsonism) and hyperkinetic disorders.

Hypokinetic movement disorders

Parkinson's disease and parkinsonism

Definition of Parkinson's disease and parkinsonism

Parkinsonism is the collective term for a group of motor syndromes characterized by tremor, bradykinesia, rigidity, and postural instability. The most common cause is Parkinson's disease (PD), which is an idiopathic neurodegenerative disorder.

Aetiology of PD and parkinsonism

Dysfunction or loss of dopamine-containing cells in the substantia nigra causes the motor signs and symptoms of parkinsonism. Parkinsonian disorders can be divided into four subtypes, based on cause and clinical phenotype:

- PD (idiopathic)
- secondary parkinsonism (due to acquired causes, e.g. cerebrovascular disease, drugs, or toxins)
- familial parkinsonism (e.g. mutations in the genes LRRK2 and SNCA)
- Parkinson plus syndromes: these are idiopathic conditions in which parkinsonism is associated with the following additional clinical features:
 - progressive supranuclear palsy (restriction of voluntary eye movements and dementia)
 - multisystem atrophy (cerebellar or autonomic dysfunction)
 - corticobasal degeneration (dementia with features of frontal and parietal lobe dysfunction)

Typical symptoms of PD, and less common symptoms

Tremor at rest, bradykinesia (slowness in initiating and maintaining movements), rigidity, and postural instability are the cardinal features of PD. Patients with PD usually have asymmetric motor symptoms. They also commonly have anosmia, hypomimia, hypophonia, focal dystonia, constipation, hypersialorrhoea, and gait difficulty. In addition, cognitive impairment affects a significant proportion of PD sufferers and can lead to dementia.

Demographics of PD

In the UK, the prevalence of PD is estimated to be 100–180 per 100 000 population, with an incidence of 4–20 per 100 000. Both prevalence and incidence increase with age, and men are more likely to be affected than women.

Natural history of PD, and complications of the disease

PD is a chronic and progressive condition with symptoms, such as anosmia, sleep disturbance, depression, and constipation, starting up to 10 years prior to the diagnosis. Following diagnosis, patients develop worsening symptoms of bradykinesia, tremor, rigidity, and gait disturbance to varying degrees over several years. As the

disease progresses, often 5–15 years post diagnosis, increasingly, motor complications (e.g. dyskinesias, gait freezing, axial deformities, dysarthria, and dysphagia) as well as non-motor complications (e.g. cognitive decline, depression, and autonomic dysfunction) become prominent.

Approach to diagnosing PD

Careful history taking and examination is the mainstay of diagnosis of PD, which is clinical. Particular focus should be paid to comorbidities (e.g. vascular risk factors), current and previous medications, drug use, family history, and non-motor features which patients may not think relevant to volunteer.

Other diagnoses that should be considered aside from PD

Wilson's disease, Huntington's disease, Hallervorden–Spatz disease, and neuroacanthocytosis can all present with parkinsonian features. In the context of cognitive impairment, Alzheimer's disease and Lewy body dementia should be considered.

'Gold-standard' diagnostic test for PD

As there is no reliable laboratory or imaging modality validated in isolation, clinical assessment remains the 'investigation' of choice.

Acceptable diagnostic alternatives to the gold-standard test for PD

DAT-SPECT (dopamine transporter single-photon emission CT) imaging, a SPECT that detects radioactively labelled dopamine transporters and shows initially asymmetrical decreased signal in PD, can be used to differentiate essential tremor, drug-induced parkinsonism, and vascular parkinsonism from PD. In the non-PD conditions, uptake is either unchanged or symmetrically reduced. Trials of treatment with medications such as levodopa are not useful.

Other relevant investigations for PD

MRI of the brain can identify structural causes of parkinsonism, such as cerebrovascular disease. This modality can also potentially identify features of Parkinson plus syndromes. SPECT imaging can differentiate dementia syndromes. Genetic screening for common mutations should be considered in young patients or when there is a family history. Laboratory tests for thyroid function, parathyroid function, heavy metals (e.g. Mn, Hg), acanthocytes (to look for neuroacanthocytosis), and copper can be useful in the appropriate clinical setting.

Prognosis of PD, and how to estimate it

Life expectancy in patients with PD is significantly reduced in patients with a younger age of onset, dementia, and dysphagia. Outside these groups, the life expectancy is near normal but the disability shows a predictable progressive pattern.

Treatment of PD, and its effectiveness

For effective management, a multidisciplinary approach to ameliorate the variety of disabling symptoms patients develop is required. The mainstay of drug therapy remains dopaminergic medications, which treat the motor features of PD. They have limited efficacy in treating the Parkinson plus syndromes and tend to be ineffective in secondary parkinsonism.

Levodopa preparations (in combination with a peripheral decarboxylase inhibitor to augment the half-life) are considered by many the most effective treatment. Side effects include confusion, hallucinations, gastrointestinal symptoms, orthostatic hypotension, and motor complications (such as dystonia and dyskinesia). Catechol-O-methyl

transferase inhibitors are used to block the residual breakdown of levodopa in the gastrointestinal tract, thus extending the availability and half-life.

Dopamine agonists can be used synergistically in combination with levodopa or as monotherapy. The side effects are similar in nature to levodopa but can also cause additional neuropsychiatric symptoms, including obsessional behaviours, addiction (e.g. gambling, hypersexuality), hallucinations, and psychosis.

Other drug treatments include anticholinergics (particularly for tremor), amantadine, and monoamine oxidase inhibitors. Cholinesterase inhibitors have a role in patients with dementia.

Deep brain stimulation is effective in a select group of patients, mitigating motor symptoms and reducing medications (and therefore the side effects of medications).

Hyperkinetic disorders

Essential tremor

Definition of essential tremor

Tremor is the rhythmical oscillatory movement of any body part and may feature as a part of a number of disorders. The term 'essential tremor' is used to describe a progressive tremor syndrome which usually includes an upper limb tremor and for which no underlying cause or alternative diagnosis is identifiable.

Aetiology of essential tremor

About half of patients with essential tremor have a family member with tremor. Genetic studies have identified a number of candidate genes which need confirmation.

Typical symptoms of essential tremor, and less common symptoms

Nearly all patients with essential tremor have an upper limb tremor, but they can also have a tremor in the lower limbs, head, jaw, tongue, trunk, and voice. Typically, the tremor has a postural component (present on maintenance of a posture, such as when the arms are outstretched) and a kinetic component (present when moving a body part, such as a hand, towards a target).

Demographics of essential tremor

Essential tremor can start at any age but is more common in adults.

Natural history of essential tremor, and complications of the disease

In essential tremor, the tremor lasts for life, progressing slowly over time, and can cause some difficulty with embarrassment in social situations and possibly activities of daily living. Life expectancy is not affected.

Approach to diagnosing essential tremor

In essential tremor, careful assessment for features of alternative conditions is required, as this tremor can represent a number of other conditions.

Other diagnoses that should be considered aside from essential tremor

Enhanced physiological tremor (e.g. due to hyperthyroidism, anxiety, or medication) can mimic essential tremor. Additional neurological features such as pyramidal signs, extrapyramidal signs, cerebellar features, and dystonia can point to alternative diagnoses.

'Gold-standard' diagnostic test for essential tremor

There are no diagnostic investigations for essential tremor, aside from clinical assessment.

Acceptable diagnostic alternatives to the gold-standard test for essential tremor

In essential tremor, the response to alcohol or characterization of the tremor in terms of amplitude and frequency are not specific enough to be discriminatory.

Other relevant investigations for essential tremor

Thyroid function can exclude thyrotoxicosis. DAT-SPECT imaging can be used to discriminate PD from essential tremor in the case of indeterminate tremor.

Prognosis of essential tremor, and how to estimate it

Life expectancy is generally not affected by essential tremor, but some studies have linked essential tremor with alcoholism.

Treatment of essential tremor, and its effectiveness

Up to two-thirds of patients describe their tremor improves with alcohol, although this is not recommended as treatment. The first-line medications are propranolol and primidone, which both have trial data to support their use. Propranolol is less effective for head and voice tremor than for hand tremor. Topiramate, gabapentin, benzodiazepines, and other beta blockers have been studied and may also improve symptoms. Other anticonvulsants, botulinum toxin injection, and surgical therapies (such as deep brain stimulation) can be considered but remain controversial.

Tics

Definition of tics

Tics are sudden, often brief, involuntary movements (motor tics) or sounds (vocal tics) which occur intermittently and are often repetitive or stereotyped. Tourette's syndrome is the most common tic disorder. Lasting for at least 1 year after starting in childhood, it is characterized by a broad spectrum of motor and vocal tics as well as behavioural disorders.

Aetiology of tics

Most cases are idiopathic but a genetic basis is increasingly being recognized. The pathogenesis is uncertain but there is evidence for a neurological rather than psychogenic origin.

Typical symptoms of tics, and less common symptoms

Prior to expression, patients often describe a localized feeling of discomfort or a general urge, which settles after the tic. Simple motor tics can manifest as jerking, slow, forceful, or isometric muscle contractions. Simple vocal tics can be meaningless sounds such as coughing, sniffing, or throat clearing. Complex tics are coordinated sequenced movements or sounds, which can seem with or without purpose. Motor examples include facial grimacing, jumping, and pinching while vocal examples include parts of words or phrases repeated. They are usually voluntarily suppressible for at least a short time until the urge becomes overwhelming.

Demographics of tics

Onset of tics usually occurs in childhood, with a high male-to-female ratio. However, while the incidence is thought to be about 2%, accurate data is difficult to estimate, as perhaps up to a third of patients are unaware of their tic.

Natural history of tics, and complications of the disease

Tic disorders commonly occur transiently in childhood. Of these, up to a third will last for 2–3 years or longer. Symptoms starting in older children tend to persist longer and, in a minority, can last for life.

Other diagnoses that should be considered aside from tics

Secondary tic disorders are increasingly recognized. Drugs such as stimulants and dopaminergic or antiepileptic medication can cause or exacerbate tics. Infective, toxic, and neurodegenerative causes, amongst others, should be considered, with careful assessment for additional neurological features.

'Gold-standard' diagnostic test for tics

There are no diagnostic tests necessary for tics in the absence of additional neurological features.

Treatment of tics, and its effectiveness

Education of the condition for the patient, parents, and teachers or work colleagues is important to manage the symptoms. Counselling

and behavioural therapies can achieve tolerable suppression of the tics. If daily life continues to be affected, dopamine-receptor-blocking drugs and monoamine-depleting drugs are the most effective medications, with a reduction in tic frequency of up to 80%.

Dystonia

Definition of dystonia

Dystonia is described as involuntary forceful or sustained contraction of muscles that can cause slow twisting movements, abnormal posturing, or rapid jerking movements, such as tremor.

Aetiology of dystonia

Dystonias can be primary or secondary. Primary dystonias are, by far, the most common and can be sporadic or inherited (usually in an autosomal dominant pattern).

Typical symptoms of dystonia, and less common symptoms

Dystonia can be focal, multifocal, segmental, or (rarely) generalized. Focal dystonias affect a single body part and are classified by location (e.g. cervical dystonia (spasmodic torticollis)). Task-specific dystonias are a subgroup of these, only occurring on a specific action, such as writer's cramp. Segmental dystonia affects two or more contiguous body parts. Generalized dystonia affects one or both legs, the trunk, and at least one other body part.

Stress and fatigue often worsen symptoms, while sensory tricks can relieve them (a 'geste antagoniste'). For example, touching the chin in cervical dystonia can correct the posture.

Demographics of dystonia

Symptoms of dystonia can start at any age, with no gender preference.

Approach to diagnosing dystonia

Family history and current and previous medications, as well as exposure to toxins, should all be carefully explored. Clinical assessment should focus on determining the presence of additional neurological features which could suggest a secondary cause.

Other diagnoses that should be considered aside from dystonia

Primary dystonia syndromes include dopa-responsive dystonia, myoclonic dystonia, and parkinsonian syndromes. Secondary causes include medications (including dopaminergic, antipsychotic, and anti-convulsant medications), toxins, and focal structural lesions (particularly in the basal ganglia). Inherited neurodegenerative and metabolic disorders can cause dystonia.

'Gold-standard' diagnostic test for dystonia

There are no confirmatory laboratory tests for sporadic dystonias, but genetic testing is available for certain forms of the inherited dystonias.

Other relevant investigations for dystonia

MRI of the brain and spinal cord is indicated to look for a structural lesion. Copper studies, including tests for caeruloplasmin and urinary copper, can exclude Wilson's disease. The presence of additional features would prompt investigation into specific secondary causes.

Prognosis of dystonia, and how to estimate it

Onset of limb dystonia in childhood is associated with an increased risk of developing generalized dystonia.

Treatment of dystonia, and its effectiveness

The first-line treatment for focal dystonia is botulinum toxin injected into the affected muscles. If this fails, then anticholinergics or muscle relaxants (such as baclofen or benzodiazepines) can be used as alternatives or adjuncts. For segmental and generalized dystonia, anticholinergics, tetrabenazines, and muscle relaxants can be tried. Intrathecal baclofen pump implantation, deep brain stimulation, and surgical denervation can be considered for refractory cases. For secondary dystonia, the underlying cause should be treated. Examples

include removal of precipitating drugs or copper chelation in Wilson's disease.

Chorea and Huntington's disease

Definition of chorea and Huntington's disease

Chorea is defined as rapid, involuntary jerking movements which are irregular and purposeless. This is in contrast to athetosis, which is characterized by slow, writhing movements; a combination of the two is called 'choreoathetosis'. The most common cause for these movements is Huntington's disease (HD), which is a progressive, autosomal dominant genetic disorder.

Aetiology of chorea and HD

Insult to the corpus striatum (putamen, globus pallidus, and caudate) due to degeneration, structural abnormalities, or biochemical or metabolic disturbance can cause these symptoms.

Typical symptoms of HD, and less common symptoms

HD commonly causes chorea, dementia, and personality change. Imbalance, bradykinesia, dysarthria, dysphagia, dystonia, and depression may all occur as the disease progresses.

Demographics of HD

Precise figures are not known, but the figure in the UK is estimated to be 12.4 symptomatic patients per 100 000, based on figures from the Huntington Disease Association.

Natural history of HD, and complications of the disease

HD demonstrates anticipation, with each following generation which inherits the mutation likely to suffer symptoms earlier. Onset can vary but is often in the fourth or fifth decade of life.

Approach to diagnosing HD

To diagnose HD, clinical assessment with a detailed exploration of the family history is required.

Other diagnoses that should be considered aside from chorea and HD

Other causes of chorea include medications (such as dopaminergics or hormonal contraception), Sydenham's chorea (a manifestation of rheumatic fever), and chorea gravidarum (in association with pregnancy). Autoimmune conditions (such as SLE), neuroacanthocytosis, and polycythaemia vera can also be associated with chorea.

'Gold-standard' diagnostic test for HD

Genetic testing is available for the mutation which is diagnostic for HD: the expanded trinucleotide repeat in the IT15 gene, which is located on the short arm of Chromosome 4. Genetic testing should be done with appropriate counselling.

Other relevant investigations for chorea and HD

MRI of the brain can be done to look for structural damage to the basal ganglia. Other investigations, such as a blood film (to look for acanthocytes), thyroid function tests, and tests for glucose levels, copper levels (to exclude Wilson's disease), and antiphospholipid antibodies, should be guided by associated features.

Prognosis of HD, and how to estimate it

The neurological and psychiatric disability of HD is progressive, with life expectancy estimated to be limited to between 15–25 years following the onset of symptoms.

Treatment of chorea and HD and its effectiveness

A multidisciplinary approach is required for the treatment of chorea and HD, with input from neurologists, psychiatrists, and therapists. Treatment is supportive, with the focus on managing the symptoms individual to each patient. To date, there are no proven disease-modifying therapies. Tetrabenazine, haloperidol, and levetiracetam have all been used to treat chorea, with some success. Disruption of the

sleep cycle can be disturbing, in which case lifestyle advice and medications (such as benzodiazepines) can be helpful.

231 Multiple sclerosis

Andrew Weir

Definition of the disease

Multiple sclerosis (MS) is an idiopathic inflammatory disorder of the CNS. The characteristic pathological feature is the occurrence of 'plaques': well-defined areas of myelin loss, with relative axonal preservation.

Aetiology of the disease

The cause of MS is not known.

Genetic factors play a role; the risk of MS is raised in relatives of patients, and varies with degree of genetic relatedness (25%–30% for monozygotic twins, 3% for siblings, and 2% for half-siblings). The most important specific genetic influences lie in the HLA region of Chromosome 6, and the Class II allele HLA-DRB1*1501 is the strongest genetic risk factor. The way the HLA region influences risk is complex and likely involves interactions between different parts of the region on both chromosomes. Genome-wide association studies have identified weaker modifiers of risk in other genes, including those for the IL2 and IL7 receptors.

Genetics, however, leaves much unaccounted for. Epidemiological patterns hint at various environmental factors. Current factors receiving research attention include vitamin D levels, and exposure to EBV.

Typical symptoms of the disease, and less common symptoms

The temporal pattern of symptoms in MS is important, and two major patterns are recognized. In a **relapse**, symptoms come on subacutely (typically over days or hours), stabilize, and then improve (rather more slowly than they evolved), so that significant (sometimes complete) resolution occurs. In **progressive** disease, symptoms evolve over months and years (and do not recover); progression is therefore often only clear in retrospect.

MS that is causing relapses without progression is said to be 'relapsing–remitting'. MS that is progressive from onset is 'primary progressive'. When progression develops after a period of relapsing–remitting disease, MS has become 'secondary progressive'.

Typical sites for lesions causing relapse include the optic nerve, the spinal cord, and the brainstem (although many other areas may be involved and multifocal relapse also occurs). In optic neuritis, vision blurs and loses colour intensity in one eye, often with retro-orbital pain made worse by eye movement. In acute partial transverse myelitis (the 'partial' emphasizes that usually not all the cord structures at one level are affected), there may be weakness, but sensory symptoms often dominate, for example those ascending from leg to abdomen. A subjective sensory level ('like a belt hugging around my tummy'), and altered perineal sensation ('it feels odd when I wipe') are frequent complaints. Lhermitte's phenomenon (an electric shock sensation in the back or limbs on neck flexion) may occur. In brainstem relapse, typical symptoms are vertigo, diplopia, areas of facial numbness, and disequilibrium. Trigeminal neuralgia, especially in the young and if bilateral, may be the first presenting symptom.

Progressive-onset MS most often initially causes a subtle myelopathy, so patients complain of gait upset. Typical first symptoms are asymmetrical, with a leg that becomes stiff or drags after particularly long walks. Progressive cerebellar, sensory, or visual syndromes also occur.

Demographics of the disease

Across the UK, the prevalence of MS is 1–2 in 1000. Prevalence varies greatly around the world, likely due to a combination of genetic and environmental geographical effects. A latitudinal gradient has been described, with higher prevalence at greater separation from the equator. MS is commoner in women than men, and the sex ratio may be increasing towards 3F:1M. The peak age of onset lies in the late twenties/early thirties, although perhaps 5% of cases start under 16, and 5% over 50.

Natural history, and complications of the disease

MS usually runs its course over decades (early death or severe fixed disability can occur, but are rare). Eighty per cent of cases initially take a relapsing–remitting course. Secondary progression ensues in the majority but usually only after many years: after 20 years, half will be secondary progressive; 10%–20% of relapsing–remitting MS cases never become progressive.

MS can affect almost every aspect of neurological function. Typically, a patient becoming moderately disabled will have a spastic paraparesis, ataxic upper limbs, and sensory symptoms and signs. Pain may be neuropathic, although assuming this can lead one to miss other causes. Visual symptoms and signs are common. Bladder, bowel, and sexual function are frequently affected, but this may only be revealed on direct questioning. Cognitive problems are common on formal testing, and may contribute to the high rates of employment and relationship difficulties observed. Patients often rate fatigue as a major difficulty.

Approach to diagnosing the disease

The occurrence of episodes of neurological dysfunction affecting different parts of the CNS at different times ('dissemination in time and space'), with appropriate exclusion of other possibilities is the key. Paraclinical tests (MRI, and sometimes examination of CSF or evoked potential studies) provide support, but the diagnosis of MS remains clinical.

Other diagnoses that should be considered

The relevant differential varies greatly and depends on the mode of onset (relapsing or progressive) and the part of the CNS affected. For example, primary progressive MS causing a progressive myelopathy could be due to cervical spondylosis, primary lateral sclerosis, or a hereditary spastic paraparesis. Relapsing–remitting neurological syndromes can occur in the connective tissue diseases (especially SLE, Sjögren's syndrome, and the antiphospholipid syndrome), the vasculitides, and neurosarcoidosis. Neuromyelitis optica (Devic's disease) causes optic neuritis and transverse myelitis, and the brain MRI can also mimic MS.

'Gold-standard' diagnostic test

There is no gold-standard test for MS. Brain biopsy (done in rare circumstances to exclude other possibilities) can be hard to interpret, and the pathological features of MS are found in about 0.1% of routine post-mortems. Schemes to formalize the clinical diagnosis are used, especially for research purposes, but sometimes neurologists

have to fall back on saying that 'multiple sclerosis is what a good clinician calls multiple sclerosis'.

Acceptable diagnostic alternatives to the gold standard

Several sets of diagnostic criteria have been proposed to help clinicians diagnose MS, for example the Schumacher criteria, the Poser criteria, and the Macdonald criteria. An innovation of the Macdonald criteria was to allow a changing MRI scan to satisfy 'dissemination in time', in some circumstances without a second clinical event. The current widely used criteria are a modification of these (Table 231.1). Future further modification seems likely.

Other relevant investigations

Other relevant investigations will be determined by the relevant differential. Imaging will rule out structural disease. Serological tests may indicate a connective tissue disorder or a metabolic cause for a myelopathy. Neuromyelitis optica is suggested by finding longitudinally extensive lesions on cord MRI (extending over more than three vertebral bodies); antibodies against aquaporin 4 are specific.

Prognosis and how to estimate it

Twenty years after onset the 'average patient' (i.e. someone with the median disability level) needs a stick to walk 100 m. The variation about this midpoint is, however, very considerable. A number of factors prognostic for the median course of groups of patients have been described (e.g. older patients tend to develop disability more quickly) but, even in combination, these do not allow accurate prediction of an individual's clinical state 5–10 years into the future.

Treatment and its effectiveness

Short courses of high-dose methylprednisolone (regimes recommended by the National Institute for Health and Care Excellence (NICE) include 500 mg orally for 5 days, or 1 g IV for 3 days) hasten recovery from relapse without changing final outcome. They are usually used therefore for relapses with significant impact on current function.

Interferon beta (as regular subcutaneous or intramuscular injections) and glatiramer acetate (as subcutaneous injections) are licensed in relapsing–remitting MS, and have been used for almost 20 years. They reduce the relapse rate by about a third. More recently, NICE have recommended three oral agents (fingolimod, dimethyl fumarate,

Table 231.1 The 2010 McDonald criteria for diagnosis of multiple sclerosis

Clinical Presentation	Additional Data Needed for MS Diagnosis
≥2 attacks ^a ; objective clinical evidence of ≥2 lesions or objective clinical evidence of 1 lesion with reasonable historical evidence of a prior attack ^b	None ^c
≥2 attacks ^a ; objective clinical evidence of 1 lesion	Dissemination in space, demonstrated by: ≥1 T2 lesion in at least 2 of 4 MS-typical regions of the CNS (periventricular, juxtacortical, infratentorial, or spinal cord) ^d ; or Await a further clinical attack ^a implicating a different CNS site
1 attack ^a ; objective clinical evidence of ≥2 lesions	Dissemination in time, demonstrated by: Simultaneous presence of asymptomatic gadolinium-enhancing and nonenhancing lesions at any time; or A new T2 and/or gadolinium-enhancing lesion(s) on follow-up MRI, irrespective of its timing with reference to a baseline scan; or Await a second clinical attack ^a
1 attack ^a ; objective clinical evidence of 1 lesion (clinically isolated syndrome)	Dissemination in space and time, demonstrated by: For DIS: ≥1 T2 lesion in at least 2 of 4 MS-typical regions of the CNS (periventricular, juxtacortical, infratentorial, or spinal cord) ^d ; or Await a second clinical attack ^a implicating a different CNS site; and For DIT: Simultaneous presence of asymptomatic gadolinium-enhancing and nonenhancing lesions at any time; or A new T2 and/or gadolinium-enhancing lesion(s) on follow-up MRI, irrespective of its timing with reference to a baseline scan; or Await a second clinical attack ^a
Insidious neurological progression suggestive of MS (PPMS)	1 year of disease progression (retrospectively or prospectively determined) plus 2 of 3 of the following criteria ^d : 1. Evidence for DIS in the brain based on ≥1 T2 lesions in the MS-characteristic (periventricular, juxtacortical, or infratentorial) regions 2. Evidence for DIS in the spinal cord based on ≥2 T2 lesions in the cord 3. Positive CSF (isoelectric focusing evidence of oligoclonal bands and/or elevated IgG index)

If the Criteria are fulfilled and there is no better explanation for the clinical presentation, the diagnosis is 'MS'; if suspicious, but the Criteria are not completely met, the diagnosis is 'possible MS'; if another diagnosis arises during the evaluation that better explains the clinical presentation, then the diagnosis is 'not MS'.

^aAn attack (relapse; exacerbation) is defined as patient-reported or objectively observed events typical of an acute inflammatory demyelinating event in the CNS, current or historical, with duration of at least 24 hours, in the absence of fever or infection. It should be documented by contemporaneous neurological examination, but some historical events with symptoms and evolution characteristic for MS, but for which no objective neurological findings are documented, can provide reasonable evidence of a prior demyelinating event. Reports of paroxysmal symptoms (historical or current) should, however, consist of multiple episodes occurring over not less than 24 hours. Before a definite diagnosis of MS can be made, at least 1 attack must be corroborated by findings on neurological examination, visual evoked potential response in patients reporting prior visual disturbance, or MRI consistent with demyelination in the area of the CNS implicated in the historical report of neurological symptoms.

^bClinical diagnosis based on objective clinical findings for 2 attacks is most secure. Reasonable historical evidence for 1 past attack, in the absence of documented objective neurological findings, can include historical events with symptoms and evolution characteristics for a prior inflammatory demyelinating event; at least 1 attack, however, must be supported by objective findings.

^cNo additional tests are required. However, it is desirable that any diagnosis of MS be made with access to imaging based on these Criteria. If imaging or other tests (for instance, CSF) are undertaken and are negative, extreme caution needs to be taken before making a diagnosis of MS, and alternative diagnoses must be considered. There must be no better explanation for the clinical presentation, and objective evidence must be present to support a diagnosis of MS.

^dGadolinium-enhancing lesions are not required; symptomatic lesions are excluded from consideration in subjects with brainstem or spinal cord syndromes.

MS—multiple sclerosis; CNS—central nervous system; MRI—magnetic resonance imaging; DIS—dissemination in space; DIT—dissemination in time; PPMS—primary progressive multiple sclerosis; CSF—cerebrospinal fluid; IgG—immunoglobulin G.

Reproduced with permission from Polman et al., Diagnostic criteria for multiple sclerosis: 2010 Revisions to the McDonald criteria, *Annals of Neurology*, Volume 69, Issue 2, pp. 292–302, Copyright © 2011 John Wiley and Sons.

and teriflunomide) which reduce the relapse rate by about a half, and two monoclonal antibodies (natalizumab and alemtuzumab) which reduce it by about two-thirds, for subgroups of people with relapsing–remitting MS. Some of these agents are associated with a small risk of serious side effects, both infectious (including progressive multifocal leucoencephalopathy) and secondary autoimmune disorders. The effects of these agents on the risk of fixed disability in the long term (or the risk of transition to secondary progressive disease) are hard to confidently measure in trials lasting only a few years; the balance of risk and benefit, and cost-effectiveness, therefore, has been

controversial. There are currently no agents that have been definitely shown to change the rate at which disability develops in primary or secondary MS.

232 Motor neuron disease

Martin R. Turner

Definition of the disease

Motor neuron disease (MND) is characterized by progressive muscular weakness due to simultaneous degeneration of lower and upper motor neurons (L/UMNs). Involvement of LMNs, arising from the anterior horns of the spinal cord and brainstem, leads to secondary wasting as a result of muscle denervation. Involvement of the UMNs of the motor cortex and corticospinal tract results in hyperreflexia, sometimes with spasticity. In ~85% of cases, there is clinical involvement of both, and the condition is termed 'amyotrophic lateral sclerosis' (ALS; a term often used synonymously with MND). In ~13% of cases, there may be only LMN signs apparent, in which case the condition is termed 'progressive muscular atrophy', although such cases have a natural history similar to that for ALS. In a very small group of patients (~2%), there are only UMN signs for at least the first 4 years, in which case the condition is termed 'primary lateral sclerosis' (PLS); such cases have a uniformly slower progression. There is clinical, neuropathological, and genetic overlap between MND and some forms of frontotemporal dementia (FTD).

Aetiology of the disease

The causes of MND (which is a syndrome rather than one disease) are not clear, but in nearly all cases there are abnormal cytoplasmic inclusions of a protein TDP-43 in brain and spinal cord cells. Epidemiological studies have excluded a range of environmental insults as independent causes. It is possible that a complex genetic profile renders an individual at risk of MND, with as yet unidentified triggers. Approximately 5% of cases report a family history. Of these, up to 40% are associated with an intronic hexanucleotide expansion in C9ORF72, whose phenotype can be 'pure' FTD as well as ALS-predominant. A further 20% are found to have mutations of the gene SOD1 encoding superoxide dismutase-1, which is involved in the processing of free radicals. A smaller proportion (~5%) have mutations of the TARDBP and FUS genes, which encode proteins involved in RNA regulation.

Typical symptoms of the disease, and less common symptoms

The onset of MND is insidious, and the lack of a specific test results in a mean delay in diagnosis of 12 months. Those with an aggressive disease course tend to be diagnosed earlier.

The site of initial symptoms is approximately equally divided amongst the lower limb territory, the upper limb territory, and the 'bulbar' territory of the brainstem (cranial nerves IX, X, and XII). Limb onset is typically asymmetric prior to spread, which is usually to contiguous body regions. Tripping up, dragging the leg, weak shoulder abduction, and poor grip are all common early symptoms, and without prominent sensory involvement. Fasciculations, although characteristically florid in MND often go unnoticed by the patient.

Those with bulbar onset report dysarthria preceding dysphagia, and may be mis-referred to ENT or TIA clinic. Rarely, there may be a period of some months in which a patient who becomes rapidly anarthric remains ambulant with good limb function (historically referred to as 'progressive bulbar palsy').

In <3% cases, the presenting symptom may be respiratory, with orthopnoea due to diaphragm weakness. This may present as an emergency in the context of a secondary pneumonia.

Frank dementia affects up to 15% of MND cases (typically before the onset of motor symptoms). Milder cognitive deficits (particularly verbal fluency) may be detectable in up to 50%.

Demographics of the disease

MND has a global incidence of 1–2 in 100 000 per year, and a UK prevalence of ~5000. There is a slight male predominance, but more females amongst bulbar-onset patients.

The mean age of onset is the early sixties, and the majority of cases present in the sixth and seventh decades, but with rare cases seen as young as the teens. The perception of relative athleticism premorbidly in MND patients is unproven.

Natural history, and complications of the disease

Limb weakness leads to increasing dependency for activities of daily living. Loss of ambulation may be preceded by falls, and those with upper limb weakness are at high risk of head injury.

Bulbar involvement occurs in at least two-thirds of patients, with dysarthria limiting verbal communication, and dysphagia leading to poor nutritional intake and risk of aspiration. Choking is, however, exceptional as a mode of death. Sialorrhoea results from reduced swallowing frequency and can be treated with anti-cholinergic medication. While emotionality is common in MND (due to corticobulbar neuronal involvement), depression is rare. Progressive diaphragm weakness results in increasing dyspnoea with orthopnoea. Chronic nocturnal hypoventilation with hypercapnoea may cause sleep fragmentation, early morning headache, and daytime somnolence.

Death in MND typically occurs as a result of respiratory failure, often in the context of superimposed bronchopneumonia. Sudden death occurs in a small proportion of cases (<5%), some of whom may have occult pulmonary embolism.

Eye movements and bladder and bowel sphincters are generally spared in the course of MND, although oculomotor function may be impaired in the very late stages.

Approach to diagnosing the disease

The grave implication of a diagnosis of MND means it should not be suggested where there is significant doubt. Equally, however, fear of missing a treatable but implausible mimic leads to unnecessary delay in initiating community support, with loss of precious quality of life for those facing a life-shortening illness. A formal neurological opinion should therefore be sought as soon as possible in suspected cases.

MND should be considered in someone with a history of progressive muscle weakness over weeks or months without prominent sensory symptoms, particularly where there is wasting (which frequently involves the first dorsal interosseous) or dysarthria (especially with tongue wasting) and in the context of pathologically brisk reflexes in the same body territory. If signs are entirely confined to a single limb, then other causes are more likely.

Supportive examination features are the observation of florid fasciculations (commonly missed over the anterior shoulders and quadriceps if the patient is not undressed) and reduced vital capacity. Neck flexion weakness, emotionality, or primitive facial reflexes, are useful signs that limit the differential diagnosis considerably.

Other diagnoses that should be considered

There are few mimics of MND in its typical mixed UMN and LMN form, and particularly when there is clear bulbar involvement. Myasthenia gravis is usually possible to distinguish on clinical grounds, invariably due to ocular involvement in the context of bulbar symptoms.

Cervical spondylotic myeloradiculopathy may produce a syndrome of progressive limb weakness with relative sparing of sensory and sphincter functions, and mixed UMN and LMN signs. It should be considered in those with symptoms confined to the limbs, and excluded if necessary with MRI, bearing in mind that many patients in the age group for MND will have coincident cervical spine disease.

The rare autoimmune multifocal motor neuropathy may be considered in pure LMN presentations, especially involving finger extensors, and requires careful neurophysiological assessment to detect the characteristic (sometimes elusive) conduction block. Post-radiation lumbar radiculopathy may produce a syndrome similar to lower limb onset MND, with presentation occasionally delayed by decades. Inclusion body myositis is very rare and usually suggested by the predominant quadriceps or medial forearm involvement. HIV infection has been rarely associated with a motor neuropathy.

Progressive pure UMN syndromes need exclusion of a structural or inflammatory cause within the cord and brain, as well as exclusion of vitamin B₁₂ and copper deficiencies. Primary progressive forms of multiple sclerosis occasionally mimic PLS.

The concept of 'paraneoplastic MND' is overstated and controversial as a distinct entity.

'Gold-standard' diagnostic test

The gold-standard diagnostic test for MND is post-mortem demonstration of characteristic motor neuronal cytoplasmic protein inclusions.

Acceptable diagnostic alternatives to the gold standard

An acceptable diagnostic alternative to the gold-standard test for MND is clinical examination by a neurologist, ideally one specializing in MND.

Other relevant investigations

Electromyography should not be considered a 'test for MND' but provides supportive evidence of LMN involvement in non-wasted muscles. It can be normal in isolated bulbar-onset MND.

Serum creatinine kinase level is neither sensitive nor specific but frequently mildly raised, reflecting muscle denervation. Values >2000 should prompt diagnostic re-evaluation.

Lumbar puncture and muscle biopsy are rarely indicated.

The lack of knowledge of the genes implicated in 30% of familial cases, the unreliability of a negative family history and the variable penetrance of those genes that are known, mean that genetic testing in established MND requires careful counselling.

Prognosis and how to estimate it

The median survival in MND is 3 years from the onset of symptoms. This tends to be shorter in patients with bulbar onset and those with associated FTD, and longer in those aged <40 at onset. In aggressive cases, survival can be as little as 6 months from diagnosis, but there is a marked variability in prognosis, with a small but consistent proportion of patients (10%) surviving more than 10 years from symptom onset. PLS patients characteristically survive for 10–20 years. The pace of deterioration in MND is generally fixed throughout the course of the disease, and no sustained 'plateau' should be expected.

Treatment and its effectiveness

The most useful intervention is early referral to a tertiary MND clinic, which can coordinate community-based palliative care (details via the Motor Neurone Disease Association UK; see <http://www.mndassociation.org>), which has been shown to improve survival as well as quality of life.

Riluzole is the only UK licensed disease-modifying drug for the treatment of MND (in its ALS form), at a dose of 50 mg twice daily. Thought to have broadly anti-glutamatergic properties, clinical trials suggests a <10% increase in overall survival, but this cannot be quantified for an individual, and neither will they experience improvement subjectively. The drug is usually well tolerated, but ~10% of patients may experience unacceptable lethargy or nausea. A full blood count and liver function tests are required at baseline and monthly for the first 3 months, 3-monthly for the first year, and annually thereafter. Significant rises in alanine transferase levels require initial dose reduction and withdrawal, if persistent.

Gastrostomy (typically percutaneous endoscopic gastrostomy) can improve the quality of life for patients with significant dysphagia. The device should ideally be inserted before the development of significant respiratory weakness (forced vital capacity >50%) in a centre with experience of this patient group.

Non-invasive ventilation is a valuable intervention for the effective relief of symptoms associated with hypercapnoea, and has an additional survival benefit. It requires close liaison with an experienced respiratory team, and those with prominent bulbar involvement may find it harder to use effectively. Invasive ventilation (tracheostomy) is rarely requested. Any perceived benefits are often unrealistic and do not take into account the inevitable total physical dependency, being 'locked in', or the possibility of dementia later in the course of the disease.

233 Spinal cord disease

Stephan Hinze and Paul Davies

Definition and aetiology of the disease

Injury to the spinal cord (myelopathy) can be due to many causes (see Table 233.1).

Typical symptoms of the disease, and less common symptoms

Symptoms will depend on the localization and extent of spinal cord damage and the nature of the pathology. Rapid damage, as in stroke or rapid inflammation, will cause spinal shock (flaccid paralysis and hypo/areflexia), which looks very different from the spasticity seen when there is slow onset of damage to the same area. Pathology progressing at intermediate rates (e.g. demyelination) often produces spreading numbness or weakness of appropriate anatomical distribution to the expanding lesion. Depending on the site of the lesion, the legs and arms can be affected to varying degrees, but strictly unilateral symptoms are uncommon. Weakness can affect both legs (paraparesis) or all four limbs (quadriparesis).

There are a number of classic patterns of symptoms due to the location of spinal cord damage (e.g. syringomyelia damages central crossing spinothalamic neurons and anterior horn cells in particular to produce a dissociated sensory loss and lower motor neuron signs; patients in this case might present with a history of burns and cuts to their hands and arms).

Patients with spinal cord problems often present with gait disturbance and imbalance. As a result of spasticity, they might report stiffness and jerking of their legs or loss of dexterity in their hands, although strength may be good or normal.

Autonomic symptoms can occur. Bladder symptoms are particularly important to recognize, as delayed treatment of cord compression may lead to permanent incontinence. Bowel symptoms and erectile dysfunction can be present as well. More infrequently, respiratory weakness can occur or paroxysms of hypertension and sweating.

Pain is often a prominent feature in degenerative and other compressive pathologies (e.g. spondylosis, disc prolapse, spinal metastasis, or epidural abscess) but can also occur with non-compressive etiologies like transverse myelitis, where it is especially located in the interscapular region.

The pathology may affect other parts of the nervous system (e.g. spinal cord) and there may be additional peripheral neuropathy, as in subacute combined degeneration of the cord, or an additional optic neuritis, as in neuromyelitis optica. There may also be systemic features, as in vasculitis.

Neurogenic claudication is often reported in lumbar spinal canal stenosis. It presents with cramping lumbar pain radiating to the legs; the pain occurs during walking and improves following flexion of the spine, for example when cycling. It does not improve, however, while standing (in contrast to vascular claudication). The patients often describe a feeling of heavy legs.

In the rare event of subarachnoid haemorrhage (SAH) of the spinal cord, patients can present with typical symptoms of cranial SAH (occipital headache, meningism, photophobia). Spinal cord tumours can occasionally produce papilloedema.

Although not in the scope of this chapter, there may be additional diseases below the level of L1 (the lower limit of the spinal cord), like cauda equina damage.

Demographics of the disease

Degenerative compressive causes are the most common spinal cord problems. They mainly occur in the older population (cervical spondylotic myelopathy, for example, especially in 40–60 year olds) with a predominance of men over woman (3:2). Symptomatic disc herniation affects 1500 per million in the US. Lumbar stenosis occurs in up to 50 per million. Degenerative changes on imaging of the cervical spine can be seen in over 50% of subjects older than 40, and in up to 89% of subjects over the age of 60. Asymptomatic cord compression can be seen in 7.5% of such patients. Cauda equine syndrome is fortunately relatively rare, occurring in only around 0.12% of all symptomatic disc herniations.

Also relatively common is spinal cord injury secondary to trauma; this mainly affects 20–40 year olds. The prevalence is estimated at 10–83 per million, and up to 1 in 40 of the patients admitted to trauma centres have spinal cord injury. The cervical cord is the most commonly affected region (in 55% of all cases).

Less common, but still relatively frequent, is acute transverse myelitis, with an incidence of 1–8 (or 24, if cases due to multiple sclerosis are included) new cases per million per year. It affects younger patients, with bimodal peaks at 10–19 and 30–39 years. There is no gender, family, or ethnic difference for the group as a whole.

The incidence of subacute combined degeneration (e.g. due to vitamin B₁₂ deficiency (sometimes mimicked by copper deficiency)) has not been exactly established. Depending on the cut-off values, up to around 20% of people, especially white older woman, can be deficient in vitamin B₁₂. Not all develop neurological symptoms (74%

Table 233.1 Causes of myelopathy

Genetic causes	Familial/hereditary spastic paraparesis

Abbreviations: CMV, cytomegalovirus; HSV, herpes simplex virus; SLE, systemic lupus erythematosus; VZV, varicella zoster virus.

developed neurological symptoms, in one study which included all possible neurological symptoms).

Syringomyelia has an estimated prevalence of around 0.8 per million. It predominantly affects males in their third and fourth decade in life. It mainly occurs in conjunction with Chiari malformations, but also accompanies 25%–60% of all intramedullary tumours.

A similar prevalence has hereditary spastic paraparesis with up to around 1 per million. The mechanism is primarily autosomal dominant, but can also be X-linked recessive.

Natural history and complications of the disease

The main complications depend on the location and extend of the lesion. Motor and sensory function of the lower and/or upper limbs can be affected to varying degrees, the greatest concern being quadriplegia with higher cervical lesions. Care should be taken with regards to autonomic dysfunction involving loss of bowel function, urinary retention, and incontinence, as well as the potential, but fortunately rare, problems with lability of blood pressure and respiratory function. Severe damage causing paraplegia or quadriplegia, may lead to pressure sores, urinary infections, septicaemia, deep vein thrombosis, and pulmonary emboli.

Treatable diseases

Acute transverse myelitis reaches its maximum severity over 4 hours to 3 weeks, whereas vascular causes like stroke or acute compressive causes (e.g. disc prolapse) have a more rapid onset. Compressive degenerative myelopathy (cervical spondylotic myelopathy, lumbar spinal stenosis) tends to have a longer time course lasting over months to years.

Inflammatory/ infectious myelopathies are usually monophasic, with roughly one-third of cases recovering completely, one-third continuing to have residual symptoms, and the last third showing no great improvement at all. Neuromyelitis optica (NMO) in this group has to be highlighted in view of the often recurrent nature of myelitis or optic neuritis requiring early commencement of long-term immunosuppression.

Cervical spondylotic myelopathy tends to ultimately progress in an either gradual or stepwise progression in the majority of cases. But, initially, it can have a stable appearance for a few years, and a minority of patients might also improve.

Lumbar spinal stenosis, in contrast, has a more benign course, with an initially slow progression that reaches a plateau in the majority of cases with conservative management alone.

Subacute combined degeneration (vitamin B₁₂ deficiency) often progresses over months to years to an ataxic paraplegia if untreated.

Palliative

Hereditary processes (e.g. familial spastic paraparesis) are often slowly progressive with an onset of symptoms frequently between the second and of fourth decade of life. These patients often don't have a lower life expectancy.

In contrast, motor neuron disease frequently leads to death within a few years' time.

Approach to diagnosing the disease

Is it the spinal cord?

Localizing the pathology to the cord is an obvious but sometimes challenging clinical step in reaching a diagnosis. The presence of upper motor neuron signs (increased tone, sustained or asymmetric ankle clonus, hyperreflexia, and extensor plantar responses) and the presence of a sensory-level point towards a spinal cord problem. But, in the acute phase of a spinal shock, immediately after a stroke, for example, the reverse with presence of flaccid paralysis might be the case.

Ruling out other possible causes (e.g. a cauda equina syndrome (no upper motor neuron signs) or a brainstem cause (maybe only a brisk jaw jerk gives the game away)) might be one step. Just weakness of the legs (particularly proximal and symmetrical weakness)

with no sensory symptoms or signs might lead to a consideration of muscle disease (relatively rare) and, if there is variable weakness that becomes worse as the legs are used, consider myasthenia.

Where in the spinal cord?

If the legs are affected, but not the arms, a sensory level may locate the cord lesion. If all four limbs are affected and a cervical cord lesion is considered, the sensory level is often less helpful at precise localization, because the dermatomes C4 and T4 on the chest are close together. Sometimes an absent reflex locates the site (e.g. spastic legs and no biceps jerk suggests a disc at C5 (Table 233.2)). Consider diaphragmatic function in mid-cervical cord lesions.

Compression or not?

An early important question to answer is whether the underlying pathology is of acute compressive nature, since this will direct further management towards a possible urgent surgical referral. Imaging will often provide the answer. In order to determine which part of the spinal cord to image, the sensory level is an important tool. In cases of isolated leg involvement, it might not be sufficient to image the lumbar–sacral spine, since the underlying lesion could be in the thoracic region and thus one which a sensory-level examination might pick up.

Sudden onset of pain in the cervical or lumbar region, possibly with radiation along a specific nerve root and neurological deficits hint towards a compressive lesion (often prolapsed discs).

An asymmetric flaccid paresis of the lower limbs with reduced reflexes in the context of perianal/ saddle anaesthesia should raise the question of cauda equina syndrome, which often is caused by prolapsed discs but can also occur secondary to tumour, infection, stenosis, and hematoma. In suspected cases, the anal tone should be assessed.

Conus medullaris lesions, unlike cauda equina lesions, present with earlier sphincter dysfunction in context of sacral sensory loss with relatively milder motor disturbance. Here, the pathology is often inflammatory in nature.

What type of non-compressive pathology?

In non-compressive lesions, the clinical examination and history can guide towards the diagnosis.

Incomplete/partial lesions, like a hemicord syndrome (Brown–Séquard syndrome) make a final diagnosis of multiple sclerosis more likely. Brown–Séquard syndrome presents with ipsilateral pyramidal weakness and posterior column function loss (light touch, vibration, joint position) with contralateral loss of pain and temperature (crossed spinothalamic tract). In suspected multiple sclerosis, previous demyelinating events might be elicited in the history, and the MRI usually shows small (< 2 vertebral segments) and more peripheral (asymmetric) lesions. CSF examination in these cases shows unmatched oligoclonal bands (not present in a concurrent serum sample).

Table 233.2 Helpful pointers in determining the level of spinal cord involvement

Nerve root	Helpful clinical pointers in determining the level of spinal cord involvement
C5	Biceps jerk
C6	Brachioradialis jerk
C7	Triceps jerk
C8/T1	Finger jerk/Hoffmann's
T4/5	Nipple level
T10	Umbilical level
L1	Inguinal area
L2/3	Hip adductor jerk
L4	Knee jerk
L5	Hallux dorsiflexion
S1	Ankle jerk

With long lesions (>3 segments, central), neuromyelitis optica should be considered, and evidence of (past) optic neuritis should be sought, as well as further investigations with NMO antibodies thought of. In neuromyelitis optica, CSF does not show oligoclonal bands, but prominent pleocytosis instead.

Systemic markers of infection, confusion, meningism, or a rash should raise the suspicion of an infectious myelopathy. This should also be suspected in any immunocompromised patient. In infectious causes, the myelopathy is often complete, causing symmetric motor and sensory deficits with urinary dysfunction. It is important in these instances to think of CMV infections, even in immunocompetent patients.

What makes a vascular cause likely?

If clinical signs of **acute** bilateral flaccid weakness, loss of pain and temperature and sphincter function in the context of preserved dorsal column modalities (vibration, joint position) are found (anterior cord syndrome), a vascular cause should be considered, since the anterior spinal cord is supplied by a single anterior spinal artery (compared to two posterior arteries). An occlusion can occur in the context of aortic surgery or spinal angiography, but can also come from an embolic source. If an anterior cord syndrome occurs in the context of back pain and a history of physical exertion (often repeatedly), a diagnosis of fibrocartilaginous disc embolism might be present. Imaging evidence of reduced vertebral height in the area further aids this diagnosis. Sudden onset (recurrent) myelopathic symptoms during exercise or upright posture/walking are more commonly caused by an arteriovenous fistula, however. Formal angiography is often required for the diagnosis in these cases.

Other selective losses

A selective loss of posterior column function leading to unsteady gait (sensory ataxia) should raise the suspicion of vitamin B₁₂ or copper deficiency (e.g. following bariatric surgery). If the level of vitamin B₁₂ is in the lower range of normal, homocysteine and methylmalonic acid, both precursors for vitamin B₁₂-dependent chemical reactions, should be measured. Elevated levels would indicate vitamin B₁₂ deficiency in this setting.

The presence of dissociated sensory loss and lower motor neuron signs should raise the suspicion of syringomyelia, a spinal cord cavity that can cause damage to the centrally crossing spinothalamic neurons and anterior horn cells of the affected levels.

Other diagnoses that should be considered

Brain causes

Paraplegia can sometimes be caused by a parasagittal meningioma, bilateral cerebral disease (commonly vascular or demyelinating), or brainstem lesions. If no cause can be found on investigation of the spine, brain imaging should be considered.

Muscle and neuromuscular junction causes

Just weakness of the legs (particularly proximal and symmetrical) with no sensory symptoms or signs might lead to a consideration of muscle disease (relatively rare) and, if there is variable weakness which is worse as the legs are used, consider myasthenia. If a myasthenic syndrome is considered, pay particular attention to the deep tendon reflexes, which are normal in myasthenia gravis but depressed yet augment on isometric contraction in Lambert–Eaton myasthenic syndrome.

Further hereditary conditions

Other genetic causes like the X-linked recessive condition of adrenoleukodystrophy (adrenomyeloneuropathy) can cause a progressive spastic paraparesis in association with adrenal insufficiency and possible peripheral neuropathy (decreased reflexes). Very long chain fatty acids will provide the diagnosis.

Musculoskeletal

If bilateral leg weakness in association with hip pain is present, the cause might also be found in the skeletal structures, like severe bilateral osteoarthritis of the hip.

'Gold-standard' diagnostic test

Ideally, an MRI with gadolinium of the clinically suspected area of the spinal cord should be undertaken. Sometimes imaging of the entire spinal cord is needed. A lumbar puncture can help further if no compressive cause can be elicited. Often, however, in practice, a plain MRI is undertaken in first instance. An MRI will not only show whether there is reduction in CSF space around a specific area of the spinal cord, suggesting a compressive problem, but it can also demonstrate myelopathic changes (high signal intensity on T2-weighted imaging). In non-compressive lesions, gadolinium enhancement would indicate an inflammatory cause, but can also be seen in neoplastic lesions. The absence of gadolinium enhancement together with an absence of pleocytosis or oligoclonal bands on CSF examination should lead to consideration of non-inflammatory causes like ischaemia or post-radiation myelopathy, or rarer occurrences like fibrocartilaginous embolism.

Acceptable diagnostic alternatives to the gold standard

In situations where MRI imaging is not available or contraindicated or where the patient, due to pain or claustrophobia, is not able to lie still for the approximately 10 minutes required to perform the imaging, CT myelography provides an alternative. In contrast to plain CT imaging, which cannot visualize the spinal cord or nerve roots due to their similar densities compared to CSF, CT myelography allows evaluation of cord or nerve root compression by intrathecal administration of iodine. However, this benefit comes with risks of an allergic reaction to the contrast material, as well as potential complications of lumbar punctures like low pressure headache, aseptic meningitis, spinal hematoma, and arachnoiditis (inflammation of the arachnoid membrane that can lead to scarring and adhesions of spinal nerves with subsequent pain and focal neurological symptoms). CT myelography is useful in determining a compressive cause but, due to its inability to assess the spinal cord itself, it does not play a role in the differential diagnosis of non-compressive myelopathy. For surgical cases, however, it has an advantage over MRI in visualizing the bony anatomy more accurately.

Other relevant investigations

If initial investigations point towards an inflammatory origin, further MRI imaging of the brain might be indicated to determine whether the process is multifocal (e.g. multiple sclerosis, or acute disseminated encephalomyelopathy). Visual evoked potentials might also be useful in order to evaluate optic nerve involvement (neuromyelitis optica, multiple sclerosis).

If an infection is suspected, or generally in immunocompromised patients, HIV status, spinal fluid viral PCR, and VDRL (Venereal Disease Research Laboratory, syphilis), as well as bacterial and possibly fungal CSF cultures should be considered, in addition to TB screening and HTLV-1 serology.

If there are further clinical features of autoimmune problems, an autoimmune antibody screen (antinuclear antibodies, complement levels, double-stranded DNA, SS-A, SS-B, ACE, anticardiolipin, lupus anticoagulant) should be considered.

Vitamin B₁₂, methylmalonic acid, homocysteine, copper, and vitamin E levels might be indicated.

If the MRI shows a vascular anomaly (e.g. an arteriovenous dural fistula), then selective formal angiography can lead to diagnostic certainty and embolization treatment.

Prognosis, and how to estimate it

The prognosis for the individual patient is often difficult to determine.

Curable

Subacute combined degeneration of the cord (vitamin B₁₂ deficiency) stops progressing, if treated. The prognosis is better in the absence of a sensory level and extensor plantar response, as well as with younger age and shorter duration. Cord atrophy and extended cord

involvement (>7 segments) on imaging carry a poorer neurological prognosis.

Treatable: Medical

Acute transverse myelitis seems to have a better prognosis if the patient is younger, the onset of symptoms was slower (over days to weeks), recovery started earlier, and posterior column function (vibration, joint position sense), and deep tendon reflexes are spared. An acute onset of severe symptoms without recovery after 3 months, as well as the presence of incontinence and a cervical sensory level, seem to have a poorer prognosis. In addition, a positive CSF protein 14-3-3 (also found in CJD) has been associated with a poor prognosis.

The majority of idiopathic acute transverse myelitis and infectious or para-infectious myelitis run a monophasic course.

Neuromyelitis optica (NMO antibody positive with long spinal cord lesions, extending over three or more vertebral levels, and complete transverse myelitis, e.g. symmetrical motor and sensory deficits) tends to have a high risk (50%) of recurrence.

Further lesions on brain imaging and the presence of incomplete transverse myelitis (e.g. asymmetric incomplete loss of tracts) places patients at higher risk of being diagnosed with multiple sclerosis later on (88% within 20 years in the case of two or more typical multiple sclerosis brain lesions).

Treatable: Surgical

Cervical spondylotic myelopathy seems to ultimately progress in the majority of cases, whereas lumbar spinal stenosis seems to stabilize in the majority.

The prognosis of syringomyelia depends on the underlying cause (e.g. secondary to tumour vs secondary to trauma), as well as the degree of neurological deficit. The worse the deficit, the worse is the prognosis.

Palliative

Familial spastic paraparesis tends to slowly progress without affecting overall life expectancy. In contrast, motor neuron disease tends to lead to death within a few years.

Treatment and its effectiveness

Specific

Medical

No randomized controlled trials have been undertaken with regards to treatment in acute transverse myelitis (Table 233.3). High-dose IV steroids (methylprednisolone 1 g/day for 3–5 days) are usually given early in the disease course. Overall, 60%–70% of cases will improve completely or partially in the end.

In neuromyelitis optica, subsequent treatment with long-term immunosuppression, especially azathioprine, alone or with prednisolone, reduces the relapse frequency.

Subacute combined degeneration of the cord (vitamin B₁₂ deficiency) tends to respond well to cobalamin injections, but neurological improvement can take up to 6–12 months.

Table 233.3 Symptomatic pharmacological treatment options

Spasticity	Diazepam: 2 mg twice daily to max 60 mg daily Baclofen: 5 mg twice daily to 40 mg three times per day Dantrolene: 25 mg twice daily to 100 mg four times per day Tizanidine: 2 mg daily to 8 mg three times per day
Neuropathic pain	Amitriptyline: 10–20 mg to 75 mg daily Nortriptyline: 10–20 mg to 75 mg daily Gabapentin: 300 mg daily to 1200 mg three times per day Pregabalin: 75 mg twice daily to 200 mg three times per day
To facilitate bladder emptying	Prazosin: 1 mg twice daily to 2 mg three times per day Tamsulosin: 0.4 mg daily
Urge incontinence/frequency	Oxybutynin: 2.5 mg daily to 5 mg four times per day Tolterodine: 2 mg daily Imipramine: 25 mg to 75 mg daily

Surgical

A recent Cochrane review on the treatment of cervical spondylotic myelopathy did not provide reliable evidence with regards to long-term effects for surgical intervention over conservative management. But, especially in progressive markedly symptomatic cases, a neuro-surgical referral is indicated.

Lumbar spinal stenosis due to its degenerative character is unlikely to be cured by surgery, and symptoms often tend to plateau. In cases of paresis or cauda equina syndrome, surgical intervention is indicated, however.

For cauda equina syndrome, early surgical intervention within 24 hours seems to provide a better outcome, at least for incomplete syndromes without urinary retention.

There are a number of surgical interventions available for syringomyelia, ranging from suboccipital/cervical decompression over cervical laminectomy to shunting procedures. Outcome depends on the underlying cause for the syrinx.

Non-specific

The most common non-specific problems will be that of spasticity, bladder problems, and neuropathic pain. General measures like physiotherapy are important with regards to spasticity, in addition to pharmacological treatment (Table 233.3). If spasticity is localized, then focal botulinum toxin injections might be of benefit. In case of ongoing bladder problems, intermittent self catheterization or a permanent urinary/suprapubic catheter might be needed. Neuropathic pain can be difficult to control.

234 Neuropathy

Liberty Jenkins

Definition of the disease

Neuropathy is disease of the peripheral nerve. The pathological process may affect the nerve at the root (radiculopathy), the dorsal root ganglion (ganglionopathy), the plexus (plexopathy), or anywhere along the terminal pathway, typically at sites of entrapment or in a length-dependent pattern. The cranial nerves may also be affected. The process may affect a single nerve (a mononeuropathy) or multiple discrete nerves (mononeuritis multiplex) or form a confluent, typically distal, and symmetrical pattern (polyneuropathy).

Aetiology of the disease

The causes of neuropathy are myriad. It is, therefore, pragmatic to approach the etiological diagnosis according to the clinical pattern, which is considered primarily in terms of the temporal course and its distribution. The predominance of symptoms, be they sensory, motor, or autonomic, may be also be helpful (Table 234.1). Any history of a general medical disorder or its treatment may be relevant.

Acute mononeuropathies are commonly due to pressure palsy or trauma, but a spontaneous lesion occurring at a site atypical for entrapment should raise the possibility of vasculitis. This is the commonest cause of acute mononeuritis multiplex. Acute symmetrical polyneuropathy, although rare, is a medical emergency, as death may occur from rapidly ensuing neuromuscular respiratory failure or dysautonomia. Table 234.2 summarizes the commoner causes of acute neuropathies.

Chronic peripheral neuropathies are common. Acquired causes (Table 234.3) may be easily identifiable from the history, particularly

Table 234.1 Causes of neuropathy by predominant symptomatology

Predominant symptomatology	Cause
Sensory	Diabetes mellitus Alcoholism Vitamin B ₁₂ , B ₁ , and B ₆ deficiency Uraemia Leprosy Paraproteinaemic neuropathies Paraneoplasia Sjögren's syndrome Chronic idiopathic sensory neuropathy
Motor	Charcot-Marie-Tooth disease Guillain-Barré Syndrome Chronic inflammatory demyelinating polyradiculoneuropathy Multifocal motor neuropathy Lead toxicity Acute intermittent porphyria Diphtheria Hereditary distal motor neuropathy
Autonomic and small fibre (pain)	Diabetes mellitus Amyloidosis Fabry's disease Tangier's disease Hereditary sensory and autonomic neuropathy

Table 234.2 Causes of acute neuropathies

Mononeuritis multiplex	Vasculitis (primary systemic; systemic secondary to associated connective tissue disease, infection, or malignancy; or non-systemic, being confined to the peripheral nervous system) Diabetes mellitus Sarcoidosis Lyme disease Lymphomatous or carcinomatous infiltration Amyloidosis Leprosy Multiple pressure palsies, including hereditary neuropathy with liability to pressure palsies (although rarely acute)
Generalized polyneuropathy	Guillain-Barré syndrome Vasculitis Toxic or drug-induced acute neuropathy Critical illness neuropathy Thiamine deficiency Diabetes mellitus Acute intermittent porphyria Sarcoidosis Lymphomatous neuropathy Rabies Diphtheria

in the context of diabetes, alcohol misuse, or certain drugs, as these account for the majority of cases in primary care. Nutritional deficiencies and metabolic, haematological, or endocrine derangements may be identified on simple investigation. Toxin exposure or infection may be relevant: leprosy is the commonest cause of peripheral neuropathy worldwide, while HIV is more frequently encountered in the UK. Paraneoplasia, malignancy, and inflammatory/immune-mediated causes may need particular consideration. Charcot-Marie-Tooth disease is the most frequent hereditary neuropathy. However, neuropathy may also be the sole manifestation of other genetic diseases or form part of a multisystem disorder. No cause is identified in 25% of cases.

Typical symptoms of the disease, and less common symptoms

Symptoms reflect the distribution of the nerve(s) involved and the predominant subpopulation of fibres affected.

Median nerve compression at the wrist (carpal tunnel syndrome) results in intermittent pain and tingling which is worse at night or on use or elevation of the hand and is relieved by shaking. The symptoms are not confined to the median innervated digits (although they are typically worse in these), with the pain often extending above the wrist. Ulnar nerve entrapment at the elbow results in tingling and numbness in the ring finger and the little finger. The degree of

Category	Cause
Hereditary	Charcot–Marie–Tooth disease Hereditary neuropathy with liability to pressure palsies Hereditary sensory and autonomic neuropathy Distal hereditary motor neuropathy Neuropathy associated with hereditary multisystem disease (e.g. metachromatic leukodystrophy, mitochondrial diseases, familial amyloid polyneuropathies, ataxia–telangiectasia)

Category	Cause
Haematological	Paraprotein-associated neuropathy Amyloidosis due to plasma cell dyscrasia or myeloma
Malignancy related	Paraneoplasia Carcinomatous Lymphoma
Inflammatory/immune	Chronic inflammatory demyelinating polyradiculopathy Multifocal motor neuropathy Sarcoidosis Sjögren's syndrome Rheumatoid arthritis
Idiopathic	

associated weakness is variable. Other less common mononeuropathies include radial nerve palsies (wrist and finger drop with impaired sensation over the anatomical snuffbox if occurring in the spiral groove of the humerus; finger drop without sensory disturbance if the lesion is more distal), compression of the lateral cutaneous nerve of the thigh (meralgia paresthetica: tingling and numbness over the lateral aspect of the thigh), and peroneal nerve palsies (foot drop with weak eversion and sensory disturbance affecting the lateral aspect of the lower leg and dorsum of the foot if the superficial branch is involved, or just the web between the first and second toe if the deep branch is solely affected).

Abrupt painful onset of a mononeuropathy or mononeuritis multiplex should raise the suspicion of vasculitis.

In the common chronic symmetrical polyneuropathies, distal paraesthesiae (tingling, prickling, or numbness) predominate. The feet are first affected, with gradual proximal extension prior to any upper limb symptoms, reflecting the length-dependent process. A sense of unsteadiness, particularly in the dark, is common. This 'sensory ataxia' is due to a loss of large-fibre sensory function. Impaired small-fibre function is associated with a prominent, painful, burning dysaesthesia, possibly with impaired autonomic function, resulting in symptoms of postural hypotension and impotence. Neuropathy predominantly or purely affecting the motor fibres is less common, but results in weakness, such that the patient may first complain of tripping when stepping up kerbs, before noticing a change in the sound when walking, with their feet slapping the ground. Later, upper limb involvement may result in difficulty opening jars or turning keys in a lock. Proximal weakness is unusual in neuropathy but can be seen in the rare demyelinating neuropathies. In the acquired form, these may also be distinguishable by a relapsing course. Hereditary neuropathies may be suggested by delayed motor milestones, difficulty fitting shoes, and failing to keep up with peers in school sports.

Acute symmetrical peripheral neuropathy is most commonly caused by Guillain–Barré syndrome (GBS). There is often an antecedent history of gastrointestinal or respiratory infection 1–2 weeks prior to the onset of distal paraesthesiae together with progressive weakness, evolving over hours. Pain, especially lower back pain reflecting radicular involvement, is common. Later onset of facial and bulbar weakness is typical, resulting in slurred speech and difficulty swallowing. The patient is unlikely to have symptoms of respiratory compromise even when neuromuscular respiratory failure is imminent. Autonomic dysfunction is common.

Demographics of the disease

The prevalence of a symptomatic chronic symmetrical peripheral neuropathy is 2400 in 100 000 (2.4%). This increases with age, being approximately 8% in those over 55. Reports of the prevalence in the diabetic population vary, but it is probably in the order of 35%. Charcot–Marie–Tooth disease has prevalence of 40 in 100 000. Carpal tunnel syndrome has a lifetime incidence of 10%. The annual incidence of GBS is 1–2 in 100 000.

Natural history, and complications of the disease

In patients with a chronic symmetrical axonal peripheral neuropathy, treatment of the underlying cause will usually halt progression, but the accumulated axonal damage may persist. In patients in whom investigation fails to identify a specific cause, an indolent course is to be anticipated. In demyelinating neuropathies, be they the acute symmetrical neuropathy of typical GBS or the focal entrapment mononeuropathies, treatment should result in remyelination of the affected segment, resolution of the conduction block, and, hence, a return to normal function. However, recovery of any axonal damage already sustained is protracted: peripheral nerve axons have the capacity to regenerate at a rate of 1 mm per day. Chronic axonal damage is often painful and results in secondary complications of ulceration and injury due to impaired sensory protective measures. The onset of neuropathy in childhood may result in deformity of the feet ('pes cavus').

Approach to diagnosing the disease

Having obtained a suggestive history, the clinical examination should be focused on detecting the classical lower motor neuron signs of a neuropathy. In the case of the common chronic symmetrical neuropathies, wasting of the small muscles of the feet, weakness of toe extension and (often subtly) of ankle dorsiflexion, loss of the ankle jerks, and impaired sensation in a stocking (and, later, glove) distribution should be anticipated with a positive Romberg's test. More widespread areflexia would be atypical and should alert the clinician to the possibility of a more unusual pathogenesis, such as demyelination. Areflexia is a classic finding in GBS but may not be present in the early stages. Wasting is not a feature of the acute neuropathies, typically taking weeks to months to develop. If the history is suggestive of a mononeuropathy or mononeuritis multiplex, then the function of the individual nerves should be mapped out. A general medical examination is imperative. Once a clinical diagnosis of a neuropathy has been established, investigations should be tailored appropriately.

Other diagnoses that should be considered

The cardinal history of distal numbness and paraesthesiae is strongly suggestive of peripheral neuropathy but, rarely, may reflect pathology of the CNS, particularly a myelopathy. Transient episodes of paraesthesia may also occur in hyperventilation. Distal weakness of the legs may infrequently be due to bilateral L5 radiculopathies. Distal myopathies are an even rarer cause. If proximal weakness is present, however, then myopathy or polyradiculopathy must be actively considered. Small-fibre neuropathies typically have a paucity of signs, and the pain needs to be distinguished from that arising from ischaemia or musculoskeletal disease.

'Gold-standard' diagnostic test

Nerve biopsy demonstrating typical pathological changes of the underlying process can be definitively diagnostic. However, demonstrating established non-specific axonal damage will not further the diagnostic process, and the procedure is not without associated morbidity. As such, biopsy is only performed in carefully selected cases, particularly where vasculitis is suspected and prompt but potentially toxic treatment is to be instigated.

Acceptable diagnostic alternatives to the gold standard

In the vast majority of cases, neurophysiological assessment is a satisfactory alternative, enabling the extent and type of neuropathy to be established (the principle aim being to distinguish the potentially specifically treatable demyelinating neuropathies from the axonal neuropathies). The motor and sensory function of accessible nerves can be studied using nerve conduction techniques to assess for points of entrapment, axonal loss, or demyelination. More proximal nerves can be studied indirectly by looking for secondary changes in the muscle as a result of denervation, using electromyography. The standard testing protocols are unable to assess small-fibre function and are normal in these cases. A typical history is usually sufficient.

Other relevant investigations

Given the multitudinous potential causes of a chronic symmetrical peripheral neuropathy, a staged approach to the investigations is recommended. A clinical diagnosis without investigation is appropriate in typical and proportional cases with a predictable cause, such as diabetes. All other patients should initially undergo the investigations in Table 234.4, Section A. If these fail to identify a cause or the case appears atypical, then specialist opinion should be sought. Of the second-tier investigations (Table 234.4, Section B), neurophysiological assessment is paramount. A third stage of investigations (Table 234.4, Section C) is performed selectively and reflects whether a demyelinating or axonal neuropathy has been identified electrophysiologically.

Acute symmetrical neuropathy requires urgent specialist investigation. Frequent vital capacity and cardiac monitoring are essential. In addition to routine medical investigations, specialist tests are likely to include those in Table 234.4, Section D.

Neurophysiological assessment provides the lynchpin of mononeuropathy investigation. Focused investigation for vasculitis should be rapidly instigated in cases of acute painful onset multiple mononeuropathies, together with a lower threshold for nerve biopsy.

Prognosis and how to estimate it

In general, recovery of axonal damage is protracted and often incomplete or with aberrant reinnervation. Clinically, this means that recovery is unlikely if marked muscle wasting is present or in proximal axonotmesis lesions. Neurophysiology can provide a more quantitative tool to guide prognosis, giving an indication of the pathophysiological process, degree of axonal damage, and secondary reinnervation that has occurred. In the established chronic axonal peripheral neuropathies, a guarded prognosis is recommended even on reversal of the cause, with the principle aim being to prevent progression. Conversely, should the neurophysiology show a purely demyelinating neuropathy, be it focal at a point of entrapment or generalized, one can be optimistic that treatment will be effective.

In GBS, poor prognostic factors include advanced age, onset following campylobacter infection, rapid onset and progression, severe muscular weakness, and the axonal variant.

Treatment and its effectiveness

The mainstay of treatment is reversal of the underlying cause.

Recognition of the demyelinating neuropathies is important, as specific treatment is effective. In chronic inflammatory demyelinating polyradiculoneuropathy, administration of corticosteroids, IV immunoglobulin, or plasma exchange is usually efficacious, with other immunosuppressive drugs used in refractory cases. In GBS, supportive medical care is paramount. IV immunoglobulin (or plasma exchange) hastens recovery and reduces long-term disability. Vasculitic neuropathy is commonly treated with a combination of corticosteroids and cyclophosphamide. Entrapment neuropathies may respond to conservative measures. In carpal tunnel syndrome, wrist splints and steroid injections may suffice, as may measures to prevent further insult to the nerve, for instance not leaning on the elbow in ulnar nerve entrapments. Persistent symptoms should prompt referral for consideration of surgical decompression.

Generic treatments to limit secondary complications include foot care, orthoses, and walking aids. Neuropathic pain is common and often responsive to a number of agents, including tricyclic antidepressants, duloxetine, and gabapentin. Autonomic features may be symptomatically ameliorated with compression stockings, raising the head of the bed, and sildenafil.

235 Myopathy

Liberty Jenkins

Definition of the disease

Myopathy refers to disease of skeletal muscle, which may be accompanied by cardiac or smooth muscle involvement.

Aetiology of the disease

The myopathies are a heterogeneous group of conditions of myriad and diverse aetiology. Box 235.1 provides a structure by which to classify these. An initial attempt to narrow the etiological diagnosis must be made, as no such list is exhaustive or of particular use to the clinician if approached blindly. Attention to the age of onset, family history, rate of progression or fluctuation, and any associated systemic disease or its treatment is, therefore, crucial.

In clinical practice, the commonest causes of significant secondary myopathy are alcohol misuse, corticosteroid administration (which results in a painless, slowly progressive myopathy with normal plasma creatine kinase (CK)), and, increasingly, statin-related myopathy. The latter may be associated with problems ranging from an asymptomatic raised CK, requiring no alteration in management, to significant myalgia and cramps, to acute necrosis with rhabdomyolysis. The inflammatory myopathies are treatable and, hence, an important diagnosis to consider. They may occur in isolation or in the context of systemic connective tissue diseases.

Typical symptoms of the disease, and less common symptoms

Muscle has a limited repertoire of response to damage, regardless of the causative insult. In the vast majority of cases, this is limited to **weakness** of the affected muscles. The **distribution** of this weakness may be suggestive of a specific diagnosis, particularly in the primary muscle diseases (be they inherited or acquired), but a non-specific pattern of symmetrical proximal limb-girdle weakness is much more common. The patient describes difficulty using the arms above shoulder height, such as when washing their hair or reaching up into cupboards, and of the legs, when rising from a chair or climbing stairs. The walk may be described as 'waddling'. In the secondary myopathies, the symptomatic weakness is typically restricted to this, but more widespread symptomatology may be present in the primary myopathies. Facial or bulbar weakness results in indistinct speech, weak eye closure, ptosis, difficulty using a straw, whistling, and swallowing. Distal weakness is uncommon but manifests as difficulty turning door handles or keys in a lock, and catching the toes when walking due to foot drop. Weakness of the ocular muscles may be seen on examination, but is infrequently symptomatic: complaints of double vision should raise the possibility of myasthenia gravis. Respiratory muscle weakness manifests as orthopnoea, excessive daytime sleepiness, and morning headache (due to hypercapnoea). Symptoms due to cardiac muscle involvement are those of heart failure and dysrhythmia, with dyspnoea, peripheral oedema, palpitations, and syncope.

The rate of **progression** of the weakness may be acute (as in some toxic myopathies and, infrequently, in the inflammatory myopathies), subacute (more typical of inflammatory cases and other secondary myopathies), or chronically progressive (as in the dystrophies). Alternatively, the weakness may be static over time (most congenital myopathies) or may be episodic, with or without insidious underlying progression (metabolic myopathies and channelopathies). The **age at onset** of the weakness may be indicated by reduced fetal movements, a 'floppy' baby at birth, poor feeding or respiratory

Box 235.1 Causes of myopathy

Primary muscle diseases

Inherited

- muscular dystrophies:
 - dystrophinopathies (Duchenne muscular dystrophy and Becker's muscular dystrophy)
 - myotonic dystrophy (types 1 and 2)
 - limb-girdle muscular dystrophy (types 1A–G and 2A–K)
 - Emery–Dreifuss muscular dystrophy
 - oculopharyngeal muscular dystrophy
 - facioscapulohumeral muscular dystrophy
 - scapulohumeral muscular dystrophy
 - congenital muscular dystrophies (including collagen VI disorders (e.g. Ullrich congenital muscular dystrophy, Bethlem myopathy), laminin- α -2 deficiency, Walker–Warburg syndrome, muscle–eye–brain disease, Fukuyama congenital muscular dystrophy, rigid spine syndrome)
 - distal myopathies/dystrophies (including Udd myopathy, Nonaka myopathy, Myoshi myopathy, Laing distal myopathy, and Welander distal myopathy)
- congenital myopathies:
 - central core disease
 - nemaline rod myopathy
 - myotubular myopathy
 - mini-core myopathy
 - type 1 fibre predominance
- metabolic myopathies:
 - mitochondrial disorders (including chronic progressive external ophthalmoplegia, Kearns–Sayre syndrome, MELAS, MERRF, Leber's hereditary optic neuropathy, and Leigh's syndrome)
 - disorders of beta oxidation (including carnitine pantoic acid transferase deficiency and VLCAD)
 - disorders of carbohydrate metabolism (including acid maltase deficiency (Pompe's disease) and myophosphorylase deficiency (McArdle's disease))
- channelopathies:
 - periodic paralyses (hypo- or hyperkalaemic, and Andersen–Tawil syndrome)
 - myotonia congenita (Thomsen disease and Becker's muscular dystrophy)
 - paramyotonia congenita
 - potassium-aggravated myotonia
 - malignant hyperthermia
 - central core disease

Acquired

- inflammatory:
 - dermatomyositis
 - polymyositis
 - inclusion body myositis

Secondary muscle diseases

- toxic and drug induced:
 - alcohol
 - amiodarone
 - amphetamines
 - ciclosporin
 - cimetidine
 - cocaine
 - corticosteroids

Box 235.1 (Continued)

- fibrates
- gemfibrozil
- gold
- heroin
- hydralazine
- isoniazid
- labetalol
- lithium
- L-tryptophan
- nifedipine
- penicillamine
- procainamide
- propofol
- quetiapine
- salbutamol
- statins
- vincristine
- zidovudine
- endocrine derangement
 - thyroid disease (hypo- or hyperthyroidism)
 - adrenal disease (hypo- or hyperadrenalism)
 - vitamin D deficiency (osteomalacia)
 - hyperparathyroidism
 - hypopituitarism
 - acromegaly
- infective
 - viral (Coxsackie virus, influenza virus, parainfluenza virus, HIV, HTLV1, adenovirus, echovirus, CMV, herpes simplex, EBV)
 - bacterial (*Staphylococcus aureus*, *Streptococcus viridans*, *Streptococcus pyogenes*, *Streptococcus pneumoniae*), *Salmonella enteritidis*, *Klebsiella pneumoniae*, *Clostridium freundii*, bartonella, *Escherichia coli*, *Pseudomonas aeruginosa*, neisseria, yersinia, *Morganella morganii*, citrobacter, mycobacterium avium-intracellulare complex)
 - parasitic (cysticercosis, trypanosomiasis, Lyme disease, trichinosis, toxoplasmosis, toxocarasis, amoebiasis, echinococcosis)
 - fungal (cryptococcus, candida, histoplasma, coccidioides, aspergillus, pneumocystis, fusarium, actinomyces)
- electrolyte disturbance
 - hyper- or hypokalaemia
 - hypercalcaemia
 - hyper- or hypomagnesaemia
- inflammatory myopathy associated with connective tissue disease:
 - SLE
 - mixed connective tissue disease
 - scleroderma
 - Sjögren's syndrome
 - rheumatoid arthritis
- miscellaneous causes of inflammatory myopathy:
 - eosinophilic myositis
 - vasculitis associated with granulomatosis (sarcoidosis)
 - graft versus host disease
 - macrophage myofascitis

Abbreviations: CMV, cytomegalovirus; MELAS, mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes; MERRF, myoclonic epilepsy with ragged red fibres; VCLAD, very long-chain acyl-coenzyme A dehydrogenase deficiency; HTLV1, human T-lymphotrophic virus 1.

effort, delayed motor milestones, failure to keep up with peers in school sports, or normal achievement until later in life.

Myalgia is common complaint in general practice, but muscular pain is, in fact, a relatively rare feature of the myopathies. It is reported by some patients with inflammatory myopathy and myotonic dystrophy, and, more frequently, in the toxic myopathies and those associated with hypothyroidism and vitamin D deficiency. Transient myalgia is common in the context of systemic infection.

Episodic pain with myoglobinuria (dark 'coca-cola' coloured urine) is a particular feature of the metabolic myopathies but occurs with other causes of rhabdomyolysis.

Other symptoms of muscle disease are rare but may be more specific with regards to aetiology. Patients may report marked muscle **stiffness** (to be distinguished from common mild symptoms) due to myotonia. **Cramps** are more frequently a neurogenic symptom but occur in certain drug and metabolic myopathies. **Enlargement** of the muscles, most often of the calves, may result in difficulty fitting clothes. Pseudohypertrophy is marked in Duchenne muscular dystrophy and Becker's muscular dystrophy. True hypertrophy is rare but occurs in myotonia congenita and neuromyotonia. **Wasting** is common to many muscle diseases. A careful systemic enquiry is essential to identify **non-myopathic symptoms**. These may indicate a specific diagnosis and include, for example, those due to neuropathy, CNS disease, cataracts, retinopathy, endocrine dysfunction, or rash.

Demographics of the disease

There are approximately 50 000 people in the UK with a primary muscle disease. Many more have secondary muscle dysfunction but the prevalence is unknown. Duchenne muscular dystrophy is the commonest childhood-onset dystrophy, with an incidence of 1 in 3300 boys. Myotonic dystrophy occurs in 1 in 8000 people. The inflammatory myopathies have an incidence of approximately 5–10 in 100 000. Inclusion body myositis is the commonest primary myopathy in those over 50.

Natural history, and complications of the disease

The natural history depends on the etiological diagnosis. The spectrum ranges from transient, self-limiting symptoms to death in infancy. In the majority of patients with a secondary myopathy, reversal of the cause will ensure gradual restoration of normal muscle function. Inexorably progressive muscular weakness, regardless of aetiology, results in loss of mobility with the predictable **skeletal** complications of kyphoscoliosis (restricting respiratory function); contractures (although prominent, early contractures are a particular feature of some genetic myopathies); and skin damage. Pre-emptive management is required. **Respiratory** failure due to diaphragmatic weakness may be the presenting feature of the myopathy (as occurs in some inherited myopathies and occasional cases associated with hyperthyroidism or electrolyte dysfunction) or occur late in the disease. Interstitial lung disease complicates 10% of autoimmune inflammatory myopathies. **Cardiac** involvement, with heart failure and/or dysrhythmias, is common in specific genetic myopathies, and may be disproportionate to the limb weakness, but also occurs in secondary myopathies. Underlying **malignancy** is present in approximately 25% of patients with dermatomyositis (the association with polymyositis is weaker): screening is recommended in treatment-resistant cases in patients over the age of 40. **Rhabdomyolysis** may complicate acute severe muscle damage of any cause, with life-threatening renal complications, metabolic disturbance, and disseminated intravascular coagulation. **Malignant hyperthermia** is the commonest cause of death during general anaesthesia. Similar reactions may be seen in certain channelopathies, dystrophies, and metabolic muscle disease.

Approach to diagnosing the disease

Having established a suggestive history, the clinical examination should be focused on detecting the cardinal lower motor neuron signs of a myopathy. The classical clinical picture is of symmetrical proximal wasting (if chronic) and weakness. The pelvic girdle is more severely affected than the shoulder. The reflexes are preserved (except in advanced disease) and the sensory examination is normal. Functional assessment, for example the ability to stand from sitting, may be more useful than the documented Medical Research Council score in assessing this. Facial weakness is usually symmetrical and may

be missed (look for failure to 'bury the eyelashes' on eye closure). Distal weakness is rare. However, weakness of the finger flexors and quadriceps is a hallmark of inclusion body myositis, and selective muscle weakness is a remarkable feature of the dystrophies. Muscle bulk, abnormal movements, contractures, and myotonia should be specifically examined for. A detailed general medical examination is imperative.

Given a clinical picture consistent with a myopathy, it is sensible to review parts of the history or examination that may narrow the differential diagnosis. If a satisfactorily explanatory secondary cause is apparent, then further investigation is unnecessary. In others cases, simple blood tests may suffice. In complex cases or where a primary muscle disease is suspected, early referral to a neurologist is warranted.

Other diagnoses that should be considered

The main differential diagnoses to be considered are other causes of lower motor neuron muscular weakness. Pure motor syndromes are likely to cause the greatest diagnostic challenge. Fatigable weakness is the hallmark of neuromuscular junction disorders, such as myasthenia gravis. Diplopia with complex external ophthalmoplegia is highly suggestive of this. Lambert–Eaton myasthenic syndrome is a rare disorder but typically presents with symmetrical leg weakness. The reflexes are absent on initial examination, being 'potentiated' by muscular contraction. Weakness with evidence of denervation (fasciculations and impaired deep tendon reflexes) and coexisting upper motor neuron signs is consistent with motor neuron disease, which is rarely as symmetrical as the classical myopathy picture. Spinal muscular atrophy may be difficult to distinguish clinically, especially in the neonatal population, but signs of denervation will again be present. Pure motor neuropathies are unusual, and the presence of any sensory symptoms is obviously inconsistent with a myopathy. In a neuropathy, the clinical picture is predominantly distal, and the reflexes are reduced or absent. Bilateral radiculopathies may result in proximal weakness but are associated with dermatomal sensory disturbance and loss of the innervated reflex arc. Upper motor neuron lesions are rarely troublesome but the asymmetry of some genetic myopathies, such as facioscapulohumeral dystrophy, may initially be misleading.

In general practice, symptoms of muscle pain, weariness, or fatigue are extremely common. The absence of demonstrable weakness (with a normal CK and no history of myoglobinuria) makes an underlying myopathy unlikely. Fibromyalgia or chronic fatigue syndrome may need to be considered. Ill-defined global muscle dysfunction is common in the elderly, the immobile, and those with critical illness or cancer but rarely requires investigation in its own right.

'Gold-standard' diagnostic test

There is no single test that can be considered the 'gold standard'. In certain inherited myopathies, genetic testing or a specific enzyme assay is the only investigation required and can be considered 'first line' in the appropriate clinical setting. In other myopathies, muscle biopsy with immunohistochemical staining will prove definitively diagnostic. Selecting which muscle to biopsy is important: close collaboration with a muscle pathologist is essential. A histologically proven diagnosis should be considered a prerequisite in inflammatory myopathies, where potentially toxic immunotherapy is to be instigated.

Acceptable diagnostic alternatives to the gold standard

CK is useful as a non-specific marker of muscle damage. However, the degree of elevation is not a reliable indicator of the aetiology, or, in some cases, the severity (but changes in the level may be helpful in monitoring treatment response if used together with clinical

observation). Potentially misleading elevations are also 'normal' in Afro-Caribbeans, trauma, sepsis, exercise, hypothermia, myocardial injury, and severe denervating disorders.

Electromyography can also be useful but has similar caveats: the electrophysiological features of a myopathy are qualitative and non-specific. Neurophysiological assessment may, however, be valuable in excluding neuromuscular junction and neurogenic disorders and may identify myotonic discharges. Specific protocols are used in the assessment of the periodic paralyses.

Other relevant investigations

Given the multitudinous potential causes, directed, successive investigation is essential. Sensible 'screening' investigations include CK; full blood count; urea; electrolytes, including calcium, phosphate, and magnesium; liver function tests; and thyroid stimulating hormone. Other blood tests that may be pertinent include inflammatory markers, anti-nuclear factor, lactate, parathyroid hormone, vitamin D, cortisol, pituitary function tests, and serology, including HIV testing. Urinalysis for myoglobinuria is useful in an acute attack. Additional specialist tests are probably best deferred to the neurologist or geneticist but may include specific assays for metabolic muscle disease, molecular genetics, MRI, and muscle biopsy. In myopathy patients at risk of cardiac or respiratory disease, regular electrocardiograms, echocardiograms, and vital-capacity monitoring are essential.

Prognosis and how to estimate it

Prognosis depends on the specific diagnosis. The inherited myopathies are incurable but life expectancy and disability vary widely, even, in some cases, within the same genotype. The majority are slowly progressive degenerative conditions. Boys with Duchenne muscular dystrophy are now surviving into adulthood but are rarely ambulant beyond the age of 12. Most patients with dermatomyositis and polymyositis are responsive to treatment, but a poorer prognosis is seen in older patients and those with underlying malignancy or associated respiratory or cardiac disease. Inclusion body myositis is chronically progressive and generally resistant to all therapy. Secondary myopathies are usually reversible on treatment of their underlying cause.

Treatment and its effectiveness

Specific treatments are available for a minority of myopathies. Corticosteroids form the mainstay of dermatomyositis and polymyositis treatment. An alternate day regime reduces side effects. Which steroid-sparing immunosuppressant is superior is unclear but methotrexate and azathioprine are most widely used. Steroids are now also frequently used in Duchenne muscular dystrophy. Respiratory and cardiac interventions prolong life expectancy. Exon skipping antisense oligonucleotide therapies are appropriate in some. Enzyme-replacement therapy is available for acid maltase deficiency. Several agents, particularly mexiletine, may be useful for myotonia. In a number of the metabolic myopathies and periodic paralyses, the frequency of attacks may be reduced with preventative measures. In most secondary myopathies, treatment of the underlying cause is effective. The management of rhabdomyolysis is largely supportive, with correction of the fluid and electrolyte abnormalities.

Generic treatment strategies to limit the complications of muscle disease are essential and require a well-integrated multidisciplinary team. Exercise, nutritional support, mobility aids, pain management, and skin care are all important. Surgical intervention for kyphoscoliosis and contractures may be required. Genetic counselling should be offered where appropriate.

236 Vasculitis in neurology

Ben Wakerley

Definition

Vasculitis syndromes are characterized by inflammation of blood vessel walls, which may result in interruption of blood flow with resulting ischaemia or haemorrhage. Patients present with a variety of systemic and neurological symptoms which relate to the size and location of affected vessels.

Classification

Size (large, medium, small) and location (systemic, CNS, peripheral nervous system (PNS)) of affected vessels determine the symptoms associated with each specific vasculitis syndrome. Primary vasculitis occurs in isolation whereas secondary vasculitis is associated with underlying connective tissue disorders or infections (see Box 236.1).

Clinical manifestations

Clinical features vary considerably depending on which vessels are involved, and in each case specific differential diagnoses should be excluded. Localized visceral symptoms, relate to vessel size and location. Large and medium vessel vasculitis results in organ damage more often associated with ischaemia or haemorrhage and may mimic stroke or arterial occlusion. Small vessel vasculitis commonly affects the skin, kidneys, and peripheral nerves. Systemic manifestations of inflammation may include unexplained fever, generalized fatigue, and weight loss but are not always present.

Box 236.1 Classification of vasculitis

Primary

Large vessel vasculitis

- Takayasu arteritis
- giant cell arteritis

Medium vessel vasculitis

- polyarteritis nodosum
- Kawasaki disease
- primary angiitis of the CNS

Small vessel vasculitis

- microscopic polyangiitis
- Wegener's granulomatosis (granulomatosis with polyangiitis)
- Churg–Strauss syndrome
- Henoch–Schönlein purpura
- essential cryoglobulinaemic vasculitis
- non-systemic vasculitic neuropathy

Secondary

Connective tissue diseases

- SLE
- rheumatoid arthritis
- relapsing polychondritis
- Behçet's disease

Viral infections

- hepatitis B
- hepatitis C
- HIV
- CMV
- EBV
- parvovirus

Vasculitic strokes/encephalopathy

CNS vasculitis usually presents in one of two ways, depending on the distribution and size of vessels involved:

- stroke-like episodes indicate focal neurological deficit and occur with large vessel disease
- encephalopathy (reduced cognition, altered mental state, headaches and personality change) indicates more global neurological dysfunction and occurs with small vessel disease

Often, there is evidence of both processes and, in many cases, headache is the presenting feature with seizures occurring at any stage of disease.

Vasculitic neuropathy

Vasculitic neuropathy presents in three distinct patterns: mononeuritis multiplex, polyneuropathy, or radiculopathy/plexopathy. Onset can be abrupt or insidious and altered sensation and motor weakness is usually associated with pain.

Mononeuritis multiplex

Mononeuritis multiplex is the commonest presentation of vasculitic neuropathy and is defined as nerve damage in two or more peripheral nerves in separate parts of the body. The frequency of nerve involvement is length dependent, and involvement of the sciatic nerve, causing foot drop, is common. Other nerves commonly affected include the tibial, ulnar, and median nerves. With disease progression, other nerves may become involved and mimic symmetrical polyneuropathy.

Polyneuropathy

Vasculitic polyneuropathy is often difficult to distinguish from other distal symmetrical polyneuropathies.

Radiculopathy/plexopathy

When symptoms cannot be attributed to a single nerve then radiculopathy or plexopathy should be considered. This may be a feature of polyarteritis nodosa.

Diagnostic approach

Vasculitis is usually progressive but can be controlled with appropriate immunotherapy, which makes early diagnosis and treatment imperative. Vasculitis can be difficult to diagnose and may mimic other conditions; therefore, a detailed history and careful examination, including systems review, is essential. Serological tests and biopsy specimens are frequently negative, and imaging, including MRI and arteriography, can be non-specific. Important considerations to guide further investigations are:

- are symptoms limited to the nervous system or is there evidence of systemic disease (e.g. weight loss, fever, fatigue, hypertension, renal failure, skin rashes)?
- are there any features to suggest that vasculitis could be secondary to an atypical infection, connective tissue disease, or malignancy?

Investigations

All patients should have the following routine investigations:

- bloods (full blood count, clotting, urea and electrolytes, liver function tests, creatine kinase level, erythrocyte sedimentation rate (ESR), and C-reactive protein levels (CRP))
- urinalysis (protein, microscopy for blood cells/casts)
- ECG
- chest X-ray

A vasculitis blood screen is useful and should include antineutrophil cytoplasmic antibody (ANCA; myeloperoxidase (MPO)/proteinase 3 (PR3) if primary vasculitides are suspected or antinuclear antibodies, double-stranded DNA, complement, anti-phospholipid/cardioliipin antibodies, anti-Ro, anti-La, anti-Sm, and rheumatoid factor for those associated with connective tissue disorders.

Blood/urine/tissue cultures to exclude *Treponema pallidum*, *Borrelia burgdorferi*, bartonella, and *Mycoplasma tuberculosis* can be useful.

Those presenting with features of CNS involvement should have CNS imaging (CT, MRI, angiography) and depending on the clinical picture, CSF analysis (microscopy/cell count, protein, glucose, viral PCR) and/or biopsy (temporal artery or brain) may be indicated. Arteriography is more sensitive than magnetic resonance angiography and may reveal beading, skip lesions, aneurysms, occlusions, or vessel wall irregularities in large and medium vessels.

Electroencephalography may demonstrate diffuse encephalopathy or epileptiform activity. Patients with mononeuritis multiplex should have nerve conduction studies and a nerve biopsy. A skin biopsy may determine the cause of a vasculitic rash, while a kidney biopsy is useful if there is renal involvement. A muscle biopsy can also be helpful. Additional blood tests including hepatitis serology, cryoglobulins, and HIV are often indicated.

Arteriography remains the most useful diagnostic test for large and medium vessel vasculitis, while the diagnosis of small vessel disease relies more on the presence of certain antibodies and immune

complexes in the blood and characteristic histology on tissue biopsy (brain, nerve, skin, or kidney).

Differential diagnosis

The differential diagnosis of CNS vasculitis and mononeuritis multiplex is outlined in Box 236.2.

Treatment: General principals

Vasculitis, by definition, has an inflammatory basis and therefore effective treatment only occurs if the immune system is adequately suppressed. In the case of large and medium vessel disease, this can usually be achieved with oral corticosteroids (prednisolone 1 mg/kg per day), which can be slowly reduced over several months once there is clinical and laboratory evidence of remission. Small vessel disease is usually treated with high-dose glucocorticoids (methylprednisolone 1 g for 3 days) followed by oral steroids. Frequently, especially if there is systemic involvement, remission can only be induced with more potent immunosuppressants such as cyclophosphamide or, in some cases, IV immunoglobulin or plasma exchange. Once the patient is in remission, steroid-sparing agents including azathioprine, methotrexate, or mycophenolate may need to be continued for several years. Patients should be carefully followed up to ensure adequate immunosuppression and identification of disease recurrence. Long-term immunosuppression increases the risk of infections and tumour formation, and treating physicians should be aware of drug-specific adverse reactions (Table 236.1). Bone protection is advocated in patients receiving prolonged courses of steroids, and prophylaxis against pneumocystis pneumonia should be considered in patients receiving more potent immunosuppressants.

Specific diseases

Large vessel vasculitis

Large vessel vasculitis affects the aorta and its main branches to the extremities, head, and neck and includes Takayasu arteritis and giant cell arteritis, which is sometimes called temporal arteritis.

Takayasu arteritis

Vessel wall inflammation results in stenotic lesions and aneurysms in the aorta and its major branches to the extremities, head, and neck. Takayasu arteritis is nine times more frequent in women, with peak

Box 236.2 Differential diagnosis of CNS vasculitis and mononeuritis multiplex

CNS vasculitis

Infections:

- bacterial (endocarditis, meningitis, syphilis, TB)
- viral (HIV, CMV, herpes zoster virus)
- fungal (histoplasmosis, aspergillus)

Drug use:

- cocaine
- amphetamines

Haematological causes:

- intravascular lymphoma*
- thrombotic thrombocytopenic purpura

Vasculopathy:

- malignant hypertension
- vasospasm with intracerebral haemorrhage
- radiation damage
- moyamoya disease
- atherosclerosis

Cardiac causes:

- atrial myxoma
- cardioembolic disease

Mononeuritis multiplex

Diabetes

Sarcoidosis

Infections:

- leprosy
- Lyme disease
- HIV
- hepatitis C

Nerve compression:

- multiple compression neuropathies
- hereditary neuropathy with a predisposition to pressure palsy

Multifocal motor neuropathy

Lymphoma

*Intravascular lymphoma is characterized by extra-nodal clonal expansion and proliferation of B-lymphocytes in small vessels, which may occlude, typically affecting the skin and CNS.

Table 236.1 Monitoring and adverse reaction in the treatment of vasculitis

Treatment	Monitoring	Adverse reactions
Steroids	Bone density Blood sugar Ocular pressures	Osteoporosis Diabetes Hypertension Cataract/glaucoma
Cyclophosphamide	Full blood count Liver function tests	Hepatic dysfunction Haemorrhagic cystitis Malignancy Infertility Cytopenia
Azathioprine	Full blood count Liver function tests	Hepatic dysfunction Cytopenia
Methotrexate	Full blood count Liver function tests	Hepatic dysfunction Cytopenia Teratogenic Interstitial pneumonia
IV immunoglobulin	Blood pressure	Hypertension Anaphylaxis Rashes
Plasma exchange	Blood pressure	Vascular instability Line infections

age of onset in the early twenties. Prevalence is highest in Japan and the Middle East.

Patients usually present with systemic features of inflammation and neck pain in conjunction with symptoms associated with ischaemia. Takayasu arteritis should always be considered in young Asian females presenting with stroke-like symptoms.

Symptoms of Takayasu arteritis

The major clinical features of Takayasu arteritis are as follows:

- carotid artery: neck pain, headache (25%), dizziness, visual impairment
- coronary/pulmonary arteries: shortness of breath, atypical chest pain
- subclavian artery: arm fatigue and sensory disturbance
- hypertension
- different blood pressures between arms
- absent/reduced peripheral pulses
- vascular bruits and heart murmurs

Diagnosis of Takayasu arteritis

There are no specific blood tests for Takayasu arteritis, although the presence of raised inflammatory markers correlates well with active disease. Demonstration of arterial damage in the great vessels by arteriography is highly suggestive, although three or more of the following six criteria are needed to establish diagnosis:

- age of onset <40 years
- claudication of extremities
- absent pulses
- difference in blood pressure of 10 mm Hg between arms
- subclavian/abdominal aorta bruits
- arteriographic narrowing of aorta/primary branches

Treatment/prognosis for Takayasu arteritis

In addition to immunosuppression, patients may require surgical intervention (aortic valve replacement, coronary artery bypass grafts, aortic root replacement, arterial grafts), which should be performed when in remission. Early diagnosis and treatment improve prognosis, although the outcome is poorer in patients with renal artery stenosis, aortic coarctation, aortic valve insufficiency, or aneurysms.

Giant cell arteritis

Giant cell arteritis characteristically affects large and medium vessels within the CNS. Histologically, inflamed arteries show evidence of mononuclear/multinucleated giant cell infiltrates. Women are more commonly affected and the age of onset is usually over 50.

The majority of patients feel constitutionally unwell with symptoms relating to ischaemia in large intracranial vessels, although extracranial involvement may also occur.

Symptoms of giant cell arteritis

The major clinical features of giant cell arteritis are:

- scalp tenderness over the temporal artery
- visual impairment (50%)
- jaw claudication
- pain and stiffness around the neck and shoulders, suggestive of polymyalgia rheumatica (30%)

Amaurosis fugax indicates involvement of the posterior ciliary, ophthalmic, or central retinal arteries. Arteritic anterior ischaemic optic neuropathy has a poor prognosis unless treated early and, in 10%–20%, visual loss is permanent. Less commonly, brainstem involvement may present as diplopia, and abdominal pain may occur if there is mesenteric ischaemia.

Diagnosis of giant cell arteritis

Early diagnosis and treatment are imperative if there are visual symptoms. Although giant cell arteritis is an uncommon cause of stroke, raised CRP and ESR confirm ongoing inflammation, and a temporal artery biopsy may confirm diagnosis. Temporal artery biopsies should be carried out before commencing glucocorticoids, if possible, and be >2 cm in length. False negatives are frequently >15% and, in such cases, MRI, ultrasonography, and PET are quite useful. The

diagnosis is established if three or more of the following five criteria are present:

- age of onset > 50 years
- localized new-onset headache
- tenderness over scalp/temporal artery
- ESR > 50 mm
- arterial biopsy showing mononuclear cells/multinucleated giant cells

Treatment/prognosis for giant cell arteritis

Immunosuppression is usually with oral glucocorticoids, although cytotoxic drugs are advocated in resistant cases. It remains unclear whether low-dose aspirin helps reduce cerebral infarcts, which occur in 5% of patients. Prognosis is generally good and after steroid tapering, and treatment is usually complete within 2 years.

Medium vessel vasculitis

Polyarteritis nodosa

Polyarteritis nodosa is a systemic vasculitis characterized by necrotizing vasculitis in medium and small vessels but does not involve arterioles or capillaries and therefore does not cause glomerulonephritis. It is rarer than other forms of vasculitis and typically affects men. There is an association with hepatitis B in Europe and the US.

Symptoms of polyarteritis nodosa

Major clinical findings of polyarteritis nodosa include:

- prolonged fever (>38°C) and weight loss
- rapidly progressive renal failure, hypertension
- **cerebral haemorrhage/infarction (30%)**
- pleurisy
- gastrointestinal haemorrhage/infarction
- mononeuritis multiplex (>50%)
- subcutaneous nodules, purpura, livedo reticularis
- polyarthritides, myositis

Diagnosis of polyarteritis nodosa

There are no specific blood tests for polyarteritis nodosa, although there is an association with HBV and some patients (<20%) have ANCA. Characteristically, multiple aneurysms and strictures are seen in small/medium vessels with arteriography. Tissue biopsy (kidney, muscle, or nerve) demonstrates the presence of fibrinoid necrosis in small/medium vessels and helps to differentiate it from small vessel vasculitis (e.g. microscopic polyangiitis), in which inflammation is also present in capillaries.

Treatment/prognosis of polyarteritis nodosa

Immunosuppression with oral steroids or in some cases cytotoxic drugs is advocated. When in association with hepatitis B virus, then antivirals and plasma exchange may be beneficial. Early treatment improves outcome, although relapse is common (40%).

Kawasaki disease

Kawasaki disease is characterized by vasculitis of large, medium, and small blood vessels, especially those arising from the heart. Typically, it affects children, although cases have been reported in adulthood.

Symptoms of Kawasaki disease

Major clinical features of Kawasaki disease include:

- fever
- conjunctival injection, oral mucous membrane changes, palm erythema/oedema/desquamation, polymorphous rash
- cervical lymphadenopathy
- neurological involvement (stroke, seizures, or myositis; occurs in 1%)
- coronary vasculitis

Treatment of Kawasaki disease

Treatment of Kawasaki disease involves IV immunoglobulins and high-dose aspirin.

Primary angitis of the CNS

Primary angitis of the CNS (PACNS) is characterized by inflammation of small and medium vessels restricted to the brain and spinal cord. PACNS can occur at any age but is more common in middle-aged males.

Clinical manifestations vary considerably and the differential diagnosis is therefore wide. Diagnostic tests, including neuroimaging and brain biopsy, can be unrevealing; therefore, taking a detailed clinical history and excluding mimics is essential. PACNS should be suspected in patients presenting with features of chronic meningitis, unexplained focal neurological deficit, or unexplained diffuse brain dysfunction in the absence of systemic disease.

Symptoms of PACNS

Typically, symptoms progress over several weeks or months, with patients complaining of reduced cognition, altered mental state, headaches, and personality change. Focal neurological deficits may occur acutely secondary to ischaemic or haemorrhagic strokes, and seizures are common. Spinal cord disease may present as painful myelopathy.

Diagnosis of PACNS

Organs outside the CNS are not involved and therefore systemic features of vasculitis, including raised inflammatory markers (ESR, CRP) and active urinary sediment, are invariably absent. CSF is non-specifically abnormal (lymphocytosis, raised protein) in 80% of cases but is nevertheless useful to exclude infectious causes. MRI is not diagnostic and often demonstrates non-specific high-signal T2 lesions in grey and white matter areas but in the acute setting may show evidence of ischaemic or haemorrhagic stroke. Patients with normal CSF and imaging are unlikely to have vasculitis. Angiography is the gold standard but can be negative (specificity 60%, sensitivity 30%) and the presence of beading, aneurysms, or vascular irregularities may occur in other conditions. This includes reversible cerebral vasoconstriction syndrome, which is more common in women and characterized by headache, with or without focal neurological deficit but normal CSF and brain biopsy. Patients with suspected PACNS should have a brain biopsy, although vessel involvement is often patchy, and false negatives occur in up to 25% of cases. Higher yields are achieved in samples taken from radiologically abnormal areas.

Treatment/prognosis of PACNS

Untreated PACNS is usually fatal. Therapy should be individualized and tailored to disease severity. Acutely oral steroids (prednisolone 1 mg/kg per day) or pulsed steroids followed by oral steroids are indicated. These should be continued for 3–6 months before slowly tapering over 1 year. Invariably, patients require cyclophosphamide to halt disease progression.

Small vessel vasculitis

ANCA-positive small vessel vasculitis

Microscopic polyangiitis, Wegener's granulomatosis, and Churg–Strauss syndrome are systemic vasculitides which affect small vessels and cause ischaemic damage in various organs, including the brain and PNS. Males and females are equally affected, with onset typically in middle age in Wegener's granulomatosis and Churg–Strauss syndrome, and in those >50 years, in microscopic polyangiitis.

Symptoms of ANCA-positive small vessel vasculitis

Major clinical features of ANCA-positive small vessel vasculitis include:

- palpable purpura and skin ulceration
- hypertension, shortness of breath, haemoptysis, atypical chest pain
- mononeuritis multiplex
- headache, strokes, confusion, seizures

Patients with Wegener's granulomatosis frequently present with upper respiratory tract symptoms, including epistaxis, and cartilaginous necrosis may lead to saddle nose. Mononeuritis multiplex is more common in Churg–Strauss syndrome and, typically, these patients present with bronchial asthma or allergic rhinitis. Cerebral haemorrhage is less common but, together with gastrointestinal haemorrhage and myocardial infarction, frequently causes death.

Diagnosis of ANCA-positive small vessel vasculitis

Diagnosis of ANCA-positive small vessel vasculitis is based upon the clinical picture and the presence of ANCA in the blood (specifically, MPO in microscopic polyangiitis and Churg–Strauss syndrome, and PR3 in Wegener's granulomatosis). Additionally, patients with Churg–Strauss have eosinophilia (usually >10% white-blood-cell differential), although histological evidence of necrotizing vasculitis and eosinophilic infiltration is confirmatory. CNS vasculitis is common (10%–50%) in all three, but typically below the sensitivity of routine angiography.

Treatment/prognosis of ANCA-positive small vessel vasculitis

Early treatment with pulsed steroids, cyclophosphamide, or plasma exchange is indicated if major organs are involved, followed by oral glucocorticoids and milder immunosuppressants to maintain remission. Treatment should be continued for 1–2 years, and patients should be monitored for exacerbations, as active disease often recurs.

ANCA-negative small vessel vasculitis

Henoch–Schönlein purpura

Henoch–Schönlein purpura (HSP) is a systemic vasculitis characterized by small inflammation. Usually, it affects children between the ages of 4 and 7 years, although it may develop in adulthood. The disease process is thought to be mediated by IgA immune complex deposition and, in some cases, allergy towards microorganisms, food, and certain drugs can be demonstrated. Major clinical features of HSP include:

- fever
- non-thrombocytopenic palpable purpura
- abdominal pain, joint pain
- urinalysis demonstrating evidence of nephritis
- mononeuritis multiplex (less common)

Renal or nerve involvement advocates tissue biopsy to confirm diagnosis and treatment with immunosuppressants. Overall, prognosis for HSP is good, although a significant proportion of affected adults develop end-stage renal disease if nephritis has been a feature.

Essential cryoglobulinaemia

Essential cryoglobulinaemia is a systemic vasculitis characterized by small vessel inflammation that is secondary to deposition of immune complexes, and should be considered in patients with lymphoproliferative disorders, infections (e.g. hepatitis A, B, or C; Lyme disease; toxoplasmosis) or connective tissue disorders (e.g. rheumatoid arthritis, SLE) and who present with cerebral infarction or mononeuritis multiplex. Diagnosis is confirmed by the presence of cryoglobulins in serum. Treatment is often conservative but NSAIDs and glucocorticoids play a role. Prognosis is generally good, although a third of patients develop renal or hepatic failure.

Non-systemic vasculitic neuropathy

Non-systemic vasculitic neuropathy is characterized by inflammation of small vessels causing mononeuritis multiplex in the absence of other organ involvement. Patients present without features of systemic vasculitis, and early treatment with steroids or immunosuppressants is advocated to reduce permanent deficit.

Secondary CNS vasculitis

CNS vasculitis may also arise secondary to connective tissue disorders, infections, malignancy, and sarcoidosis.

Varicella zoster virus (VZV) angitis sometimes occurs after trigeminal herpes zoster in the elderly or immunosuppressed, and diagnosis can be confirmed by the presence of VZV antibodies and positive VZV PCR in the CSF. Treatment with aciclovir and steroids is advocated. Other infectious agents, including HIV, syphilis, and hepatitis C virus (without underlying cryoglobulinaemia) can also cause vasculitis.

Vasculitis is not uncommon in SLE or antiphospholipid antibody syndrome, and neuropsychiatric symptoms may precede focal neurological deficit or global dysfunction by many months. Behçet's disease, Sjögren's syndrome, and sarcoidosis may present as

relapsing–remitting or progressive diseases that are not dissimilar clinically and radiologically to multiple sclerosis. Rarely, it may complicate rheumatoid arthritis, mixed connective tissue disorders, relapsing polychondritis, or dermatomyositis.

Lymphoproliferative disorders, including lymphoma, may cause vasculitis and can be diagnosed on the basis of CSF cytology/flow cytometry and brain biopsy.

237 Neurological tumours

Christine Elwell and Kufre Sampson

Definition of the disease

Neurological tumours are categorized as follows (Louis et al., 2016):

- neuroepithelial tumours (diffuse astrocytic and oligodendroglial tumours (gliomas), other astrocytic tumours (pilocytic astrocytoma), ependymomas, other gliomas, choroid plexus tumours, neuronal and mixed neuronal-glia tumours (ganglioglioma), pineal tumours, embryonal tumours (medulloblastoma))
- cranial and paraspinal nerve tumours (schwannoma, neurofibroma, melanocytic tumours)
- meningeal tumours (meningiomas and mesenchymal non-meningothelial tumours (solitary fibrous tumour, sarcomas))
- lymphomas
- histiocytic tumours
- germ cell tumours (germinoma, teratoma)
- sellar region tumours (craniopharyngioma)
- metastases

CNS tumours were classified according to morphological features and grade. The WHO histological grading scheme used for astrocytomas is based on mitoses, nuclear pleomorphism, necrosis, and endothelial proliferation. WHO Grade I and II tumours (low grade) and WHO Grade III and IV (high grade). The 4th edition WHO classification of tumours of the central nervous system 2007 has since been updated (in 2016) to include both histopathological and molecular genetic information- 'integrated diagnosis'. This has made the greatest impact on the classification of diffuse gliomas (molecular markers are mandatory IDH, 1p19q, H3k27) and embryonal tumours as well as the recognition of new brain tumour entities and deletion of others.

Aetiology of the disease

The aetiology of the disease is unknown. Increasing age, female gender, and high socio-economic status appear to be related to increased risk. The acquired immune deficiency syndrome (AIDS) is a recognized cause of cerebral lymphoma. Other known causative factors are ionizing radiation exposure and inherited cancer syndromes, including neurofibromatosis types 1 and 2, von Hippel Lindau disease, tuberous sclerosis, Li-Fraumeni disease, Cowden's disease, Gorlin syndrome (naevoid basal cell carcinoma), and Turcots's syndrome.

Typical symptoms of the disease, and less common symptoms

Typical symptoms of the disease include:

- symptoms of raised intracranial pressure:
 - headache (frontal/generalized); worse in mornings
 - nausea and vomiting
 - altered conscious level
- seizures
- cognitive or behavioural impairment
- progressive focal neurological deficit, including
 - weakness or sensory loss
 - speech abnormalities
 - cranial nerve palsies
 - unilateral visual field loss
- hormonal dysfunction (pituitary tumours)

Demographics of the disease

Primary CNS tumours are rare. In 2007, there were 4676 new cases (7 per 100 000 population) registered in the UK, accounting for 2%

of new cases of all cancers (excluding non-melanoma skin cancer). Brain tumours can occur at any age and are the commonest site for solid tumours in childhood. There is a peak in incidence in childhood; this drops to a minimum in teenagers and rises to a larger second peak in people in their seventies. The age-standardized incidence rates for brain and CNS tumours increased between 1975 and 2007, mainly in the over-65 group.

Natural history, and complications of the disease

Gliomas

Gliomas account for 45% of all primary CNS tumours and rarely metastasize outside the CNS. Patients with low- grade gliomas tend to be young and relatively well and may have a long history of seizures. WHO Grade I tumours are usually discrete and have the potential for cure with surgery alone. WHO Grade II tumours can recur, with the potential to transform to higher grades. Patients with high-grade gliomas tend to be older and unwell, with a shorter history of symptoms. IDH mutations are implicated in the pathogenesis of malignant gliomas and are common in lower grade tumours.

Meningiomas

Meningiomas account for up to 39% of primary CNS tumours and most commonly arise in the skull vault. Most are low-grade tumours (WHO Grade I).

Primary CNS lymphoma

Primary CNS lymphoma tumours account for less than 2% of primary brain tumours; 90% are diffuse, large, B-cell lymphomas and tend to occur in the immunosuppressed. Lesions commonly occur in the brain parenchyma, although leptomeningeal, ependymal, or ocular disease may be noted. They rarely metastasize outside the CNS.

Medulloblastoma and embryonal tumours

Medulloblastomas and embryonal tumours are the commonest malignant brain tumours in childhood, accounting for 15%– 25% of all childhood primary CNS tumours. They usually occur in the posterior fossa and have a tendency to spread through CSF, with metastatic spread outside the CNS noted to bone, liver, and lungs.

Ependymoma

Ependymomas are the third most common childhood CNS tumour and usually occur in association with the ventricles. They can spread via CSF along the neuroaxis.

Pineal tumours and germ cell tumours

Pineal tumours and germ cell tumours are very rare in adults. There are three main histological types: germ cell tumours, astrocytomas, and pineal parenchymal tumours.

Pituitary tumours and pituitary-related tumours

Pituitary tumours may be functional and secrete hormones, or non-functional. The majority are pituitary adenomas (95%) with craniopharyngiomas, meningiomas, and Ranthke's cleft cysts accounting for the rest. Symptoms may include visual disturbance, as a result of pressure effects on the optic chiasm/nerves, or hormone imbalance, due to pressure effects on the pituitary gland and/or the hypothalamus.

Brain metastases

Brain metastases affect up to 20%–40% of patients with known cancer. The tumours that commonly metastasize to the brain include breast, lung cancer, melanoma, and renal cell cancers.

Spinal metastases

Common tumours causing spinal metastases include breast, lung, prostate, renal cancer, lymphoma, multiple myeloma, and sarcoma. Back pain, sensory loss, loss of sphincter function, and limb weakness are worrying signs requiring urgent oncological attention and, if left untreated, could result in paralysis and incontinence.

Approach to diagnosing the disease

The approach to diagnosing the disease should consist of the following:

- a good history, which may need to be corroborated
- physical examination
- subsequent investigation, which ideally should include imaging and, where possible, a biopsy for histological diagnosis

Other diagnoses that should be considered

Other diagnoses that should be considered include:

- metastases
- cerebrovascular event: haemorrhage or infarction
- infection: cerebral abscess
- demyelinating or inflammatory process: multiple sclerosis
- radiation necrosis

'Gold-standard' diagnostic test

The following are the gold-standard diagnostic tests for neurological tumours:

- radiology: MRI of the brain and the rest of the CNS if appropriate (the latter particularly in medulloblastomas and ependymomas)
- histology: whenever possible, a biopsy should be carried out for histopathological assessment

Acceptable diagnostic alternatives to the gold standard

CT is an acceptable diagnostic alternative for neurological tumours, if MRI is contraindicated or not tolerated.

Other relevant investigations

Other relevant investigations include:

- routine blood tests
- lumbar puncture: CSF examination (primary CNS lymphoma)
- pituitary function (pituitary tumours)
- viral serology: HIV, CMV, and HSV (primary CNS lymphoma)
- tests for alpha-fetoprotein and B-human chorionic gonadotrophin (germ cell tumours)
- visual field assessments (pituitary tumours)
- ophthalmology review (primary CNS lymphoma)
- whole-body CT (primary CNS lymphoma)

Prognosis, and how to estimate it

In general, low-grade tumours have a better prognosis than those of a higher grade, with 5-year survival rates varying from 5% (WHO Grade IV) to 65% (WHO Grade II).

Prognosis for low-grade glioma

Age (>40 years), astrocytoma histology, presence of neurological deficit before surgery, tumour diameter (>6 cm), and tumour crossing the midline are all unfavourable prognostic factors for survival, and the presence of more than two of these factors may prompt early intervention. Prognosis is often 10+ years.

Prognosis for high-grade glioma

Prognostic factors are tumour type, grade, age, fitness, presence or absence of seizures (patients presenting with fits have better prognosis than those that do not), and extent of resection. These tumours tend to have a poor prognosis (3–6 months) without intervention. Anaplastic oligodendrogliomas with chromosome deletions at 1p and 19q tend to have a better prognosis, as they are more chemosensitive; 5-year survival rates are between 5% and 25%.

Prognosis for meningioma

Most meningiomas are low-grade tumours and have a good prognosis.

Prognosis for primary CNS lymphoma

Primary CNS lymphoma is rapidly fatal if not treated. It has a 25% 5-year survival.

Prognosis for medulloblastoma and primitive neuroectodermal tumour

Prognostic factors for medulloblastomas and primitive neuroectodermal tumours include initial tumour size, brainstem infiltration, post-operative residual tumour, and metastatic disease.

Prognosis for ependymoma

The prognosis for ependymoma depends on the grade and type of the tumour. Local recurrence is a problem.

Prognosis for pineal tumour and germ cell tumour

The prognosis for pineal tumours and germ cell tumours is excellent with radical treatment.

Prognosis for brain metastasis

Brain metastasis is usually associated with a poor prognosis (months).

Prognosis for spinal metastasis

Patients who become paraplegic as a result of spinal metastasis have a poor prognosis and die within a few months.

Treatment and its effectiveness

The management of all patients with brain and other CNS tumours should be coordinated by the neuro-oncology multidisciplinary team with the aim of maximizing quality of life. Patients are likely to require physical, psychological, and social support. Treatment depends on patient fitness and the site, histological type, and grade of the tumour. The basis of treatment includes surgery, and radiotherapy with chemotherapy of proven benefit only in a select group of tumours. Surgery is often difficult due to the infiltrative nature of the tumours, which are likely to be close to vital structures.

Treatment for low-grade glioma

The treatment for low-grade glioma is 'watch and wait' and surgery, with radiotherapy if:

- there are persisting neurological symptoms and a significant residual tumour
- there is regrowth following surgery but re-excision is not an option
- there is evidence of tumour transformation to a high-grade tumour

Chemotherapy can be considered in patients with adverse prognostic factors (>40 years), residual disease).

Treatment for high-grade glioma

The treatment for high-grade glioma is as follows:

- corticosteroids
- surgery:
 - emergency decompression or ventriculoperitoneal shunts for hydrocephalus

- biopsy: partial or full debulking, depending on the site of the tumour; however, as these tumours are infiltrative, they tend to recur despite macroscopic resection
- radiotherapy: palliative or radical (the latter concurrent with chemotherapy (temozolamide) in younger, fitter patients)
- chemotherapy:
 - single agent: carmustine, lomustine, temozolamide (MGMT promoter methylation status is a good prognostic molecular marker of likely response to temozolamide in Glioblastomas).
 - carmustine implants in combination with surgical resection
 - combination therapy: PCV (procarbazine, lomustine, and vincristine)
- best supportive care (in some cases)

Treatment for meningioma

The treatment for meningioma is 'watch and wait' and surgery, with radiotherapy if:

- the tumour is WHO Grade II/III (even if the tumour is completely resected)
- there is local invasion of bone or vessels
- there is relapsed disease
- surgery is contraindicated

Treatment for primary CNS lymphoma

There is no clear consensus with regards to the management of primary CNS lymphoma:

- surgery has no role
- corticosteroids started after biopsy may relieve symptoms
- chemotherapy:
 - IV: high-dose methotrexate regimens (with leucovorin or vincristine and procarbazine)
 - intrathecal/intraventricular: for leptomeningeal disease
- radical radiotherapy:
 - can be given to the entire brain and meninges, with good responses
 - when given post chemotherapy, it may improve response rates
- palliative radiotherapy: for frail, immunosuppressed, or elderly patients

Treatment for medulloblastoma and primitive neuroectodermal tumour

The treatment for medulloblastoma and primitive neuroectodermal tumour is debulking surgery and then radiotherapy to the whole neuroaxis. Trials of chemotherapy continue.

Treatment for ependymoma

The treatment for ependymoma is debulking surgery followed by radiotherapy, sometimes to the whole neuroaxis. The role of chemotherapy has not yet been established.

Treatment for pineal tumour and germ cell tumour

The treatment for pineal tumour and germ cell tumour is as follows:

- surgery is the treatment of choice for parenchymal tumours
- radiotherapy may be required but a biopsy is needed to confirm this; note that:
 - germ cell tumours are very radiosensitive
 - craniospinal axis radiotherapy may be necessary in patients with pineoblastoma and metastatic germ cell tumours
- chemotherapy: bleomycin, cisplatin, and etoposide are used for germ cell tumours

Treatment for brain metastasis

Treatment for brain metastasis includes:

- symptom control:
 - corticosteroids
 - anticonvulsants (if the patient presents with seizures)
- palliative whole-brain radiotherapy: the main aims of this are symptom control and reducing dependence on steroid use
- stereotactic radiotherapy can be considered if there are fewer than three small metastases
- surgery: can be considered in patients with solitary metastases and a good performance status if systemic disease is controlled; is usually followed by whole-brain radiotherapy
- systemic treatment: usually ineffective for the brain

Treatment for pituitary tumour and pituitary-related tumour

Medical treatment for pituitary tumours and pituitary-related tumours includes:

- hormone replacement therapy (in the case of hyposecretion)
- somatostatin analogues (for acromegaly; in the case of hypersecretion)
- cabergoline (for prolactinomas)
- surgery (to control tumour mass effect and manage hypersecretion)

Radiotherapy can be used to treat:

- patients who are unfit for surgery
- patients with regrowth post surgery
- patients who are young and have residual disease post surgery
- patients with persistent hypersecretion

Small functional tumours can be treated via stereotactic radiotherapy. Side effects include hypopituitarism, which requires lifelong hormone replacement.

Treatment for metastatic spinal cord compression

Analgesia is very important in the treatment of metastatic spinal cord compression. In addition, corticosteroids reduce oedema and thus may help improve neurological function. Definitive treatment should be commenced within 24 hours of confirmed diagnosis. Radiotherapy is usually the preferred choice, as many of the patients with spinal cord compression are poor surgical candidates, due to advanced disease or multiple vertebral involvement. Surgery may be indicated in selected patients.

238 Non-metastatic neurological manifestations of malignancy

Nerissa Jordan

Definition of the disease

Neurological complications of systemic malignancy are frequent. They may reflect direct local effects of the tumour; CNS infection; side effects of chemotherapy or radiotherapy; nutritional or metabolic derangements; or a paraneoplastic syndrome.

The 'paraneoplastic' neurological syndromes are a group of disorders associated with a malignancy outside the nervous system. The pathophysiology is immune-mediated, with the tumour's expression of neuronal proteins invoking antibody formation, which in turn results in neurological symptoms. This chapter will mainly focus on these syndromes.

Symptoms

There are several well-defined paraneoplastic syndromes with classical symptoms and signs that can affect the central and peripheral nervous systems, the neuromuscular junction, and muscle (see Table 238.1 for the most common syndromes and their associated malignancies). Important syndromes to recognize are described in this section.

Lambert–Eaton myasthenic syndrome

Lambert–Eaton myasthenic syndrome (LEMS) is a disorder of the presynaptic neuromuscular junction, presenting with weakness which is usually maximal in the proximal lower limbs. Associated autonomic dysfunction (dry mouth, erectile dysfunction, constipation, urinary dysfunction, postural hypotension) is common. Examination findings

of weakness with reduced reflexes that increase with muscle exercise are characteristic. EMG also has a characteristic low-amplitude compound muscle action potential which increases with high-frequency stimulation and muscle exercise.

Limbic encephalitis

Symptoms of limbic encephalitis are subacute onset of seizures, confusion, and psychiatric disturbance suggesting involvement of the limbic system. MRI of the brain may show high signal in the limbic system, and inflammatory changes in the CSF.

Cerebellar degeneration

Cerebellar degeneration is the development of a progressive cerebellar syndrome affecting all areas of cerebellar function (trunk and limb ataxia, nystagmus, eye movement abnormalities, and dysarthria). There is significant disability within 12 weeks of onset, and minimal cerebellar atrophy on early imaging.

Opsoclonus myoclonus

Opsoclonus myoclonus consists of rapid, arrhythmic conjugate eye movements in multiple directions, also known as 'dancing eyes'. Patients also have myoclonus of the limbs and trunk, and gait ataxia, and encephalopathy may be part of the syndrome.

Stiff person syndrome

Stiff person syndrome is characterized by generalized stiffness which is predominantly in axial muscles, with associated painful cramps.

Table 238.1 Neurological paraneoplastic syndromes and their most commonly associated malignancies and antibodies

Clinical syndrome	Associated malignancy	Antibodies	Frequency paraneoplastic (%)
Lambert–Eaton myasthenic syndrome	SCLC	Anti-VGCC	60
Limbic encephalitis	SCLC Testicular Breast	Anti-Hu Anti-amphiphysin	20
Subacute cerebellar ataxia	Ovarian Breast SCLC Hodgkin's lymphoma	Anti-Yo Anti-Hu Anti-Tr	50
Opsoclonus myoclonus	Breast Ovarian SCLC Neuroblastoma	Anti-Ri Anti-Hu	20
Stiff person syndrome	Breast SCLC	Anti-amphiphysin Anti-GAD	20
Sensory ganglionopathy	SCLC	Anti-Hu Anti-CV2 Anti-amphiphysin	20
Dermatomyositis	Ovarian SCLC	–	30

Abbreviations: GAD, glutamic acid decarboxylase; SCLC, small cell lung cancer; VGCC, voltage-gated calcium channel.

Spasms in response to environmental stimuli are common. Psychiatric symptoms are often coexistent, including anxiety and depression. There is continuous motor unit activity on EMG in the affected muscles at rest.

Sensory ganglionopathy

Sensory ganglionopathy is characterized by asymmetrical numbness, which is often preceded by pain and paraesthesia. Examination findings are of areflexia and sensory loss, particularly loss of proprioception. There is electrophysiological evidence of a sensory neuropathy at the level of the sensory ganglion.

Dermatomyositis

Dermatomyositis is an inflammatory myopathy with progressive symptoms of muscle pain and weakness, especially proximally. Associated skin lesions assist with diagnosis. A violaceous rash over the eyes (heliotrope rash), Gottron's papules, periungual telangiectasia, and rashes over the shoulders and neck ('V sign' and 'shawl sign', respectively) are characteristic.

Demographics and aetiology

Paraneoplastic disorders are rare. LEMS is the most common, occurring in approximately 1% of patients with small cell lung cancer. Adults are more commonly affected, due to the higher incidence of malignancy. There are several syndromes more classically seen in children, such as opsoclonus myoclonus associated with neuroblastoma.

The formation of antineuronal antibodies by the immune system is the proposed underlying mechanism; however, the evidence for direct pathogenesis of the antibodies has not been found in many cases. Some antibodies, however, such as those directed at the voltage-gated calcium channels in LEMS, are directly pathogenic. Cytotoxic T-cells have been detected in the nervous system and are likely to play a role.

Natural history of the disease

Paraneoplastic syndromes may present acutely or subacutely, and typically are progressive. They may occur in patients with an existing diagnosis of cancer, or present prior to the detection of the malignancy.

Complications

Complications of the paraneoplastic syndromes are typically those of the underlying cancer.

Approach to diagnosing the disease (including diagnostic pitfalls)

Identification of symptoms suggestive of a paraneoplastic syndrome should prompt a search for an underlying malignancy. Certain malignancies are associated with particular syndromes and antibodies (see Table 238.1).

The diagnosis of a paraneoplastic neurological syndrome relies upon clinical symptoms and examination findings in association with an appropriate antibody. Paraneoplastic antineuronal antibodies may be detected at low levels in patients with a malignancy but without symptoms of a paraneoplastic neurological syndrome. Care must, therefore, be taken in the interpretation of these tests, and they should only be performed in the appropriate clinical context. Similarly, not all patients with a particular syndrome will have malignancy; for example, the majority of cases of stiff person syndrome with antibodies against glutamic acid decarboxylase are not paraneoplastic.

Diagnostic criteria have been proposed, considering the syndrome, antibody, and detection of malignancy. Patients can then be classified into categories of definite and probable paraneoplastic disorders (see 'Further Reading').

Other diagnoses that should be considered

As paraneoplastic disorders are rare, a direct effect of malignancy or treatment is much more common and must be included in the differential diagnosis. This includes metastases that may be difficult to detect, such as leptomeningeal disease or plexus infiltration. Other causes of neurological symptoms associated with cancer should be considered. This includes side effects of cytotoxic medications or radiotherapy, and nutritionally related neurological syndromes. The clinical syndromes are not always associated with cancer (see Table 238.1 for approximate frequency), and alternative causes of the condition should be sought, for example postinfectious opsoclonus myoclonus in a young adult.

'Gold-standard' diagnostic test

There is no gold-standard diagnostic test for paraneoplastic disorders. The diagnosis is made utilizing both clinical features and test results. Anti-neuronal antibodies are specific when positive in a patient with symptoms of a well-defined paraneoplastic syndrome. The tests can be performed on both the serum and CSF.

Other relevant investigations

Relevant investigations to define the syndrome should be performed, such as MRI, lumbar puncture, and EMG. Investigations to detect an underlying malignancy should be performed if the syndrome occurs in a patient prior to the diagnosis of a tumour. This can be tailored towards the most likely malignancy in the setting of the syndrome, and can include tumour markers, imaging including CT of the chest, abdomen, and pelvis; PET, for PET-avid malignancy; mammography; and endoscopy.

Prognosis and how to estimate it

The prognosis is largely dependent on the effectiveness of treatment for the underlying malignancy. Those not associated with malignancy often have a benign course.

Treatment and its effectiveness

For paraneoplastic disorders, treatment is focused on detection of and therapy for the underlying malignancy. Immune therapies have been trialled in many of the syndromes, including plasma exchange, IV immunoglobulin, steroids, and immune modulators, with some success. Certain conditions have specific therapies available, such as 3,4-diaminopyridine for LEMS, to increase the release of acetylcholine. For systemic disorders, correction of metabolic abnormalities, such as hypercalcaemia, or nutritional replacement for Wernicke's encephalopathy, may improve the relevant symptoms.

239 Neurosurgery

Erlick A. C. Pereira, Jonathan A. Hyam, and Alexander L. Green

Introduction

Neurosurgery encompasses brain, spine, and peripheral nerve disorders that may benefit from operative management. These include congenital neurological diseases, epilepsy, stroke, neurological infection, movement disorders, spinal cord disease, neurological tumours, and pituitary disorders. This chapter focuses upon head injury and subarachnoid haemorrhage (SAH), two common neurosurgical disorders not detailed elsewhere in this book.

Head injury

Definition of head injury

Skull or brain damage due to direct or deceleration trauma can be classified as primary (immediate injury) or secondary (from complications like hypoxia, seizures, infection, and hydrocephalus). Patients with head injury are stratified by their level of consciousness (as determined by the Glasgow Coma Scale (GCS); see Table 239.1) as having mild (GCS >13), moderate (GCS 9–13), or severe (GCS <9) injury.

Aetiology of head injury

Blunt or penetrating head injuries are commonly caused by road traffic accidents, especially unhelmeted activities, combat, contact sports, and falls. Falls and accidents may be secondary to a primary event such as a seizure, aneurysmal SAH (see 'SAH') or cardiac arrhythmia, necessitating a careful collateral history.

Typical symptoms of head injury, and less common symptoms

Symptoms of head injury include headache, nausea, vomiting, visual disturbance, deterioration in GCS, and limb weakness. Hypertension,

bradycardia, and altered respiratory rate (Cushing's response) are late signs of brainstem compression.

Demographics of head injury

Every year, over a million patients with head injuries present to UK emergency departments; 5000 of them die from the injuries, some inevitably but many from preventable causes. Road traffic accidents cause just a quarter of the total number of head injury cases but account for two-thirds of those ending in death, with half of such patients dying before they reach the hospital.

Natural history, and complications of head injury

Complications include epilepsy; 5% of head injury cases have early seizures, which occur mostly in the first 24 hours after the injury, and 5% have late seizures, which occur within a year of injury and are more commonly seen with intracranial haematoma or compound depressed skull fracture. CSF leak with consequent meningitis is a particular risk in the first week of injury. Postconcussional problems of headache, dizziness, irritability, poor concentration, fatigue, depression, altered hearing, and a reduced sense of smell all occur. Dementia (dementia pugilistica) is a long-term consequence of repeated head injury.

Approach to diagnosing head injury

Taking a history and a collateral history regarding the mechanism of injury are vital. For traffic accidents, speed at impact, whether a seat-belt or helmet was used, details of the extrication, the state of the vehicle, and the fate of other victims are all relevant. After ensuring airways, breathing, and circulation, assess GCS, pupil size, equality and reactivity to light, and other signs of raised intracranial pressure, such as papilloedema. Assess limb movements and cranial nerves, in particular eye movements and, in the comatose, gag, cough, and corneal reflexes. For a penetrating injury, object/missile type and distance are important.

Inspect scalp lacerations for underlying skull fractures before considering closure.

Assess for evidence of basal skull fracture (e.g. raccoon's eyes (periorbital ecchymoses), Battle's sign (postauricular ecchymoses), CSF rhinorrhoea/otorrhea, haemotympanum). Examine for facial fractures, including an inspection for orbital rim step-off, and palpation for Le Fort fractures. Auscultate the carotids and eyes for bruits suggestive of dissection or carotid-cavernous fistula. Examine the cervical spine for tenderness or step deformity.

Clarify whether there is loss of consciousness, anterograde amnesia, persisting neurological deficit, vomiting, or visual disturbance. All justify CT head. Have a particularly low threshold for radiological investigation of a child or an elderly patient.

Other diagnoses that should be considered aside from head injury

Other diagnoses that should be considered aside from head injury include cervical spine injury, alcohol or recreational drug intoxication, and primary causes of secondary head injury (e.g. syncope, primary cardiac arrhythmias, primary seizure disorder).

'Gold-standard' diagnostic test for head injury

CT head scan is indicated if there is suspicion of a significant mechanism of injury or if there is a persisting deficit, amnesia, or vomiting, all of which are very established signs (see Table 239.2). CT cervical spine should similarly be performed. Fine-cut CT facial or skull-base/temporal bone views should be considered if such injuries are suspected.

Table 239.1 The Glasgow Coma Scale

Event	Score
Best Motor response	
Commands are obeyed	6
Localises to pain	5
Flexion withdraws from pain	4
Abnormal flexion to pain	3
Extension to pain	2
No response	1
Verbal response	
Alert and orientated	5
Confused	4
Inappropriate	3
Incomprehensible	2
No response	1
Eye opening occurs

Acceptable diagnostic alternatives to the gold-standard test for head injury

Skull radiographs are no longer considered adequate to exclude most intracranial injuries, and few hospitals lack a CT scanner. Cervical spine radiographs continue to be useful where the mechanism of injury is less worrisome but the patient presents with bony tenderness or step deformity.

Other relevant investigations for head injury

Other relevant investigations for head injury include the following:

- a full blood count
- clotting
- serum glucose
- electrolytes, including sodium, to assess for hyponatraemia
- anticonvulsant drug levels
- serum alcohol or drug level, if the patient is intoxicated
- CSF beta transferrin if there is suspicion of CSF otorrhoea/rhinorrhoea without imaging evidence

Prognosis for head injury, and how to estimate it

Head injuries are broadly classified radiologically as diffuse or focal, with the latter including contrecoup contusions, subdural haematomas, and extradural haematomas (see Figure 239.1A–C). In patients with a recent deterioration in conscious level and/or large subdural or extradural haematomas with mass effect and/or hydrocephalus or subfalcine herniation, urgent neurosurgery is indicated. Contraindications to surgery include fixed, dilated pupils unresponsive to medical measures; coagulopathies; and when a significant of time has passed since observation of a mass effect (more than several hours) in patients with comorbidities. Prognosis after craniotomy in the elderly (>75 years old) is poor, with high morbidity and mortality. In patients with focal deficits and/or reduced GCS, prognosis is improved by close neurological observation and expedient consideration of transfer to specialist neurosurgical care. A quarter of patients in coma with severe head injury die within 6 months. Most recovery occurs within 6 months of severe head injury, augmented by occupational and physical therapy; <2% enter a persistent vegetative state which, if it persists for more than 3 months, makes dependency inevitable. Table 239.3 correlates GCS with clinical outcome.

Treatment of head injury, and its effectiveness

Correct hypoxia, hypovolaemia, and suture skull lacerations once depressed skull fractures are excluded. Anticonvulsants should be administered if seizures occur. Intracranial pressure (ICP) should be monitored in the intubated and ventilated patient with severe head injury, and cerebral perfusion pressure maintained > 65 (cerebral perfusion pressure = mean arterial pressure – ICP). Raised ICP can be managed by diuretics such as mannitol and furosemide, hypertonic saline, barbiturate boluses, and controlled hypocapnia (partial pressure of CO₂ = 4.0–4.5). There is little convincing evidence for high-dose steroids for elevated ICP or for the use of prophylactic antibiotics in a CSF leak without meningitis in improving outcome in head injury. Space-occupying haematomas require urgent neurosurgical evacuation, with life-saving outcomes.

SAH

Definition of SAH

SAH is bleeding from intracranial vessels in the subdural space between the overlying arachnoid membrane and the underlying pia mater, usually involving vascular anastomoses of the circle of Willis and its branches (Figure 239.1D).

Aetiology of SAH

Rupture of one or more saccular aneurysms accounts for three-quarters of SAH cases. Arteriovenous malformations cause 5% of cases, and coagulopathies, vasculitis, and neoplasia cause <5% of cases, with the remaining 15% of cases being of unknown aetiology. Atherosclerosis, hypertension, smoking, pregnancy, oral contraceptive pill use, and polycystic kidney disease are identified associations.

Typical symptoms of SAH, and less common symptoms

Symptom severity is proportional to haemorrhage severity. The classic symptom is sudden-onset, severe headache, which is often bilateral and usually occipital, with the patient feeling as if they have been hit on the back of the head. Nausea and vomiting are common. Neck stiffness and photophobia are not unusual, with meningeal irritation, developing a few hours after the event. Seizures, focal neurological deficits, and a reduction in conscious level may be seen with more severe SAH. A mild headache may represent a warning/herald/sentinel bleed before a major bleed. Cranial nerve palsies may be seen, for example oculomotor nerve palsy due to irritation and compression after rupture of a posterior communicating artery aneurysm. Fundoscopy may reveal papilloedema and also vitreous haemorrhages in 10% of patients (Turson's syndrome), again correlated with bleed severity. Mild pyrexia and reactive hypertension may be observed.

Demographics of SAH

SAH has an annual UK incidence of 10–15 per 100 000. Saccular cerebral aneurysms are present in 2% of autopsies, with aneurysmal rupture occurring in 6–8 per 100 000 people per year. Male:female ratios are 2:3 overall, but SAH is more likely to occur in males >40 years of age. Aneurysmal SAH has some hereditary basis and is more common in Finland and Japan.

Natural history of SAH, and complications of the disease

Overall mortality from aneurysmal SAH is close to 50%; 10%–15% of people die before reaching hospital, and a further 10% within a few days of onset. Rebleeding is a major risk, at 15%–20% within 2 weeks of the first bleed. Other complications are vasospasm, which often presents with focal deficit and is of highest risk 4–10 days after first bleed, and hydrocephalus, which usually manifests as headaches that are worse on waking and lying flat, together with other signs of raised ICP (e.g. nausea, vomiting, Parinaud's phenomenon). One-third of SAHs occur during sleep, and some evidence suggests there is a higher risk of SAH in spring and autumn.

Figure 239.1 (A) ‘Crescentic’ acute subdural haematoma. (B) ‘Lenticular’ acute extradural haematoma. (C) Contrecoup bifrontal contusions. (D) Subarachnoid haemorrhage.

Approach to diagnosing SAH

A history, together with symptoms and signs suggestive of SAH, should encourage close neurological observations and urgent, unenhanced CT head. If no subarachnoid blood is seen on CT head imaging, confirming safety for lumbar puncture, a lumbar puncture should be performed between 12 hours and 2 weeks after the event and

assessed both for red blood cell count, in the first and third samples, and for xanthochromia, in the second sample. Oxyhaemoglobin and bilirubin content suggestive of or unable to exclude SAH determine its empirical treatment and transfer to a neurosurgical centre for cerebral angiography to find and treat any ruptured aneurysm or arteriovenous malformation.

Other diagnoses that should be considered aside from SAH

Other diagnoses that should be considered aside from SAH include migraine, cluster headache, benign coital and exertional headache syndromes, meningitis (bacterial and viral), stroke, alcohol intoxication, and head injury.

‘Gold-standard’ diagnostic test for SAH

Lumbar puncture 12 hours to 2 weeks after the event, for xanthochromia, is an extremely sensitive test for excluding SAH. Digital subtraction angiography is the gold standard for identifying intracerebral aneurysms. If intracranial blood extravasation obscures image clarity, repeat delayed angiography is indicated.

Acceptable diagnostic alternatives to the gold-standard test for SAH

Urgent CT head is the first line of investigation for suspected SAH. MRI is similarly sensitive. Should neither reveal blood, then lumbar puncture is indicated. Should lumbar puncture have been performed

Table 239.3 Glasgow Outcome Score, correlated with severity of head injury

During hospital admission	Poor outcome (dependent for care; GOS 1–3)	Favourable outcome (independent; GOS 4–6)
Coma >6 hours duration	61%	39%
Best GCS >11	18%	82%
Best GCS 8–10	32%	68%
Best GCS <8	73%	27%
Pupils reacting to light	50%	50%
Pupils unreactive to light	96%	4%
Age <20 years	41%	59%
Age >60 years	94%	6%

Abbreviations: GCS, Glasgow Coma Score; GOS, Glasgow Outcome Score. Reproduced with permission from B. Jennett, Prognosis in Patients With Severe Head Injury, *Neurosurgery*, Volume 4, Issue 4, pp. 283–9, Copyright © 1979 Springer.

too early, late, more than once, or be equivocal in its results, then clinical suspicion should guide any decision to proceed to CT angiography or digital subtraction angiography.

Other relevant investigations for SAH

Other relevant investigations for SAH include:

- a full blood count
- a coagulation profile
- electrolytes, including sodium, for hyponatraemia
- ECG (T-wave changes sometimes seen)
- liver function tests
- chest X-ray (pulmonary oedema sometimes seen)
- close temperature and blood pressure monitoring
- ophthalmological investigations, if cranial nerve palsies are present

Prognosis for SAH, and how to estimate it

SAH can be graded by clinical severity (Table 239.4); clinical severity at presentation correlates with prognosis. Blood load on CT is also correlated with outcome.

Grade	GCS	Aphasia or hemiparesis
0	Unruptured aneurysm	No
1	15	No
2	13–14	No
3	13–14	Yes
4	7–12	Maybe
5	3–6	Maybe

Abbreviations: GCS, Glasgow Coma Score.

World Federation of Neurological Surgeons grading system for SAH.

Treatment of SAH, and its effectiveness

Best practice for SAH treatment is now considered to be early coiling or clipping of any ruptured aneurysm, to reduce the risk of rebleeding. Aneurysms amenable to coiling are managed accordingly. Clipping is usually reserved for complex aneurysms not readily amenable to coiling, or if there is an intra-cerebral haematoma which requires evacuation. Some still advocate late (after 10 days) over early clipping, as the brain is then less swollen, and the risk of vasospasm is reduced. Medical management includes analgesia; laxatives; anti-emetics; anticonvulsants, if required; aggressive hydration with 125 ml of normal saline per hour; close observation, including daily serum electrolytes to observe for hyponatraemia; administration of nimodipine 60 mg every 4 hours for 21 days post event; and ICP monitoring, if the patient is sedated. Early, aggressive treatment of suspected vasospasm is via IV fluid boluses, inotropes, and consideration of chemical angioplasty and emergent treatment of hydrocephalus by external ventricular drainage, lumbar drainage, or serial lumbar punctures. Limited evidence exists for use of statins to improve clinical outcomes. All patients with proven SAH should be investigated and managed in a neurosurgical centre; 85%–90% of people survive 5 years after coiling or clipping of a ruptured aneurysm, versus >50% mortality without initial treatment.

240 Drug-induced neurological disease

Robin Ferner and Anthony Cox

Definition of the disease

The definition of an adverse drug reaction is 'an appreciably harmful or unpleasant reaction, resulting from an intervention related to the use of a medicinal product; adverse effects usually predict hazard from future administration and warrant prevention, or specific treatment, or alteration of the dosage regimen, or withdrawal of the product' (Aronson and Ferner, 2005, p. 851).

Scope of drug-induced neurological disorders

Adverse drug reactions can cause or contribute to central and peripheral nervous system disorders, including traumatic, infective, neoplastic, demyelinating, and vascular diseases.

Diagnosis of drug-induced disease

It can be difficult to differentiate adverse drug reactions from natural disease. The crucial diagnostic tools are a thorough drug history and a good database of potential adverse drug reactions (the *British National Formulary* is the obvious starting point). Features that are said to suggest a drug cause are:

- **challenge:** the condition started after treatment with the drug, or after a dose increase—but this ignores the possibility of disease aggravation
- **dechallenge:** the condition remitted after the drug was stopped—but this does not apply to irreversible adverse drug reactions (e.g. fatal adverse drug reactions)
- **rechallenge:** the condition recurs on re-exposure to the drug—but physicians would generally be foolish to re-expose patients to drugs that caused significant adverse drug reactions merely to make the diagnosis
- **drug specificity:** the observed condition is known to occur with the drug but is not a feature of the disease being treated—but this is only useful for well-recognized adverse effects, and well-characterized diseases.

It may be more useful to analyse reactions by 'DoTS':

- **Dose relation** (did the adverse event occur at very low doses, very high doses, or standard therapeutic doses?)
- **Timing** of the reaction in relation to the start of treatment
- **Susceptibility** of the individual

A major challenge is to identify unknown adverse drug reactions in newly marketed drugs. Pre-marketing clinical trials cannot detect rare, yet important, adverse drug effects. This challenge is met in part by collecting data on suspicions of adverse drug reactions. In the UK, this is done via the Medicines and Healthcare Products Regulatory Agency (MHRA) Yellow Card Scheme (see <http://yellowcard.mhra.gov.uk>), which encourages reports from healthcare professionals and patients.

Drug-induced diseases of the CNS

Drug-induced unconsciousness

The differential diagnosis of patients admitted in an unconscious state should include drug-induced coma. In practice, common causes are opiates, GABA agonists of various sorts, and tricyclic antidepressants in deliberate overdose or as a result of error.

The clinical signs can help in differential diagnosis: pinpoint pupils and respiratory depression reversed by naloxone are the hallmarks of opiate intoxication; dilated pupils, tachycardia, and hyperreflexia

are usual in tricyclic overdose. The GABA agonists include benzodiazepines, alcohol, and barbiturates, as well as the street drug gamma-hydroxybutyric acid. They tend to cause bradycardia and respiratory depression, and there may be nystagmus. Flumazenil is a specific antagonist of the effects of benzodiazepines. In addition to these, the street drug ketamine, an antagonist of the excitatory neurotransmitter glutamic acid, can cause rapid unconsciousness and seizures, with tachycardia and hypertension.

Important secondary causes include haemorrhage related to anticoagulants and hypoglycaemia, usually due to insulin or sulfonylureas.

Stroke

Young women who take the oral contraceptive pill are at increased risk of stroke, although the absolute risk is small. The threefold relative risk becomes much more significant in women with other risk factors, such as cigarette smoking, hypertension, and increasing age, and is more important with pills containing a high oestrogen dose. The risk is also significantly increased in postmenopausal women taking hormone-replacement therapy. Although the increase in relative risk is smaller, because the deleterious effects on thrombogenesis are partly balanced by favourable effects on lipids, the absolute increase in risk is still important. Tranexamic acid, used to treat menorrhagia, is an antifibrinolytic, and as a result, increases stroke risk. Stroke has also been associated with phenylpropanolamine, which is present in some cough and cold remedies in some countries.

Stroke is an important consequence of cocaine abuse, and may either be haemorrhagic, due to rupture of a preexisting intracranial aneurysm, or thrombotic, as a result of vasospasm. The effects are a consequence of the indirect sympathomimetic action of cocaine, which can cause sudden and extreme hypertension and vasospasm.

Drug-induced encephalitis and meningitis

Drugs derived from human tissue can introduce CNS infection. Human growth hormone derived from human pituitaries led to an outbreak of the fatal prion encephalopathy Creutzfeldt-Jakob disease in the 1980s.

Immune suppression, for example with high-dose corticosteroids, can increase the risks of tuberculous meningitis and virus encephalitis. In immune-suppressed patients, exposure to chickenpox can have a fatal outcome or cause irreversible brain damage. More recently, reactivation of the JC (for John Cunningham, the initial patient) polyomavirus has been recognized as a cause of the rare condition progressive multifocal leucoencephalopathy in patients treated with monoclonal antibodies, including natalizumab (for multiple sclerosis), infliximab, and rituximab. This demyelinating disease results from lytic infection of the oligodendrocytes, which produce myelin. It characteristically presents with the triad of progressive dementia, hemiparesis, and hemianopia.

Platinum compounds and other anticancer agents, as well as interferons and some other drugs, can cause a non-infective encephalopathy (see Table 240.1). Fluorouracil and its prodrug capecitabine can provoke patchy widespread demyelination. High-dose chemotherapy, for example with cisplatin, is a recognized cause of posterior reversible encephalopathy syndrome (PRES). The clinical features are headache, altered mental state, visual disturbance that can include cortical blindness, and tonic-clonic seizures. These are accompanied by symmetrical posterior cerebral and cerebellar white matter abnormalities on CT and MRI. PRES can be fatal, but less severe cases usually resolve after removal of the cause.

Aseptic meningitis presents with symptoms of headache and fever and signs of neck stiffness indistinguishable from infective meningitis. No organism can be cultured. The CSF can show an increase in

Common causes	Clinical features	Dose relation, time, susceptibilities
Antivirals: Aciclovir	Aciclovir-induced encephalopathy in patients with renal failure resolves with haemodialysis	Usually within a few days High doses IV use Renal impairment Old age
Ciclosporin	Seizures and movement disorders occur	High doses Concurrent corticosteroids Hypomagnesaemia Systemic hypertension
Cisplatin Ifosfamide	Confusion Stupor Mutism Secondary to cerebral oedema	Renal impairment Hepatic impairment
Sodium valproate	Confusion Reduced consciousness Coma Associated with hyperammonaemia	Dose related

polymorphonuclear leucocytes or other cells, and in protein; glucose concentration is usually normal. Some drugs probably cause direct meningeal irritation. Type III delayed-type immunological hypersensitivity reaction can occur either by direct introduction into the CSF, or by crossing the blood–brain barrier. Some drug causes are listed (see Table 240.2). Even though they cause the reaction very rarely, NSAIDs are widely used and so constitute the commonest cause. The association is a potential source of confusion, as the analgesics are often taken for headache, which is an expected feature of meningitis. Patients with SLE seem to be especially susceptible, although this is hard to demonstrate, as aseptic meningitis can occur in SLE without a drug cause. Aseptic meningitis was also associated with the Urabe strain of mumps in a measles, mumps, rubella (MMR) vaccine withdrawn in 1992.

Drug-induced headache

Drug-induced headache is common, with up to 8% of headaches associated with drugs. Vasodilators, including calcium antagonists, nitrates, and hydralazine, cause the expected throbbing headache. Many patients develop the headache within an hour or two after taking standard-release calcium antagonists, when the peak plasma concentration occurs. Nitrate headache begins as soon as the nitrate is absorbed, and absorption is rapid with sublingual administration. It abates within several minutes after acute exposure, and after hours with continued exposure. However, asymmetric dosing regimens designed to reduce tachyphylaxis to the anti-anginal effect may also perpetuate the headache. Sildenafil, which inhibits nitric oxide

metabolism by phosphodiesterase type 5, can itself cause headache and can exacerbate nitrate-induced headache.

Intracranial hypertension ('pseudotumor cerebri') causes a characteristic headache that is worse with straining and on lying down, and so occurs typically after a night's sleep. The papilloedema that develops can lead to visual loss from pressure on the optic nerve. It is a recognized adverse effect of vitamin A and its derivatives, including isotretinoin and other retinoids, having been recognized in polar explorers who ate polar bear liver (which is rich in vitamin A). It may also occur with antibiotics (tetracyclines, penicillins, and nalidixic acid) and oestrogens.

'Medication-overuse headache' is a chronic headache occurring in patients with preexisting acute headache, usually migraine. In the condition, headaches occur on at least 15 days a month, in patients who have taken analgesics, ergot alkaloids, or triptans on more than 10 days each month for more than 3 months. Patients may develop a new type of headache, or their preexisting headache may be made markedly worse during overuse. Most sufferers are women. Treatment is to withdraw the medicines, but this is sometimes difficult, as the headache at first becomes worse and can persist for some months. The condition is common and under-diagnosed.

Seizures

Drugs can cause seizures by direct effects on the brain or neurotransmission (see Table 240.3) or secondarily to metabolic disturbances such as hyponatraemia (e.g. due to diuretics, antipsychotics, or selective serotonin-reuptake inhibitors), hypomagnesaemia (e.g. due to cisplatin or to proton-pump inhibitors), and hypoglycaemia (e.g. from anti-diabetic drugs).

Many drugs, even benzylpenicillin, can cause seizures at toxic doses. It is thought that the beta-lactam ring in penicillin binds to receptors for GABA, an inhibitory neurotransmitter. Tricyclic-anti-depressant poisoning is commonly associated with seizures, at least in part as a result of central anti-cholinergic effects: other anti-cholinergic compounds (such as procyclidine) can also provoke seizures. The smoking cessation treatment bupropion causes seizures in 1 in 1000 patients, and the risk is increased in those with a prior history of seizures. Theophylline, another well-recognized cause of seizures in overdose, antagonizes the effects of adenosine, which is an inhibitory neurotransmitter. Local anaesthetic drugs, formerly used as anti-arrhythmics, cause seizures as a toxic effect related to blockade of sodium channels.

GABA agonists (e.g. alcohol, benzodiazepines, barbiturates) and antiepileptic drugs can provoke seizures on withdrawal.

CNS disturbance by drugs used to treat Parkinson's disease

'Punding'—from a Swedish slang term for the behaviour of amphetamine abusers—describes repetitive and often complex, purposeless, stereotyped behaviour: for example, arranging and rearranging coins in piles of different denominations. It is now recognized as part of a wider group of compulsive behaviours in patients treated with dopamine or dopamine agonists and who may also exhibit compulsive

Common causes	Clinical features	Dose relation, time, susceptibilities
Antibiotics; co-trimoxazole (sulfamethoxazole + trimethoprim) most common	Uncertain mechanism Excess mononuclear or polymorphonuclear cells in CSF	SLE HIV Sjögren's syndrome Crohn's disease
Cytarabine	Also associated with cerebellar dysfunction	
Immunoglobulins	Affects 1%–15% of those treated with high doses Inflammatory/immune mechanism	Usually within 2 days High dose History of migraine
Infliximab	Focal neurological deficit Loss of consciousness	Repeated administration
NSAIDs	Hypersensitivity Immune complexes and intrathecal IgG detected	Usually rapid onset SLE Prior history of aseptic meningitis

Table 240.3 Drug-induced seizures

Common causes	Clinical features	Dose relation, time, susceptibilities
Antipsychotic drugs	Reduced seizure threshold	SLE
Antidepressants (especially tricyclic antidepressants)	Direct seizure effect (especially tricyclic antidepressants)	Common in overdose Sudden doses changes or abrupt withdrawals
Antibiotics: penicillins and other beta-lactams; quinolones, isoniazid	Direct toxic effect	Large doses Intrathecal use
Carbamazepine	Can paradoxically increase seizure activity	High doses
Lidocaine	Partial and generalized tonic-clonic seizures Can occur with topical use of large amounts	Prior history of seizures High doses
Pethidine (meperidine)	Due to the norpethidine metabolite	High doses Renal failure
Theophylline	Generalized tonic-clonic seizures	High doses Co-prescription with cytochrome P450 isoenzyme inhibitors, especially macrolide antibiotics
Tramadol	Under 1% of users	Prolonged prescription Age 25–54 Alcohol abuse
Drugs of abuse: cocaine, ecstasy, amphetamines	May also cause haemorrhagic or thrombotic stroke	

gambling and compulsive sexual behaviour. Direct dopamine agonists, that is, ropinirole, pramipexole, and the ergot derivatives, can induce catalepsy and narcolepsy. These drugs induce 'sleep attacks' of sudden onset and are, therefore, potentially dangerous in drivers.

Spinal cord disease

Myodil® (Pantopaque™ in North America: ethyl-iodophenyl undecanoate), used as a radiocontrast medium for myelography from the 1940s to the 1970s, was an oily suspension that remained in the spinal canal and, in a minority of patients, caused a painful and sometimes disabling arachnoiditis with spinal cord damage. The contrast medium can still be seen on plain radiographs many years after injection. Its effects evolve slowly and are long-lasting.

Drug use in pregnancy carries the risk of neurological damage to the developing fetus. The rate of neural tube defects (spina bifida) is doubled in the offspring of women taking sodium valproate in pregnancy. Folate supplementation, particularly if commenced prior to conception, may reduce the risk.

Medication errors are an important cause of potentially preventable harm. Some are so egregious that they have been labelled 'never events'—events that should never be allowed to occur—by the UK National Health Service. One of these 'never events' is the intrathecal injection of the anticancer drug vincristine, usually in patients who were intended to receive intrathecal methotrexate and IV vincristine and in whom the routes of administration have been reversed. Vincristine causes a rapidly evolving, painful, and usually fatal arachnoiditis.

A more unexpected danger to the spinal cord is nitrous oxide, which is prone to abuse and which can lead to progressive ascending numbness in the legs and sometimes the arms, accompanied by loss of power and proprioception. These are the features of subacute combined degeneration of the spinal cord, a condition usually associated with vitamin B₁₂ deficiency. While cord damage is commoner with prolonged or repeated inhalation, it has been reported after a single short exposure to nitrous oxide anaesthesia in the presence of vitamin B₁₂ deficiency.

Peripheral neuropathy

Peripheral neuropathy can be due to damage to nerve cell bodies (neuronopathy), axons, or myelin. Symptoms can include pain, sensory loss, paraesthesia, and weakness, alone or in combination. Loss of proprioception can result in an abnormal gait.

Many drug-induced neuropathies are mixed, but pure types are sometimes found. Prolonged megadose therapy with vitamin B₆ (pyridoxine), at one time advocated for premenstrual tension, can cause a progressive neuropathy with sensory ataxia, loss of vibration sense, and paraesthesia. This is due to a direct and potentially reversible effect on cell bodies in the dorsal root ganglia.

Other causes include the antibiotics metronidazole and nitrofurantoin, the antituberculous drug isoniazid, and the antiarrhythmic amiodarone (see Table 240.4). Preexisting conditions such as diabetes mellitus, alcoholism, and vitamin deficiency, and impaired drug clearance, contribute to the risk. Nerve damage is a common adverse effect of cancer chemotherapy, occurring in over 20% of treated patients. Factors that increase the risk of chemotherapy-induced peripheral neuropathy include the cumulative chemotherapy dose, the administration of high single doses, rapid infusion times, and previous or concurrent use of neurotoxic drugs.

Vincristine is a common and important cause of peripheral neuropathy, which is often dose-limiting. Loss of deep tendon reflexes is an early sign and, while sensory changes precede motor changes,

Table 240.4 Drug-induced neuropathies

Common causes	Clinical features	Dose relation, time, susceptibilities
Amiodarone	Sensorimotor neuropathy Absent tendon reflexes Sensory ataxia	Reversible in some cases
Antiretrovirals	Needs to be distinguished from HIV-associated neuropathy	Low CD4 count
Cisplatin	Mainly sensory neuropathy, painful paraesthesia, and dysaesthesia	Cumulative dose
Ethambutol	Loss of visual acuity and visual field Colour blindness	Advanced age Renal insufficiency Diabetes
Isoniazid	Sensorimotor neuropathy	Slow acetylator status Pyridoxine deficiency
Metronidazole	Sensory axonal degeneration	Prolonged use High doses
Pyridoxine (vitamin B ₆)	Paradoxical sensory neuropathy	High dose Long-term use
Statins	Rare Sensory axonal neuropathy	Prior history of neuropathy with a statin
Vincristine	Sensory neuropathy precedes motor neuropathy	High cumulative dose

sensory and motor neuropathies can coexist. Vincristine and other vinca alkaloids inhibit microtubular function, and this blocks axonal transport so that axons degenerate. Thalidomide, now used in the treatment of multiple myeloma, causes treatment-limiting peripheral neuropathy.

Demyelinating polyneuropathy and ascending paralysis with increased CSF protein concentration but without an increase in cells ('dissociation cyto-albuminique'), is the hallmark of Guillain-Barré syndrome, a delayed-type hypersensitivity disorder. It has been reported with gold, corticosteroids, penicillamine, and captopril. An outbreak of Guillain-Barré syndrome was attributed to swine influenza immunization in the United States. The attribution has been questioned. The cytotoxic T-lymphocyte antigen-4 checkpoint inhibitor ipilimumab, used to treat metastatic myeloma, can induce several autoimmune-related neurological adverse effects, including Guillain-Barré syndrome, a myaesthesia gravis-like condition, and an encephalitis.

Drug-induced movement disorders

Akathisia (motor restlessness) is a common adverse effect of phenothiazines and other rapidly acting dopamine antagonists given either for nausea or as antipsychotic medicines. In younger people, acute dopamine blockade can cause acute dystonic reactions, which are manifest as apparently bizarre hyperextension of the neck and trunk, with oculogyric crisis (upward rolling of the eyes). For this reason, the use of metoclopramide, prochlorperazine, and other dopamine antagonists should be avoided in children and young adults. The treatment for acute dystonic reactions, should they occur, is to administer a parenteral anti-cholinergic agent, such as procyclidine. In older adults, the same agents can cause parkinsonism. While this usually requires repeated administration, it can occur after a single dose. Anti-cholinergic agents were once prescribed as prophylaxis to patients treated with antipsychotic dopamine antagonists such as chlorpromazine and haloperidol, but are now reserved for treatment of overt parkinsonism.

If antidopaminergic treatment is continued over many years, patients can develop 'tardive dyskinesia', that is, abnormal involuntary

movements, especially of the lips, face, and tongue. Unconscious chewing, sucking, and tongue protrusion are characteristic. The condition is commoner in older patients, perhaps because the duration of treatment has been longer; in women; and in those who have suffered from drug-induced parkinsonism. Tardive dyskinesia can persist after drug withdrawal.

Conclusion

Drug-induced disorders can affect the central, spinal, and peripheral nervous systems and their integration. They can be manifest as almost any neurological pathology, including infective, immunological, and thrombotic. The diagnosis rests on a careful and complete drug history supplemented by clinical examination and investigation, and by literature review. Treatment is primarily removal of the suspected drug. New, unusual, or serious reactions should be reported directly to MHRA via the Yellow Card Scheme.

241 Functional and dissociative disorders in neurology

Jon Stone and Alan Carson

Definition of the disease

In this chapter, the focus is on patients who present with physical symptoms, such as weakness, or seizures, which can be positively identified as inconsistent with pathological diseases. These are called functional and dissociative neurological symptoms, although there are many other terms used, such as conversion disorder, psychogenic symptoms, somatization, hysterical symptoms, medically unexplained symptoms, non-organic symptoms, and pseudoseizures, to name a few.

Aetiology of the disease

The aetiology of functional and dissociative symptoms remains uncertain but is likely to be multifactorial. Studies consistently find emotional disorders in a proportion of patients, but not all of them. Likewise, the frequency of previous adverse life events (both childhood and recent) is higher in these patients than in matched disease controls, but many patients have no such history. Such features cannot be relied upon in making or excluding a functional diagnosis. Patients with weakness may develop their symptoms suddenly during an attack with features of panic or after a triggering event such as physical injury, or more gradually, in the context of fatigue. The prodromal symptomatology of dissociative seizures is often similar to that of panic attacks. Illness beliefs and iatrogenesis are important maintaining factors but the role of 'secondary gain' appears overestimated. Neurological disease itself is an important risk factor. Although these symptoms are traditionally conceived in purely psychological terms, there is a growing amount of literature on functional imaging and neural correlates.

Typical symptoms of the disease

Functional weakness typically presents with unilateral weakness or heaviness of limbs, although any pattern in the limbs may occur. Functional sensory symptoms are often hemisensory, and patients feel 'split in half'. Functional movement disorders include tremors, spasms, contractures, and jerks. Other functional symptoms include dysphonia, visual impairment, memory loss, and difficulty swallowing (globus).

Dissociation is a common accompaniment to many functional neurological symptoms, especially when acute, and is worth directly enquiring about if not volunteered. Depersonalization is a feeling of being disconnected from one's own body. Derealization is a feeling of disconnection from one's surroundings. Dissociative seizures involve an apparent alteration of consciousness, often preceded by dissociative or panic symptoms. Patients typically either display thrashing, large amplitude, sinusoidal movements (~70%) or lie motionless (~30%). Sudden, prolonged, motionless unresponsiveness does not occur in epilepsy and (apart from cardiac arrest) is almost pathognomonic of dissociative attacks.

Demographics of the disease

The female:male ratio for most functional neurological symptoms is 3:1, except for movement disorders, in which case it is 1:1. Functional weakness has a minimum incidence of 5 in 100 000 per year, like multiple sclerosis, with mean onset in the mid-thirties. Patients may present to a stroke unit and normally complain of fatigue and pain.

Dissociative seizures have a minimum incidence of 5 in 100 000 per year and account for up to 50% of patients admitted to hospital in apparent 'status'. Typically, the mean onset of dissociative seizures is in the twenties, with a history of other functional symptoms such as irritable bowel syndrome, but there is a subgroup with onset in middle age, equal sex distribution, and marked health anxiety (especially about heart disease).

Natural history, and complications of the disease

The spectrum of severity of functional and dissociative neurological symptoms is very wide. Some patients have only transient symptoms, while others become severely disabled and even bedbound. More severe cases may have a lifelong vulnerability to functional symptoms and multiple assessments, investigations, and repeated surgical interventions. In this case, the term 'somatization disorder' is used; this disorder has a poorer prognosis, often with onset before the age of 30. Patients with this disorder usually have a history of repeated presentation to medical services, with at least one neurological symptom, four pain symptoms, two gastrointestinal symptoms, and one sexual symptom.

Approach to diagnosing the disease

Functional and dissociative neurological symptoms should be diagnosed primarily on the basis of positive examination features of internal inconsistency, and incongruence with neurological disease. A history of multiple functional symptoms may be suggestive but is not diagnostic.

With functional weakness, some patients have a typical dragging gait with the hip inverted or everted. The key finding is internal inconsistency, for example being able to walk but having no leg power on the bed. Hoover's sign is positive when a weakness of hip extension (which in itself is unusual in neurological disease) returns to normal with contralateral hip flexion against resistance (see Figure 241.1); hip abduction can also be used. Hoover's sign may be falsely positive in cortical neglect, in mild weakness, or when there is a lot of pain. The weakness can have a 'give-way' quality. Tone and reflexes should be normal.

Functional movement disorders require particular experience to diagnose confidently, because of the sometimes unusual nature of 'organic' movement disorders. Functional tremor is typically variable in frequency, distractible (e.g. with complex motor tasks), or 'entrains' to the rhythm of copied voluntary movement in the opposite hand. Fixed dystonia usually presents with a clenched fist or a plantarflexed, inverted ankle after physical injury or immobilization, and its clinical presentation overlaps with complex regional pain syndrome type 1. Sudden jerky movements may also be functional.

Functional dysphonia is typically a whispering voice, often triggered by laryngitis. Functional word finding difficulties are common, but true dysphasia is not seen. Functional memory complaints present as attentional difficulties (e.g. failure to remember the reason for going up stairs) often accompanied by health anxiety, or as dense retrograde amnesia. Functional visual symptoms can be detected by a range of measures, including the use of tubular visual fields (e.g. the same restriction at 30 cm and 100 cm; visual fields are conical) or eliciting optokinetic nystagmus in functional blindness.

Test hip extension – it's weak

Test contralateral hip flexion against resistance – hip extension has become strong

Figure 241.1 Hoover's sign for functional weakness.

Diagnosing dissociative seizures needs a witness history; phone witnesses or ask carers to video an attack using a mobile phone. Table 241.1 describes clinical features, but any one feature in isolation may mislead.

Other diagnoses that should be considered

The differential for functional and dissociative neurological symptoms includes all neurological disorders. Comorbid neurological diseases are common (e.g. 5%–10% of patients with dissociative seizures also have epilepsy). Diagnosis is usually best confirmed by a neurologist.

Misdiagnosis occurs in less than 5% of patients in published series. It is more common in patients with frontal lobe epilepsy,

movement/gait disorder, and patients with severe psychiatric disturbance.

Factitious symptoms, symptoms deliberately simulated for medical care, and malingering symptoms simulated for material gain may present neurologically. Looking for major discrepancies in the history and using covert surveillance are the only methods for making these diagnoses.

Diagnostic tests

The diagnosis of functional and dissociative neurological symptoms is clinical and not one of exclusion. For dissociative seizures, a normal EEG during a customary attack is helpful, although this can be misleading in a patient with a deep epileptic focus. Many patients will require further investigation to exclude important alternative explanations (e.g. structural MRI in functional weakness). The patient should be forewarned that a negative result is expected.

Prognosis, and how to estimate it

The prognosis for functional and dissociative neurological symptoms is highly variable. Longer duration, personality disorder, and preoccupation with an exclusively physical aetiology appear to predict a worse outcome.

Treatment and its effectiveness

Explanation is the cornerstone of treatment. Patients are often bewildered, or frightened that they have multiple sclerosis or something similar. Make it clear that you believe the patient, that they have something common and potentially reversible, and that you do not think they are 'putting it on'. An explanation of how a positive diagnosis has been made, and, where appropriate, a demonstration of the patient's signs, for example the Hoover's sign, can help engagement with and acceptance of the diagnosis. Sensitivity about exploring psychological symptoms is required, because patients (and doctors) often connect these disorders with being 'imaginary' or 'malingering'. It is alienating, and probably scientifically inaccurate, to present a solely psychological explanation without reference to biological factors.

Symptomatic treatment of associated pain and mood symptoms, self-help (e.g. see <http://www.neurosymptoms.org>), and physiotherapy, especially for motor symptoms, is recommended. Hypnosis may be worth trying, especially for movement disorders. Studies of other functional symptoms support the use of antidepressants and cognitive behavioural therapy.

Before referral for assessment by psychiatry or psychology, ensure the clinician has specific expertise in the field.

Table 241.1 Dissociative versus epileptic seizures: Helpful and less helpful distinguishing features		
	Dissociative seizures	Epileptic seizures
<i>Helpful</i>		
Duration over 5 minutes	Common	Rare
Gradual onset	Common	Rare
Fluctuating/relapsing course	Common	Rare
Eyes and mouth closed	Common	Rare
Resisting eye opening	Common	Very rare
Thrashing, violent movements	Common	Rare
Visible large bite mark on side of tongue	Very rare	Occasional
Respiration	Often fast	Ceases
Obedying commands during generalized shaking	Rare	Should not occur
Weeping/upset after a seizure	Occasional	Rare
<i>Not so helpful</i>		
Stereotyped attacks	Common	Common
Attack arising from sleep	Occasional	Common
Aura	Common	Common
Incontinence of urine or faeces	Occasional	Common
Injury	Common	Common
Report of tongue biting	Occasional	Common

242 Palliative care in neurological disease

Bhavyang Acharya

Definition of the disease

This chapter focuses on the management of patients with terminal neurological disease. The definition of the term 'terminal' varies but could be used to describe a patient who is in the last 6–12 months of their life. Some people prefer to reserve this term for patients in the last days to weeks of their life.

Aetiology of the disease

The definition of progressive neurological conditions is those conditions which are incurable and invariably result in ongoing deterioration without the prospect of improvement. The most commonly encountered conditions are parkinsonian syndromes, motor neuron disease, Huntington's disease, prion disease, cerebellar degeneration syndromes, and muscular dystrophies. Multiple sclerosis can follow a relapsing–remitting course but can also follow a progressive form where there are no remissions. Despite these conditions having many different pathologies, the symptoms relating to the end of life are very similar.

Typical symptoms of the disease, and less common symptoms

The symptoms experienced by this group of patients include weakness, immobility, constipation, nausea, pain, fatigue, hypersalivation (drooling or choking on excessive secretions), swallowing/speech difficulties, breathlessness, weight loss/anorexia, stiffness, anxiety, cognitive decline, agitation, and falls.

Demographics of the disease

In the UK, the incidence of neurological conditions is 625 per 100 000. The prevalence of neurological conditions within the population is approximately 1 million. Of these, approximately 20% are admitted to hospital, and 10% die each year (National Council of Palliative Care, 2010).

Natural history, and complications of the disease

The challenges faced when managing these patients include the multiple different pathologies which contribute to a variable level of physical, cognitive, and emotional decline. Some conditions (e.g. motor neuron disease, especially in the case of bulbar involvement) can be associated with a rapid deterioration from the onset of diagnosis. Other conditions can deteriorate slowly over many years, usually with a more rapid deterioration in the last weeks/months of life.

Complications include:

- swallowing problems
- recurrent infections
- weakness/falls
- hospital admissions

Approach to diagnosing the disease

Recognizing that a patient is dying can present quite a challenge, especially for patients that have deteriorated very slowly over many years. A multidisciplinary approach can often be helpful. Looking at

the literature, the following factors may be helpful symptoms or signs that may help to identify patients that are dying. These are:

- swallowing problems
- aspiration pneumonia
- recurrent infections
- marked decline in performance status
- cognitive difficulties
- weight loss

Other diagnoses that should be considered

When reviewing a patient who is thought to be dying, a thorough assessment including history, examination, and, if necessary, appropriate investigations may be required to identify/exclude reversible causes. The most likely reversible causes are:

- infection
- dehydration/with renal impairment
- other metabolic abnormalities (e.g. diabetes, hypothyroidism)
- depression

'Gold-standard' diagnostic test

It is difficult to accurately predict which patients are in the terminal phase of their illness. Often the most useful predictor of prognosis is the rate of deterioration and the associated comorbidity associated with this. The Gold Standards Framework identifies parameters that may allow the recognition of the terminal phase. The first of these is the so-called surprise question. This question asks the physician if they would be surprised if the patient died within the next 6–12 months. This in itself is an important recognition that the patient may be dying. In addition to this, there are disease-specific clinical indicators that may be suggestive that a patient is dying (see 'Prognosis, and how to estimate it').

Prognosis, and how to estimate it

As discussed earlier, neurological disease represents a wide range of pathological processes and clinical presentations. However, there are clinical indicators that can help to identify the patient who is thought to be dying. In motor neuron disease, a rapid onset and loss of neurological function is likely to represent that a patient will have a poor prognosis. Symptoms and signs suggestive of respiratory failure also are strongly suggestive of a poor prognosis. The prognostic indicator guidance as described in the Gold Standards Framework describes the following clinical indicators as markers for poor prognosis:

- disturbed sleep related to respiratory muscle weakness
- breathlessness at rest
- difficulty swallowing
- poor nutritional status
- poor performance status
- medical complications (e.g. infections)

Other specific issues

There are specific issues relating to patients with progressive neurological disease; these are associated with neurological decline and worsening neurological function. These tend to apply to patients in whom the condition causes predominantly muscle weakness and wasting (rather than stiffness or sensory changes). In these patients,

there may be symptoms related to difficulty in swallowing and related to respiratory compromise.

In terms of nutrition, if a patient's deterioration is primarily related to an inability to eat due to weakness of the bulbar muscles (as in motor neuron disease), it may be important and appropriate to consider a feeding gastrostomy such as a percutaneous endoscopic gastrostomy (PEG) or radiologically inserted gastrostomy tube insertion if it is thought that the patient may still have many months left to live. The decision-making process is complex and must take into account the patient's premonitory condition prior to the problems with swallowing. It is also important to consider a PEG tube insertion as a palliative procedure to satisfy hunger and a route to enable administration of medications and water. The decision-making process needs to take into account the patient's wishes, as they may choose not to have a PEG tube inserted because not being able to eat by mouth may be impacting on their quality of life and, at this point in time, they may prefer symptom control measures rather than interventional procedures.

In terms of respiratory function, if a patient's deterioration is thought to be primarily related to respiratory muscle weakness and compromise, it may be important and appropriate to consider an assessment to see if non-invasive ventilation may be suitable for these patients (usually in the situation where a patient is expected to have many months left to live). Respiratory compromise can cause a lot of morbidity for a patient in terms of breathlessness, lethargy, fatigue, confusion, disturbed sleep, and headaches (due to the effects of hypoxia and hypercapnia).

Non-invasive ventilation in these patients may reduce their symptom burden and morbidity and improve the quality of life even in the last months of life. This needs to be weighed up against the morbidity caused travelling to a specialist respiratory centre for assessment and the burden of being attached to the ventilator. This process also involves the acknowledgement that the non-invasive ventilation may only provide temporary relief of symptoms and may need to be withdrawn if it is no longer effective, in which case pharmacological management of their symptoms will be more important (see 'Treatment and its effectiveness: Management of specific symptoms in the last weeks of life').

Treatment and its effectiveness: Management of specific symptoms in the last weeks of life

Symptom management will often involve the multidisciplinary team and include non-pharmacological and pharmacological measures. Weakness and immobility will require the input of occupational therapists and physiotherapists to improve the patient's function and symptoms using practical measures to provide comfort.

Pharmacological management may be challenging as the patient may be unable to swallow and therefore medications that cannot be swallowed in tablet form may need to be administered as syrups/suspensions. For other patients who have an existing gastrostomy tube in situ, medications may be administered via this route. For the patients who cannot use either of these routes, other routes of administration (e.g. subcutaneous, rectal, buccal, transdermal, or intra-nasal routes may need to be used).

Pain

Pain should be managed holistically, considering non-pharmacological management with input from the physiotherapists and occupational therapists. Pharmacological management should follow the WHO pain ladder, starting with simple analgesics and, if these are not effective, moving onto stronger analgesics.

Nausea

The management of nausea will need to take into account the pathophysiological process of the underlying condition. Haloperidol would be the drug of choice in most circumstances except for patients with parkinsonian conditions, where the dopamine-antagonist effect of this drug and other dopamine antagonists (e.g. metoclopramide/levomepromazine) may worsen the symptoms of the underlying condition and therefore contribute to worsening morbidity/symptoms (e.g. stiffness/tremor). Cyclizine, ondansetron or domperidone may be a better choice of drug for patients with parkinsonism. These drugs can be administered orally or subcutaneously (once daily or as an infusion over 24 hours via a syringe driver). The doses of these drugs are as follows:

- systemic cause: haloperidol 0.5–1.5 mg once daily and as needed (use above mentioned medications in parkinsonian patients)
- gastric stasis: metoclopramide 10 mg, as needed, or three times daily (use above mentioned medications in parkinsonian patients)
- levomepromazine: 6.25 mg once daily and as needed

Fatigue

Fatigue is a very common symptom in these patients and can be a very distressing symptom which impacts negatively on a patient's psychological well-being. Psychostimulants (e.g. methylphenidate) may have a role, even in the terminal phase, in improving the alertness and cognitive function of these patients, thereby allowing them to interact with family members. Psychostimulants are contraindicated in certain circumstances (e.g. in people with ischaemic heart disease) and therefore, if they are considered, specialist advice should be sought.

Secretions

Pharmacological management of secretions is as follows:

- glycopyrronium: 200–400 µg as needed (max 1200 µg in 24 hours)
- hyoscine hydrobromide: 200–400 µg as needed (max 1200 µg in 24 hours)

If these medications are ineffective and the patient is experiencing symptoms of choking (with severe distress), then use midazolam, 2.5–5.0 mg subcutaneously or buccally.

Breathlessness

Pharmacological management of breathlessness is as follows:

- low-dose opioids: morphine sulfate oral solution 2.5–5.0 mg four times daily and as needed (2 hourly)
- lorazepam: 0.5–1.0 mg sublingually (max 4 mg in 24 hours)
- morphine sulfate 1.25–2.50 mg as needed, subcutaneously
- midazolam 2.5–5.0 mg, subcutaneously

Anxiety

Pharmacological management of anxiety is as follows:

- lorazepam 0.5 mg–1.0 mg sublingually (4 mg in 24 hours)
- midazolam 2.5–5.0 mg as needed, subcutaneously/buccally

PART 11

Disorders of the skin

243 Normal skin function

Jenny Powell

Introduction

In simplest terms, our skin is a layer that separates and protects us from the external environment. This assumes the skin is a passive covering to keep the insides safe, and the outside out, and overlooks its enormous complexity. The skin is our largest organ and is constantly regenerating, but how efficiently it does so depends on a number of factors, some known, others unknown. It is an efficient mechanical barrier (designed for wear and repair), and a complex immunological membrane. It has a generous vascular, lymphatic, and nervous supply, all covering a considerable area. It has specialist structural and functional properties relating to specific areas, but also specialist cells within the layers of the skin. Most importantly, skin is the organ of display, an important part of social and sexual behaviour, immediately accessible to all, and often regarded as a barometer of the general state of health. Permanent scars inflicted on the skin may be a cause of great distress to the patient.

Skin structures

Skin consists of a superficial layer, 'the epidermis' (concerned with producing protective keratin and a pigment called melanin), which adheres closely to the deeper layer, 'the dermis' (which provides the strength of the skin, and houses the appendages), via the basement membrane. Loose connective tissue and fat underlie the dermis.

Structures found in the skin include:

- the epidermis
- the horny layer (stratum corneum)
- the granular layer
- the spinous cell layer
- the basal cell layer
- the basement membrane
- the dermis
- the papillary dermis
- the subpapillary network
- arterioles
- venules
- the deep vascular network
- lymphatics
- hair follicles
- subcutaneous fat
- sweat glands
- sebaceous glands
- melanocytes
- desmosomes
- hemidesmosomes

The structure and function of the different skin components are outlined in Table 243.1. Skin thickness varies according to function: for example, it is 0.1 mm thick over the eyelids but is 2 mm thick on the soles of the feet.

Epidermis

The epidermis is composed of stratified squamous epithelium, comprising layers of closely packed cells: the basal cell layer, the spinous layer, the granular layer, and the horny layer.

Structure	Functions
Horny layer	Barrier protection against unregulated loss of salt and water and entry of particles (e.g. chemicals, microbes)
Keratinocytes	Cytokine production, keratin production, production of vitamin D, produce endogenous antibiotics.
Basal cell layer	Reduplication and repair
Langerhans cells	Immunological defence
Melanocytes	Protection against ultraviolet radiation including DNA damage
Basement membrane	Adhesion of epidermis to underlying zone supporting dermis
Dermis	Strength with suppleness, shock absorption, (toughness over back and soles of feet, elasticity over joints, delicacy of eyelids).
Sub-cutaneous fat	Cushioning trauma, insulation and calorie reserve. Also releases hormone leptin to regulate hunger and energy metabolism via the hypothalamus.
Blood vessels	Delivery of nutrients and removal of waste; temperature regulation
Peripheral nerves	Cutaneous sensation
Lymphatics	Drainage and removal of particulate waste
Eccrine sweat glands	Temperature regulation, over most of the body surface, more numerous on hands and feet.
Apocrine sweat glands	Production of pheromones, axillae, anogenital. Wax glands of ear. Milk glands of the breast.
Sebaceous glands	Waterproofing and moisturizing
Fibroblast cells	Synthesis of collagen, elastin, collagenase, fibronectin
Phagocytic cells	Engulf and destroy bacteria
Lymphocytes	Immunological defence
Mast cells	Mediator release under antigenic stimulation, chemotaxis
Nails	Protection and stabilization of terminal phalanx, important in pinching and prising objects
Hair	Display and attraction—social and psychological value; thermal properties

Surgery (Oxford). Volume 24, Issue 1, Pages 1-4 Copyright Elsevier Limited 2006. Author is the same as the original work.

Basal layer

Cells in the epidermis are produced by cell division in the basal cell layer (a single sheet of columnar cells at the lowest level of the epidermis). At any moment, 30% of these columnar cells are preparing for division. After division, one cell remains in position, continuing the task of reduplication, repair, and adherence to the underlying basement membrane. The other cell moves towards the surface suprabasally; it is unable to divide, but differentiates into a keratinocyte. As more cells are created from the basal layer, it is pushed upwards through the spinous and granular layers.

Spinous layer

The next level of the epidermis after the basal layer is the spinous layer, so-called because cells are joined by cohesive desmosomes that resemble 'spines' under the light microscope.

Granular layer

As a keratinocyte moves upwards, it becomes part of the granular layer, two to three layers of flatter cells containing many granules. These granules are lysosomes, containing hydrolytic enzymes that destroy the cell's nucleus and other organelles, resulting in cell death.

Horny layer

As the keratinocyte moves into the horny layer, which is the uppermost epidermal layer, it dies, loses its nucleus, and becomes flattened, with thick cell membranes that enable the cells in the horny layer to adhere to each other. Gradually, these cells flake off, and are replaced by underlying cells. The time from cell division to shedding is 28 days in normal skin. There is a close matching of rate of cell production with loss in healthy skin, and it is increased in response to injury and friction. This implies a local mechanism of repair within the skin.

The horny layer is an effective barrier to most organisms, chemicals, and fluids, although it is permeable to some substances (hence topical treatments). It also protects against uncontrolled loss of fluid from the body.

Keratins

Keratinocytes synthesize keratin, a triple-stranded helical molecule, which is the main structural protein of the epidermis. Keratin filaments form a 'basket' network around the nucleus, with spokes radiating through the cytoplasm to link the nucleus with the cell surface. This network of filaments forms the cytoskeleton. Keratinocytes are involved in the response to injury (see Figure 243.1).

Thirty different keratin molecules have been identified. Keratin molecules exist in pairs: one is acidic (type I), and one is basic (type II); they are transcribed from genes found on Chromosomes 17 and 12, respectively. The keratin pair 14 and 5 is found in basal cells. Production changes to keratins 10 and 1 as the basal cell divides, and the budded cell differentiates. Keratins 16 and 6 are expressed during wound healing, within 12 hours of injury. Mutation of keratin genes results in cell fragility and lysis. The resulting clinical phenotype depends on the keratin pair affected. For example, if mutation occurs in the genes transcribing for keratins 10 and 1, the epidermis is affected suprabasally, and this results clinically in congenital bullous ichthyosiform erythroderma.

Keratinocytes are involved in the response to injury. They produce endogenous antibiotics (defensins and cathelicidins) providing an innate immune defence against bacteria, viruses, and fungi. Keratinocytes also synthesize cytokines.

Cytokines

Cytokines are chemical mediators, secreted by activated cells that affect other cells, usually by binding to cell surface receptors to modulate activity (including stimulation or inhibition of cell secretion, division, and migration, amongst other activities). Cytokines play a major role in inflammatory processes, immunoregulation, growth, and repair, allowing epidermal cells to communicate with and influence each other, and interact with dermal cells. Epidermal cells are also affected by cytokines secreted by other cells (e.g. white blood cells, mast cells, cells in vessel walls).

Cytokine production is stimulated by injury, including that caused by UV light or infection (endotoxins, antigen-T-cell reactions) and is reduced by the effect of corticosteroids. The earliest recognized cytokines include interleukin 1, interleukin 2, interleukin 3, interleukin 6, and interleukin 8; interferon alpha, interferon beta, and interferon gamma; tumour growth factor alpha and tumour growth factor beta; and platelet activators.

Tumour necrosis factor (TNF) has a central role in the immune response. It is released by cells of the immune system (e.g. macrophages, T-cells) when inflammation occurs, often after trauma or infection. Its action is mediated by two receptors, p55 and p75, which are found on the cell surface of various cells of the immune system and body tissues. Soluble p55 and p75 receptors are also found in serum and synovial fluid. Both receptors mediate the effects of fever, tissue damage, and shock. Tumour necrosis factor alpha (TNF- α) also stimulates cells in the surrounding tissue to produce chemokines, that cause the dilation of local blood vessels. TNF- α induces activation

Keratinocyte response to injury

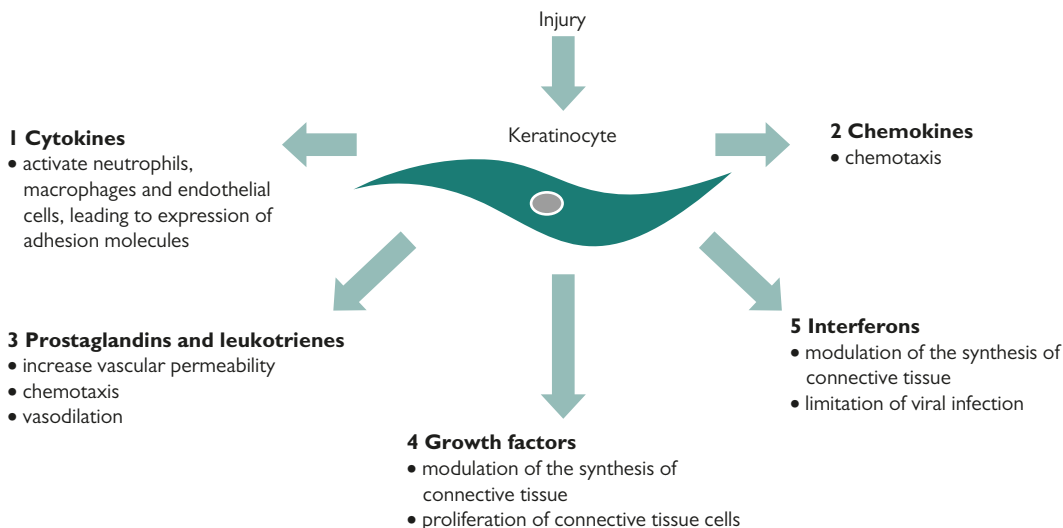

Figure 243.1 Keratinocyte response to injury.

of T- and B-cells and increases the production of cyclo-oxygenase 2. The latter is an enzyme that plays an important role in inflammation and is responsible for the production of inflammatory prostaglandins that stimulate the synthesis of other pro-inflammatory factors. TNF- α therefore acts physiologically to eradicate infection and repair damaged tissues by its direct and indirect actions. However, its central role in the propagation of the inflammatory process may become pathological if it occurs in excess, and tissue damage may result. Treatments have been developed that aim to reduce concentrations of TNF- α , and they may be effective in the treatment of rheumatoid arthritis, Crohn's disease, and psoriasis; for example, infliximab is a chimeric (human and mouse) monoclonal antibody against TNF- α , and it is an effective immunomodulator used singly or in combination. It can trigger complement-mediated lysis of cells expressing TNF *in vitro*.

Other epidermal cells

Melanocytes

Melanocytes are large dendritic cells that are interspersed amongst the basal cell layer. They originate from the neural crest in the embryo and migrate to the ectoderm, hair bulbs, retina, and pia arachnoid. Like neurons, they are terminally differentiated cells (i.e. they no longer divide under normal conditions). Melanocytes contain organelles called 'melanosomes' that synthesize the pigment melanin from the essential amino acid phenylalanine. Melanocytes are under the basal cell layer and send dendritic processes up between the basal cells. The tip of the dendrite is embedded in the cytoplasm of the basal cell and passes melanosomes directly into it. The size and number of melanosomes in the keratinocytes (and not the melanocytes) govern visible pigmentation. In dark-skinned people, there are no more melanocytes than in light-skinned people, but the melanosomes are larger and persist through the whole thickness of the epidermis. UV radiation increases melanocyte production and transfer of melanosomes, and the increased pigmentation or 'sun tan' helps to protect the skin from damage from UV light. Other influences on pigment formation include genetic factors, sex hormones, and melanocyte-stimulating hormone from the pituitary gland.

Langerhans cells

Langerhans cells are dendritic cells that are derived from bone marrow but migrate to the epidermis, and 2×10^9 of them persist in the epidermis, especially in the prickle cell layer. They are sentinel cells forming a network in the epidermis. They detect and collect exogenous antigen (i.e. anything coming through the skin), process it, and present it non-specifically to T-cells in the skin or lymph nodes. In this way, the T-cells specific for the antigen will receive some antigen, and be activated. Langerhans cells are part of the immunosurveillance system against viral and tumour antigens. They have lobulated nuclei and characteristic, racket-shaped organelles called 'Birbeck granules'. These granules arise from the cytoplasmic membrane by receptor specific endocytosis, thus internalizing human leukocyte antigen molecules from the cell membrane involved in antigen processing.

Langerhans cells possess surface receptors for the Fc portion of immunoglobulin-G and intracellular adhesion molecule 1, so they can adhere to other cells and thus permit communication. There are thousands of Langerhans cells per square centimetre of epidermis, and their interconnected dendritic arms form a network of communication through the skin. They can migrate from the epidermis to regional lymph nodes, and their mobilization is mediated through the interaction of their cell surface receptors with cytokines and chemokines. Langerhans cells can free themselves from the epidermis by the expression of and induced changes in adhesion molecules such as E-cadherin, CD44, and A6 integrins. Proteolysis must occur for the Langerhans cells to pass across the basement membrane.

Topical exposure of mice to contact allergens and skin irritants stimulates the expression of epidermal cytokines, including TNF, interleukin 1 beta, granulocyte macrophage colony-stimulating factor, and interleukin 6. The first cytokine to be identified as a stimulus for migration of Langerhans cells was TNF- α , produced by keratinocytes acting via TNFR2 receptors on the Langerhans cell surface. Langerhans cells then produce interleukin 1 beta, which acts in an autocrine manner to stimulate migration. It also stimulates further production of TNF- α by keratinocytes.

Merkel cells

Merkel cells are not dendritic, and lie near hair follicles and unmyelinated nerve endings. It is thought that they may be transducers for fine touch, but their exact role is unclear.

Dermis

The dermis lies below the epidermis and supports it structurally and nutritionally. It primarily consists of fibroblasts and the collagen they produce. Collagen is a triple helix, comprising three polypeptide chains. Fibres are packed in bundles and give enormous tensile strength. The dermis also contains elastin fibres that provide stretch. The fibres sit within a matrix of amorphous mucopolysaccharide ground substance. This binds water to facilitate passage of nutrients and other chemicals, acts as a lubricant to allow skin movement, and provides bulk to aid shock absorption. The dermis contains blood vessels, lymphatics, and sensory nerves.

Blood vessels

Blood vessels form a deep plexus in the subcutaneous fat, to supply the sweat glands, the hair papillae, and a superficial plexus in the papillary dermis. Vasodilation can increase blood flow by a factor of 100, a reserve essential for thermoregulation, wound healing, and repair.

Lymphatics

Lymphatics collect tissue fluid and particulate matter by passive drainage and form part of the immune defence system. Lymphoedema results if they fail or are blocked or damaged, and can cause considerable disability.

Sensory nerves

Sensory nerves are abundant in the skin, and are used for touch, heat, pain, and itch. Mechanical, chemical, and cytokine stimuli affect fine, free nerve endings at the dermo-epidermal junction. Pruritus can be reduced by agents that interfere with the effect of cytokines on 'itch' fibres (e.g. topical corticosteroids, antihistamines).

Basement membrane zone

The basement membrane zone forms an adhesion complex between the dermis and epidermis, providing support for the basal cells to allow growth, multiplication, and migration, and allowing nutrients and cells to cross from the dermis (see Figure 243.2). Antibodies to specific components of the basement membrane zone may be found, via immunobiochemistry, in autoimmune blistering diseases and can be seen with fluorescein labelling. Antibody action leads to destruction or damage of the specific target component, which causes lack of cohesion and blistering (e.g. bullous pemphigoid). Blistering may also be genetic, and result from faulty production of one or more basement components (e.g. dystrophic epidermolysis bullosa).

Components of the basement membrane

Components of the basement membrane include:

- collagen types I and III (from the dermis)
- basal cells (from the epidermis)
- keratin intermediate filaments
- hemidesmosomes (on plasma membranes)
- the lamina lucida (electron-lucent zone), which contains laminin and fibronectin
- the lamina densa (electron-dense zone), which contains collagen type IV
- anchoring filaments:
 - anchoring fibrils, which are made up of collagen type VII
 - anchoring plaques, which are made up of collagen type IV

Keratinocyte response to injury

Keratinocytes respond to injury by secreting chemokines, cytokines, prostaglandins, leukotrienes, growth factors, and interferons. Chemokines mediate chemotaxis. Cytokines activate neutrophils,

Figure 243.2 Components of the basement membrane.

Reproduced with permission from the Oxford Handbook of Medical Dermatology: Blisters, edited by Susan Burge, Dinny Wallis. Oxford University Press 2010.

macrophages, and endothelial cells, leading to the expression of adhesion molecules. Prostaglandins and leukotrienes increase vascular permeability, cause vasodilation, and mediate chemotaxis. Growth factors modulate the synthesis of connective tissue, and the proliferation of connective tissue cells. Interferons also modulate the synthesis of connective tissue, and act to limit viral infection.

The skin and psychological stress

Psychological stress may precipitate or aggravate chronic disorders of the skin (e.g. atopic eczema, psoriasis). Skin permeability is altered at times of stress; in animal studies, this coincides with corticosteroid secretion and can be reversed by giving anxiolytics or glucocorticosteroid receptor antagonists. In humans, there is a disruption of the epidermal barrier function during times of increased stress. This may explain why hypnosis is helpful in the treatment of psoriasis. It also explains the reduced resistance to the scratch reflex during times of stress.

Conclusion

Skin disease may be life-threatening. The incidence of fatal malignant melanoma is increasing, and erythroderma resulting from eczema, psoriasis, or lymphoma may cause death. Less well recognized is the disability caused by mild disease of the skin and minor blemishes, including scars. Skin is the organ of display, and abnormalities can disrupt patients' ability to physically and emotionally cope with themselves, their families, and their homes. Education, employment, and relationships may suffer if the patient perceives his or her skin as abnormal.

244 Approach to diagnosing skin disease

Jenny Powell

Introduction

Making a diagnosis in dermatology may seem daunting when there are 6 000 or more possibilities, and the terminology seems so complex. This chapter suggests a systematic approach to picking up clues from symptoms and signs, and understanding how to describe skin disease; this approach, together with experience (obtained through seeing patients, asking more experienced colleagues, and reading) will help with pattern recognition and, sometimes, lead to the answer.

The skin has such a wide range of structural and functional varieties that disorders of the skin are not only common but also very variable. However, it is important to be able to give a patient a diagnosis. This 'working label' means that the patient fits into a known group not only in their typical presentation but also as a guide for response to treatment, prognosis, and, sometimes, for explanation of aetiology and whether genetic or infective factors are important; that is, it is helpful in explaining the disease to the patient.

Despite the complexity of the skin, making a diagnosis in dermatology is no different from making a diagnosis in other areas; it is based on taking a history, examining the patient, and performing investigations, if indicated.

History

A complete history is made up of the following parts: the basic history, a past history, a family history, a social history, and treatments, as well as further enquiry, if necessary.

Basic history

The basic history gives an idea of the patient's personality (and sometimes their theory of the diagnosis; this may or may not be helpful!) and establishes the onset and duration of the problem. It also establishes how the problem has evolved, changed, and spread; skin problems are often 'dynamic' and patients may bring photographs of previous stages of their evolving rash, as, for example, there may have been a 'herald patch' which has almost healed by the time the patient presents with the widespread smaller patches of pityriasis rosea. In addition, it allows the patient to admit how self-conscious they feel about the problem (this may be to the point of disgust and despair) and how it affects their quality of life at home or at school/work, their sleeping, and their personal relationships.

It is important to ask whether the problem is associated with itching, burning, or soreness. Pain is rare but can be diagnostic (e.g. pain on sun exposure with erythropoietic porphyria). Some lesions may be very tender or painful (e.g. lipoangiokeratoma, glioma). Itching (or 'pruritus') is a frequent complaint and can be further elucidated; when severe, it may be described as worse than pain, preventing sleep and interfering with work or school. The itch of Hodgkin's disease and that of dermatitis herpetiformis is very intense. The itch of scabies may be worse at night, whereas urticarial itch tends to be worst on waking. Many rashes cause no itching, but pruritus may occur with no rash, other than excoriations from scratching.

Past history

Past history enquiry may provide information about previous skin disease, allergies, and systemic illnesses, such as diabetes.

Family history

A family history may provide clues about genetic disorders (e.g. atopy, psoriasis, autoimmune diseases, skin type, skin cancer, etc.) and infectious diseases (e.g. warts, scabies, chicken pox).

Social history

A social history gives information on occupational risks, hobbies, and sun exposure.

Treatments

Treatments prescribed by medical practitioners, including complementary medicine, and those tried by the patients themselves may all affect the skin. These can include huge numbers of topical treatments and cosmetics, most of which patients may not mention or remember.

Further enquiry

Further enquiry is often made once the examination is underway. Detailed accounts of foreign travel, sexual history, and exposure to all possible allergens are only needed if unusual infection, sexually transmitted disease, or allergic contact dermatitis, respectively, are suspected.

Examination

It is best to examine the whole of the patient's skin, inspecting and palpating, in daylight. The presenting problem may be a solitary warty lesion on the nose, but full inspection may reveal an unnoticed malignant melanoma on the back. It is important with rashes to know their extent and full distribution.

A dermatological assessment involves determining the answers to the following questions:

- How is the patient's general health?
- Where is the problem and how widespread is it?
- What type of lesion is involved?
- What are the characteristics of the lesion(s)?
- Are any other areas affected in similar or different ways ('secondary' sites)?
- Are special techniques for examination needed?
- Are further tests or investigations needed?

How is the patient's general health?

A general assessment of the patient's health often provides information that will help the diagnosis. The age, sex, race, shape, and mental state of the patient may be noted automatically but it still contributes to the arrival at a diagnosis of a skin complaint. Obese patients are more likely to have intertrigo (secondarily infected areas of skin in the sweaty skin flexures), whereas thin, cachectic patients are more likely to have a paraneoplastic skin problem related to an underlying malignancy. If anaemia is suspected, it may explain why the pruritus is so severe, since iron deficiency worsens the sensation of pruritus. Is there obvious sun damage to the skin, or a high tan? Many skin problems, including photosensitivity and skin malignancy, are sun related.

Ageing patients may develop multiple lesions that cause anxiety but are entirely benign. The most common of these are seborrhoeic keratoses, which are discrete lesions of benign epidermal hyperplasia, and Campbell de Morgan spots, which are benign haemangiomas. Darker skinned patients often show more variation in pattern of pigmentation than do Caucasians.

Where is the problem and how widespread is it?

Determining the site(s) and extent of the problem is very important; for example, atopic eczema occurs mostly in the flexures in children, whereas psoriasis affects the extensor surfaces of knees and elbows,

as well as the scalp and sacrum. Acne appears mainly on the face and the upper back and chest, whereas basal cell carcinomas occur mostly on sun-exposed areas of the head and neck. Necrobiosis lipoidica causes circumscribed lesions on the shins of diabetic patients, whereas keratosis pilaris is most often found on the upper outer arms. A symmetrical rash suggests an endogenous underlying cause, whereas a unilateral rash may suggest an external aetiology, such as allergic contact dermatitis (e.g. jewellery and nickel dermatitis) or an infection (e.g. herpes simplex or tinea corporis). In addition, localization may occur with other external factors (e.g. the photosensitivity of porphyria cutanea tarda; blistering caused by footwear in epidermolysis bullosa; reactions to treatments seen in facial rosacea induced by topical steroids).

What type of lesion is involved?

Learning and using the correct terms to describe a skin lesion not only help to make a diagnosis but also help in recording the problems and communicating with colleagues. It is not really complicated, and the use of a systematic scheme of description soon becomes automatic.

The following terms can be used to identify the different types of lesions that can be seen:

- macule: a flat, impalpable, defined area of skin discolouration
- papule: a raised, palpable, defined area <0.5 cm in diameter
- nodule: a raised, palpable, and visible lump >0.5 cm in diameter
- vesicle: a small, visible, fluid-filled lesion (blister) <0.5 cm in diameter
- bulla: a large, visible fluid-filled lesion (blister) >0.5 cm in diameter
- pustule: a visible, pus-filled lesion
- plaque: a defined, raised, disc-shaped area of skin; considered large if >3 cm in diameter
- ulcer: a loss of epidermis and, in some cases, of dermis also
- weal: a well-defined area of raised cutaneous oedema (often called a 'hive')
- comedo: an open, raised lesion with a central white point (in which case the comedo is termed a 'whitehead') or a closed, dilated, blocked follicle (in which case the comedo is termed a 'blackhead'); both types of comedo are found in acne
- excoriation: a region of damage caused by scratching; may be linear
- horn: a raised projection of keratin
- telangiectasia: a visible small blood vessel in thinned skin, caused by sun damage or topical steroid use; also seen in benign spider naevi in children, or running over the pearly edge of a nodular basal cell carcinoma
- stria: a linear, atrophic (dermally thinned) lesion often secondary to increased growth at puberty; the expansion of the abdomen in pregnancy; or corticosteroid use

What are the characteristics of the lesion(s)?

The characteristics of a lesion include its size, shape, border, colour, and surface texture.

Size

Measure the size of the lesion in centimetres. Many clinicians also approximate the size to fruit, vegetables, or coins.

Shape

Record the shape of the lesion; it may be round, discoid, oval, annular (ringlike), linear, irregular, or regular. An annular shape often suggests that there has been central healing of the lesion, such as in the fungal infection tinea corporis (ringworm) or in granuloma annulare. Lichen planus that has moved or 'koebnerized' into a scratch or scar will have a linear shape. A dysplastic naevus with pigment spreading beyond the smooth border will have an irregular shape. A regular shape with straight edges suggests injury or an allergic response to an applied agent (e.g. allergic contact dermatitis to colophony, which is found in some sticking plasters).

Border

Look at the lesion's border; this may be well defined, as in psoriasis, or less so, as in eczema.

Colour

The colour of the lesion may be characteristic; for example:

- pink red: in common exanthems and inflammatory conditions such as eczema, psoriasis, and urticaria
- reddish-brown: in seborrhoeic dermatitis; pigmented purpuric dermatoses; and apple jelly nodules in cutaneous tuberculosis (*lupus vulgaris*)
- scarlet red: if there is a notable arterial component, as in pyogenic granuloma or spider naevus
- dark red: in vascular lesions such as haemangiomas and telangiectasias
- white: in post-inflammatory hypopigmentation, or depigmentation caused by vitiligo
- silvery: in psoriasis scale
- yellow: in xanthomatous disorders, jaundice
- orange: seen with haemosiderin in lichen aureus
- violet: seen in eyelids and dorsum of the fingers in dermatomyositis
- purple: in the pruritic, polygonal papules of lichen planus
- brown: in pigmented naevi, suntanned areas, or staining of the skin
- slate grey: in minocycline-induced pigmentation
- black: in malignant melanoma and dried, crusted blood
- blue-black: in rubber bleb and blue naevi

In addition, tattoos and bruising may introduce many other colours!

Surface texture

The surface texture of the lesion can help differentiate many diagnoses:

- smooth: if the lesion is superficial, it may be a macular lesion, such as a pigmented lentigo; if deep, it may be a dermal problem, such as granuloma annulare, or indicate swelling with no break in the epidermis, as occurs in urticaria
- scaly: a scaly texture results from the presence of flakes of accumulated epidermal cells, as occurs in psoriasis and fungal infections
- crusted: dried exudate forming a scab indicates a healing ulcerated lesion or wounds; alternatively, it may indicate impetigo, with serum crusting in bacterial infection
- macerated: softening and swelling of the skin occurs secondary to long-standing exposure to moisture
- lichenified: this is thickening and hardening of the skin and occurs in response to prolonged scratching
- blanching: this is loss of colour in response to pressure; it is seen with most inflammation but, importantly, is not seen in the palpable purpura of the vasculitis, as found in meningococcal septicaemia

Are any other areas affected in similar or different ways ('secondary' sites)?

Often it is possible to confirm a diagnosis by examining sites distant to that at which the patient has noticed a problem; for example:

- nails may be dystrophic with pits and onycholysis in psoriasis
- there may be telangiectasias in nail folds in dermatomyositis and lupus erythematosus
- the buccal mucosa may show a white lacy pattern and/or erosions in lichen planus
- the fingers may show burrows in scabies
- the genitalia may exhibit pallor, atrophy, and scarring in lichen sclerosis
- the toe web spaces may show 'athlete's foot' in fungal infections
- the iris may be flecked in atypical mole syndrome
- the appearance of a herpes simplex (a cold sore) on the lips may precipitate the widespread rash of erythema multiforme with target lesions
- lymph nodes may be enlarged from the secondary spread of malignant melanoma

Are special techniques for examination needed?

Special ways to examine the skin further are as follows:

- a hand lens and a dermatoscope can be used to magnify the changes seen on the skin and hair surface, to identify nits (head lice egg cases) and see fungal disease

- a Wood's lamp (UV light) can be used to show characteristic skin fluorescence in certain conditions, and urine fluorescence in some porphyrias
- skin scrapings may be looked at in clinic for fungi and yeasts, as well as being sent for culture
- smell can help in detecting anaerobic infection or the rare condition trimethylaminuria
- a wheal-and-flare reaction appearing after a scratch to the skin, or 'dermographism', is more commonly found in patients with urticaria
- a crust may be removed to ascertain the nature of the underlying lesion
- paring the skin may make it possible to differentiate between a wart and a corn
- a psoriatic plaque may be scratched to look for capillary bleeding
- if the lesions in a blistering disorder are superficial, as in pemphigus, the intact blister may be extended with gentle pressure (Nikolsky's sign)
- pinprick sensation may be lost in leprosy; the response to a light touch may be impaired in diabetic neuropathy
- glass slides may be used to look for blanching, as well as in diascopy, where pressure reveals the brown lesions of cutaneous tuberculosis when apple jelly nodules are flattened
- measuring the elasticity of the skin can be used to detect changes in growth of connective tissue; this skin will be more

rigid in scleroderma but will exhibit extra mobility in Ehlers–Danlos syndrome

- sweating from the skin can be measured via the starch–iodine method; sweating will be increased in hyperhidrosis and reduced or absent in some ectodermal dysplasia syndromes
- the length, colour, and diameter of hair can be determined with a hand lens, and the surface of the hair can be examined via light and electron microscopy; growth can be assessed by looking at dye/bleach growth margins

Are further investigations needed?

Further investigations may be needed to make or confirm the diagnosis; these include:

- swabs, scrapes, and tissue samples, to look for infection
- blood tests, to look for underlying disease, or for genetic testing
- skin biopsy, for histopathology
- patch testing, to look for allergic contact dermatitis

245 Investigation in skin disease

Jenny Powell

Special investigation techniques in skin disease

When taking a history and examining the patient do not provide all the information required, further investigation is possible. This may be to provide a diagnosis, to add to prognostic information, to help with treatment required, or to find an associated systemic disorder or underlying genetic disorder.

Blood tests

Blood tests that may be used to investigate skin disease include:

- haematology and biochemistry:
 - for diagnosis and for monitoring the effect of systemic treatments
 - infections and inflammatory disorders may produce a neutrophilia and raised inflammatory markers (erythrocyte sedimentation rate and C-reactive protein)
 - eosinophilia ($>0.44 \times 10^9/l$) is seen in atopy, parasitic infestations, allergy to drugs, bullous disorders, eosinophilic fasciitis, and some cases of polyarteritis nodosa
- immunological studies:
 - to diagnose connective tissue disease
 - IgE and radioallergoabsorbent tests in allergy/atopic diseases
 - specific antibodies to diagnose autoimmune blistering disease
- genetic studies

Wood's lamp

A Wood's lamp is a UV lamp; in the light produced by it, visible rays are excluded via the use of a nickel oxide filter. Use of Wood's lamp aids in making a diagnosis in the following conditions:

- fungal infections: tinea capitis caused by *Microsporum* spp. appears fluorescent green, while pityriasis versicolor appears yellow; however, most fungi do **not** fluoresce
- bacterial infections: erythrasma caused by Gram-positive corynebacteria glows coral pink, while that caused by *Pseudomonas pyocyanea* appears yellow-green
- pigmentary change (e.g. vitiligo; ash leaf macules in tuberous sclerosis; café-au-lait patches in neurofibromatosis) is made more visible
- porphyrias: urine and faeces fluoresce in porphyria cutanea tarda; teeth fluoresce in erythropoietic porphyria; and blood fluoresces in protoporphyria

Identification of scabies mites

Scabies mites may be visualized with a dermatoscope (illuminated magnification), but it is possible to extract a mite from a burrow with a needle, see it using a microscope, and then show it to the patient to prove the diagnosis. Potassium hydroxide (10%) added to the scrapings under a coverslip helps dissolve the cell membranes. Gentle scraping of a burrow (e.g. in an affected interdigital space) may reveal the mite, its eggs, and its faecal pellets.

Swabs, scrapings, and clippings

Material from the skin, hair, or nails can be used for examination under the microscope or cultured to look for evidence of infection. This is especially useful in suspected fungal infections.

Skin biopsy

Microscopic examination of tissue in a skin biopsy is an important technique often used to confirm or establish a diagnosis and also to

Figure 245.1 A punch biopsy.

Reproduced with permission from the Hampshire Hospitals NHS Foundation Trust.

remove malignant lesions. The procedure can be performed under local anaesthetic (1% or 2% lignocaine, with or without adrenaline to reduce bleeding, unless performed on the fingers or toes) in an outpatient setting with the patient's consent. It is important to check that the patient is not being treated with an anticoagulant and to warn that scars on the upper trunk may heal with keloid formation and that scars on the lower legs of elderly patients may suffer from slow healing.

A punch biopsy is a quick method used to obtain a small piece of skin. The biopsy is obtained by pushing a round, sharp-ended metal cylinder blade into an area of anaesthetized skin, with a downward twisting movement (Figure 245.1). The small plug of tissue is removed from the cylinder, and the base of the wound is treated with pressure, electrocautery, or a small suture to achieve haemostasis (Figure 245.2).

An elliptical biopsy provides larger samples for diagnosis or complete removal of even quite large lesions from an area of anaesthetized skin. An incisional diagnostic biopsy should be taken at right angles to the margin and include a margin of normal perilesional skin. Excisional biopsies require a wide-enough ellipse around the

whole lesion, with a margin of normal skin. The edge must be cut vertically and not slant in towards the tumour. The long axis of the wound should follow the natural creases of the skin. The edges are brought neatly together with sutures, some subcuticular absorbable ones if necessary, and the finest possible sutures in the skin itself give a good cosmetic result with a fine linear scar.

Curettage is a useful device for removing hyperkeratotic lesions. A sharp-edged, spoonlike curette is used to remove the lesion from anaesthetized skin, and the wound is cauterized to achieve haemostasis. It may be difficult to assess the adequacy of removal.

A shave biopsy is used for the removal of protuberant superficial lesions; in this procedure, the lesion is removed with a sharp blade flat to the skin. A snip biopsy is used for the removal of skin tags.

Following the biopsy, the specimen is transported in a buffered formalin solution. It is processed, cut up, and stained, usually with haematoxylin and eosin, but there are numerous 'special' stains (e.g. Ziehl-Neelson stain for acid-fast bacilli; Congo Red stain for amyloid). In addition, there are many immunochemistry panels for specific cell markers (e.g. S-100 1, for melanocytes; tryptase 1, for mast cells; IgG and IgM for immunofluorescence labelling; and numerous markers for lymphoma and leukaemia). It is important to give the histopathologist good clinical information so the correct stains can be employed to confirm or refute the diagnosis.

Skin testing for suspected allergy

Substances introduced to the skin can give valuable information about immunological and pharmacological reactions. The significance of the results has to be interpreted according to each patient's individual clinical details.

Epicutaneous/patch tests are used to find out if a suspected allergic contact dermatitis exists; this is a test for delayed hypersensitivity. Possible allergens, diluted in suitable vehicles, are placed in small discs in contact with the skin, most often on the back (Figure 245.3). There are several 'batteries' of allergens, for specific conditions; some (e.g. standard, facial, and hairdressing batteries) may be applied together with one or two allergens prepared from suspected substances brought by the patient. The patch testing may be extended to include testing for photoallergy, and often for possible sunscreen allergy. The discs are removed at 48 hours, and the results are read at 48 and 96 hours. A positive reaction with erythema and palpable swelling at 48 and/or 96 hours confirms delayed hypersensitivity to the allergen in the disc at that site.

Intradermal injection or prick tests are used to see if there is an immediate hypersensitivity to a particular allergen. In this test, a drop of the test solution is placed on the skin, and a sharp needle is used to make a small prick through the drop. The size of any resulting weal-and-flare reaction is measured at 15 minutes and is compared to positive (histamine) and negative controls. When testing patients with severe allergic reactions (e.g. to peanuts), it is important to be prepared for the severe reactions that occasionally occur with prick

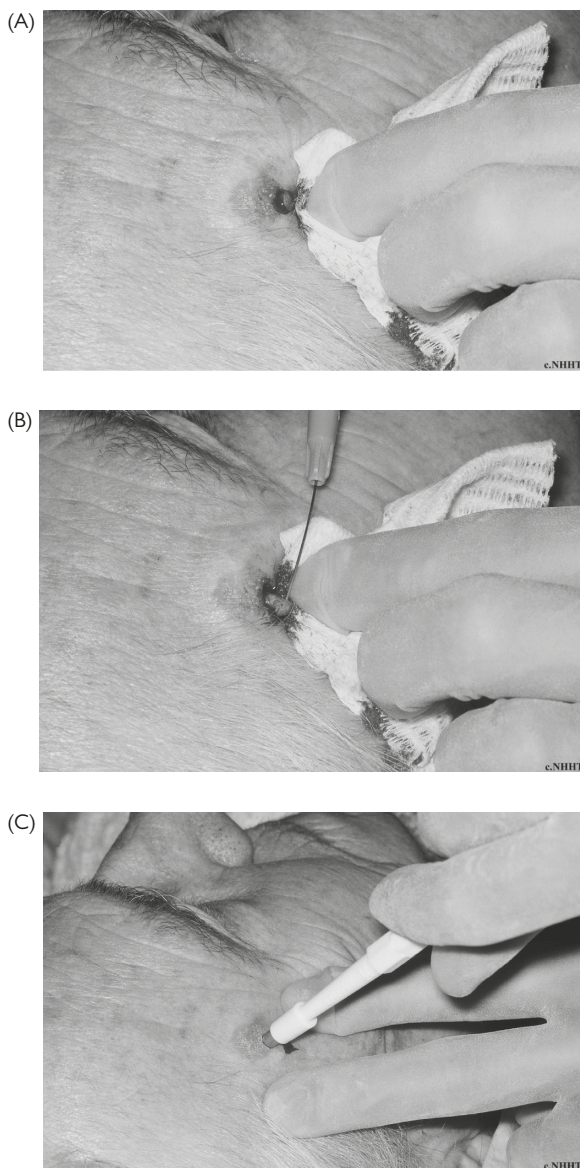

Figure 245.2 A punch biopsy procedure.

Reproduced with permission from the Hampshire Hospitals NHS Foundation Trust.

Figure 245.3 Patch tests, applied to the back.

testing. In addition, larger doses of allergen may be injected intradermally to test for delayed hypersensitivity to bacterial, fungal, and viral antigens indicating infection (e.g. the tuberculin test).

Moderate to large doses of corticosteroids may inhibit the positive response to patch tests but have no effect on prick-test reactions. Antihistamines, however, inhibit the weal-and-flare reaction of prick tests.

Radiology and imaging

In most patients with a skin problem, the skin can be seen and felt and further imaging is not necessary. However, imaging via X-rays, MRI, PET, and/or high-resolution ultrasound is useful for:

- detecting lymphadenopathy or metastatic skin cancer
- guiding biopsies
- determining the extent of an infection
- differentiating between cellulitis and necrotizing fasciitis
- detecting an internal disease that is linked to a skin condition (e.g. nervous system involvement in neurofibromatosis; muscle involvement in dermatomyositis; chest involvement in sarcoidosis)
- examining peripheral lower leg arteries (via Doppler assessment) before using high-compression bandaging in the treatment of venous leg ulcers

Photography and telemedicine

Photography may be used to document the size, extent, and nature of skin changes. This aids the detection of ongoing change in the skin (e.g. looking for worrying changes in atypical naevi, documenting improvement of a rash with treatment, showing healing or extension of a leg ulcer). Photography is also helpful when the patient suffers an intermittent rash, as a photograph is better than the patient's description in many cases.

Telemedicine can be effective if it is difficult for the patient to reach the dermatologist (because the patient is from abroad, live in a remote area, or has a disability) but is not as efficient or diagnostically reliable as the patient attending the dermatologist's clinic in person. Images may be sent electronically, and if the telemedicine consultation is set up well, with good photography and a primary care physician present (a 'real-time' teleconsultation), the accuracy of the diagnosis, as well as satisfaction with the consultation, is improved.

246 Skin infection and infestation

Christine Soon

Definition of the disease

An infection of the skin means a breach of the skin barrier has resulted in an organism gaining an opportunity to infect the area and causing inflammation, pain, erythema, and swelling. There can be associated systemic unwellness such as pyrexia, tachycardia, and hypotension.

An infestation occurs when creatures inhabit the skin, lay eggs, and multiply. These creatures are usually dependent on their host for food and transmission to others. They typically cause intense pruritus in the affected areas.

Aetiology of the disease

Organisms causing infection of the skin include bacteria, viruses, fungi, and yeast. Bacterial infection can lead to cellulitis, impetigo, cutaneous tuberculosis, leprosy, and others. Viral infections include herpes simplex, varicella, herpes zoster, HHV8, and HPV.

Fungi infections include trichophyton infections, microsporum infections, deep fungi infection, histoplasmosis, and so on. Yeast infections are caused by organisms such as candida, *Malassezia furfur*, and so on.

Infestations of the skin include scabies and those caused by lice and fleas.

Typical symptoms of the disease, and less common symptoms

Symptoms will depend on the aetiology. A bacterial infection such as cellulitis is typically caused by staphylococci or streptococci. The skin will become warm, erythematous, tender, and swollen. It may occur after a break in the skin barrier and can be associated with systemic symptoms such as malaise, pyrexia, nausea, tachycardia, and rigours. There may be associated lymphadenopathy. If the area affected becomes too swollen, blisters may occur.

Impetigo is a common skin infection in children. The causative agents are usually staphylococci or streptococci. The lesion is erythematous and often has a golden crust. It is contagious. In severe cases, blistering is seen.

Cutaneous tuberculosis has several different types of presentations: lupus vulgaris, scrofuloderma, tuberculid, military tuberculosis, and verrucosa cutis. It can be associated with lung tuberculosis or it can run a fairly indolent course.

Other mycobacterium infections include *Mycobacterium marinum* infection. It usually spreads in a sporotrichoid fashion up one limb such as the arm. It often lives in tropical fish tanks, and owners of tropical fish are more at risk.

Leprosy can present as hypopigmented patches of skin with loss of sensation and thickened nerves. It can also resemble a widespread erythematous rash with nodules, papules, and plaques.

Infestations with scabies mites, fleas, and lice are usually intensely pruritic. Patients may scratch themselves constantly and present with excoriations, bleeding on skin, scratch marks, and general distress. In scabies, burrows may be present. They sometimes have urticated lesions as well. Infants with scabies can have pustules on their palms and soles.

Flea bites often present as erythematous, itchy papules, especially on the lower limbs.

Head lice cause intense itching on the scalp. The eggs of the head lice, known as nits, may be seen on affected hair shafts. Nits and even the lice themselves may be extracted through the use of a

very fine-toothed comb. Pubic lice cause itchy papules in the genital region. Bedbugs are experiencing resurgence. Their bites appear as itchy red papules, often grouped in a linear fashion and colloquially referred to as 'breakfast, lunch, and dinner'.

Viral infections of the skin may present as vesicles and erythema, as in varicella. Varicella affects the mucous membranes as well and may result in difficulty eating and drinking. It is also typically itchy. Shingles, or herpes zoster, is reactivation of the varicella virus. It tends to affect a single nerve root and, therefore, the appearance is of erythema, vesicles, and crusting affecting just one dermatome. It seems to be more common when a person's immunity is compromised or when there is increased stress. It affects the elderly more often and can result in post-herpetic neuralgia. This can persist despite the skin lesions settling.

Herpes simplex is commonly seen as a crusted nodule around the mouth or nose. It can also present in the genital area as a crop of intensely tender vesicles. Genital herpes is considered a sexually transmitted disease.

Fungus infection of the skin can appear as an itchy, erythematous, scaly, annular lesion with a well-defined ring. It can appear as numerous lesions or as a solitary lesion. It can also present as a scaly area on the scalp, often associated with some hair loss. When it affects the nails, the nails often become thickened, brittle, and yellow.

Less commonly, deep fungal infections of the skin occur, especially in the immunocompromised. This can present as erythematous nodules that may exude pus and ulcerate.

The most common yeast infection seen is thrush, caused by candida. It can affect the moist skin-fold areas and cause erythema and soreness. It is often associated with satellite lesions. Candida in the genital area is often accompanied by a white, cottage-cheese-like discharge. Oral candida appears as white patches on the tongue and oral mucosa. It can be very sore.

Malassezia can cause pityriasis versicolor. This presents as flaky, pigmented patches typically on the upper back and chest in a Christmas tree distribution. When it settles, it can leave hyperpigmentation or hypopigmentation of the skin.

Demographics of the disease

Cellulitis is more common in skin that has been damaged, creating an opportunity for the organism to invade the skin. It is also more common in patients with damaged lymphatic flow, such as patients with lymphoedema.

Scabies commonly occur in institutions where individuals are in close proximity with each other. This can be in residential and nursing homes, hospitals, or hostels.

Tinea capitis (fungal infection of the scalp), head lice, and impetigo are more common in children and are often passed on through close play and contact with others.

Pubic lice, genital herpes simplex, and HPV genital warts are sexually transmitted and seen more often in the sexually active.

Fleas tend to originate from animals, and flea bites are more common in pet owners, although fleas can survive in carpets and soft furnishing for many months after the pet has been removed.

Other animals such as cats, dogs, and horses can transmit fungal infection.

Leprosy and tuberculosis are more common in the developing world and are spread by droplet infection.

Bedbugs live in mattresses and soft furnishings such as carpets and cushions, and can be transmitted via suitcases and clothing to other areas.

Natural history, and complications of the disease

Most infections and infestations have a good prognosis. They are, however, contagious, and care should be taken to give adequate advice to patients and their close contacts. It is important to establish the diagnosis and treat appropriately. They can be more common in immunocompromised patients, the elderly, children, and patients with underlying conditions such as diabetes.

Most viral infections are self-limiting and will resolve on their own. Post-herpetic neuralgia is a complication of herpes zoster. Cervical and anal cancer can be a complication of HPV genital warts.

Bacterial infections can be more troublesome and often require a course of antimicrobials. It is helpful to establish the organism and treatments that it is sensitive to. Recurrent cellulitis can lead to damage of the lymphatic system and cause lymphoedema.

Leprosy can have long-term complicated sequelae, including mutilating disease such as deformation of digits. Both leprosy and tuberculosis may involve other systems of the body and, if inadequately treated, can result in significant morbidity.

Scabies requires a host to survive. It can spread amongst individuals. Norwegian scabies is a crusted form that is particularly virulent and spreads easily. Norwegian scabies is more common in the very old, the very young, and immunocompromised individuals.

Approach to diagnosing the disease

A careful history should be sought. This includes time of onset; duration of symptoms; area affected; distribution of the lesions; history of contact with other affected people and animals; social history; and systemic symptoms. Examination is important for making the diagnosis. In infestations, the mites, fleas, or lice may be seen. Close contacts may need to be examined, too.

Other diagnoses that should be considered

The differential diagnoses for cellulitis would include deep vein thrombosis. A history of recent long distance travel, major surgery, long periods of inactivity, oral contraceptives, or a family history of clotting disorders should help point towards this diagnosis.

Dermatitis can be difficult to differentiate from scabies, as scabies sufferers often have a widespread rash that is easy to mistake as dermatitis.

Granuloma annulare is often mistaken as ringworm. The clue is that granuloma annulare is usually asymptomatic and non-scaly.

Psoriasis can also cause discoloured, thickened nails. It is important here to examine other parts of the body, including the scalp, to look for signs of psoriasis plaques.

'Gold-standard' diagnostic test

The gold-standard diagnostic test for skin infection and infestation is the isolation and identification of the organism. In infestations, the offender can often be caught. It is important to look in the correct area; for example, look for scabies mites in burrows; fleas in the carpet, pets, and soft furnishings; bedbugs in the mattress, where blood stains can often be seen; and head lice in the hair, using a fine-toothed comb.

Skin scrapings can be taken of superficial fungal and yeast infections of the skin, nails, and scalp. Hair pluckings and nail clippings can also be taken. Often, hyphae and spores can be seen when examined under the microscope.

Skin swabs should be taken from bacterially infected skin and sent for microscopy, culture, and sensitivities. In deep fungal infections, tuberculosis, and leprosy, a skin biopsy could be sent for culture. PCR can also be carried out on the skin biopsies. In leprosy, split skin smears can be taken from the ear and sent for culture. Periodic acid–Schiff staining of skin biopsies may also help to identify fungal spores.

PCR can also be carried out on viral swabs for the identification of the virus.

Acceptable diagnostic alternatives to the gold standard

A good history and high clinical suspicion are very important. Blood tests are sometimes carried out to support the diagnosis. For example, a hot, red, swollen lower limb associated with a high white blood count and raised level of C-reactive protein would be a good pointer towards cellulitis as a diagnosis.

Other relevant investigations

In bacterial infections, blood tests with raised acute inflammatory markers and a white blood cell count will be helpful.

In tuberculosis, a chest X-ray, a T-spot test, or a Mantoux test should be carried out. Bronchoscopy, if there is chest involvement, may be helpful for obtaining further evidence of the infection.

Prognosis and how to estimate it

If treated appropriately, most infections and infestations will resolve. However, some such as tuberculosis and leprosy will require prolonged treatment for many months. Patient compliance can therefore be an issue. It is very easy to be reinfected in infestations, and education is important.

Treatment and its effectiveness

Head lice are becoming more resistant to topical insecticides. Treatment can be applied to wet hair and washed off after the recommended time. Retreatment is recommended after a week. It is important to check the hair of close contacts and treat them if they are affected as well. It is very easy to get reinfection with head lice. Avoiding close head-to-head contact with affected individuals is a good way of preventing reinfection. Using a hair conditioner and a fine-tooth comb to comb hair for a number of weeks may avoid the use of topical insecticides.

Body lice are spread through clothing. Pubic lice are spread through close contact and sexual contact. Washing clothes at 60°C should kill the lice and eggs. Affected individuals can be treated with topical insecticides.

Scabies causes intense itching. Symptoms appear 2–6 weeks after exposure in people affected for the first time, and 1–4 days after re-exposure. Treatment with topical insecticide such as malathion 0.5% liquid or permethrin 5% cream is commonly used in UK. All skin surfaces, including the genital areas, the soles of the feet, and under the nails, should be treated. In children, the scalp should be treated too. With malathion 0.5% liquid, treatment is left for 24 hours and then washed off. With permethrin 5%, treatment is left on for 8–12 hours. Retreatment a week later is recommended. All close contacts should be treated at the same time to prevent recurrence. Clothes should be washed at 60°C. It is common to have a post-scabies itch, which can persist for a few weeks despite successful eradication.

With fleas, pets in the family should be treated. The premises and soft furnishings should be treated as well. This is especially important for bedbugs. Suitcases have become a popular vector of transmission for bedbugs.

Bacterial infections should be treated with the appropriate antibiotics. As most skin bacterial infections are caused by streptococci or staphylococci, penicillin and flucloxacillin are usually the first choice to try. If cultures and sensitivities have been taken, it will be helpful to ensure that the antibiotic is sensitive to the particular strain of bacteria.

Impetigo can be treated with topical antiseptics and topical antibiotics such as fucidin.

Fungal infections can be treated with terbinafine cream. Nail fungal infections will require a course of oral antifungals such as oral terbinafine or pulsed itraconazole. Tinea capitis may require oral terbinafine or griseofulvin. Topical azoles can help in the treatment of yeast infections.

The treatment for tuberculosis and leprosy can involve a prolonged course with multiple agents. In the UK, these diseases are seen less commonly and it is important to seek the advice of experts who may be based in tertiary centres.

Antiviral such as aciclovir can be used in varicella, herpes zoster, and herpes simplex. However, treatment should be given promptly, ideally within 24 hours of the first symptoms occurring.

247 Cutaneous vasculitis

Christine Soon

Definition of the disease

Vasculitis is inflammation of the blood vessels. It can affect large vessels, medium-sized vessels, or small vessels. Cutaneous vasculitis is inflammation of the blood vessels of the skin. This can include the capillaries, the venules, and the arterioles.

Aetiology of the disease

There are many possible causes of cutaneous vasculitis. These include infection, medication, and underlying disease such as connective tissue disease, solid-organ malignancies, haematological malignancies, inflammatory bowel disease, and other conditions. However, in many cases, an underlying cause is not found.

Typical symptoms of the disease, and less common symptoms

Purpura and petechiae are the common signs of cutaneous vasculitis. Symptoms usually present on the lower limbs first. Purpura is an area of extravasation of red blood cells under the skin. Petechiae are small areas of purpura. In severe cases, the overlying skin may become necrotic. The patient may complain of pain, bleeding, or itching. Livedo reticularis may be seen in association with connective tissue disease and is a lacelike, reddish-purple discoloration of the skin caused by capillary dilatation and the stagnation of blood within it. Occasionally, gangrene of the peripheries may be seen and necrotic ulcers may also be a feature. Oedema, nodules, vesicles, bullae, pustules, plaques, and urticated papules or plaques may also be noted.

Systemic symptoms such as fever, malaise, gastrointestinal symptoms, or arthralgia may also occur.

Demographics of the disease

Vasculitis can affect children or adults. A common childhood vasculitis is IgA vasculitis (Henoch–Schönlein Purpura). This is an IgA-mediated immune-complex vasculitis. It affects small blood vessels and may involve the gastrointestinal system, the skin, and the kidneys. It is usually self-limiting, and supportive treatment is usually enough. The lower limbs and buttocks tend to be affected.

Amongst adults, cutaneous small vessel vasculitis tends to be one of the most commonly seen forms of cutaneous vasculitis. It commonly affects women and tends to affect the lower limbs. It is a small vessel vasculitis. Urticarial vasculitis is a form of cutaneous vasculitis that presents as urticated papules and plaques which persist for more than 24 hours.

Erythema elevatum diutinum is a form of leucocytoclastic vasculitis that can be seen in adults. It appears as reddish-violaceous papules, plaques, or nodules that occur symmetrically over the dorsal surfaces of the knees, the hands, the Achilles tendons, and the buttocks.

Granuloma faciale is a rare cutaneous vasculitis characterized histologically by a prominent eosinophilic infiltrate that appears as nodules on the face. It typically affects white males.

Natural history, and complications of the disease

Cutaneous vasculitis without systemic involvement is usually a self-limiting condition.

Approach to diagnosing the disease

When diagnosing cutaneous vasculitis, a careful history is required. Systemic symptoms such as arthralgia, pyrexia, and general malaise are important. Dipstick of the urine should be carried out to detect any abnormalities. A comprehensive drug history must be taken. Family history and racial origins are important. Shortness of breath, chest pain, headaches, abdominal pain, and polyarthritis are all important to elucidate. A vasculitic screen is usually carried out to identify any underlying cause and to determine whether any internal organs are involved.

Other diagnoses that should be considered

Meningococcal septicaemia can present with a purpuric eruption. The speed of onset of the eruption and associated systemic symptoms such as headache, pyrexia, and photophobia are important clues to aid diagnosis.

Platelet and coagulation disorders can lead to purpura occurring in the skin. A full blood count, coagulation screen, and liver function tests should help in aiding the diagnosis.

Raised intravascular pressure can lead to petechiae or purpura appearing on lower legs, such as in gravitational or venous stasis, and on the face after prolonged coughing or vomiting.

Petechiae can be a sign of embolism from endocarditis, atrial myxoma, fat embolism after trauma, or cholesterol embolism.

In amyloidosis, pseudoxanthoma elasticum, and Ehlers–Danlos syndrome, the decreased vascular support can lead to purpura.

‘Gold-standard’ diagnostic test

Skin biopsies for histology and immunofluorescence would confirm the diagnosis.

Acceptable diagnostic alternatives to the gold standard

Acceptable diagnostic alternatives to the gold-standard diagnostic test are good history taking and examination, together with characteristic clinical appearances.

Other relevant investigations

Other relevant investigations include:

- chest X-ray
- ECG
- full blood count
- urea and electrolytes
- erythrocyte sedimentation rate
- C-reactive protein level
- antineutrophil cytoplasmic antibody assay
- antinuclear antibody assay
- extractable nuclear antigen antibody assay
- complement level
- immunoglobulin and serum electrophoresis
- urine dipstick test
- urine protein estimation
- T-spot test
- anti-streptococcal antibody test
- serology for hepatitis B and C
- cryoglobulins

Prognosis and how to estimate it

The prognosis will depend on the underlying cause. Leucocytoclastic vasculitis tends to be self-limiting, and patients generally do well. Cutaneous vasculitis occurring as part of a systemic vasculitis tends to run a more chronic course. Vasculitis can occasionally recur.

Treatment and its effectiveness

Supportive treatment to keep the patient symptom free is usually all that is required. This would include analgesia for pain, with rest and elevation of the lower limbs. In more severe cases, topical steroids

or even systemic steroids might be required. Second-line agents such as dapsone and methotrexate have been used in refractory cases. If an underlying cause such as infection has been identified as the trigger, it is important to treat this, as treatment of the trigger usually helps the rash.

248 Acne

Ben Esdaile

Definition of the disease

Acne vulgaris is a common, chronic inflammatory disorder of the pilosebaceous unit (the hair follicle and accompanying sebaceous gland). It can be classified as mild, moderate, or severe. Mild acne is characterized by comedones (non-inflammatory lesions: 'blackheads' and 'whiteheads') being the predominant lesions. Papules and pustules may also be present but are few in number. Moderate acne is defined by more inflammatory lesions such as papules and pustules, with comedones also usually present. Severe acne is defined as widespread inflammatory lesions, nodules, cysts, and scarring. Moderate acne that has not settled within 6 months of treatment, or acne that is causing serious psychological effects, is also categorized as severe.

Aetiology of the disease

The exact cause of acne vulgaris is not fully understood. The aetiology is complex with multifactorial influences on the pilosebaceous unit. There appears to be a genetic predisposition to acne, based on strong concordance in twin studies and family history. There appear to be four main contributors to the pathogenesis of the disease:

- blocking of the hair follicle with the formation of the comedone
- androgenic stimulation of the sebaceous gland, leading to increased sebum production
- colonization of the hair follicle with the gram-positive bacteria *Propionibacterium acnes*
- inflammation of the hair follicle and its surroundings

Typical symptoms of the disease, and the less common symptoms

The production of sebum from the sebaceous glands often results in 'greasy' skin. The skin lesions, namely comedones, papules, and pustules, are often asymptomatic but some of the large pustules, nodules, and cysts can become extremely tender. The prominent cosmetic distribution of acne can lead to a great psychological impact on the patient, and support groups can be extremely helpful.

A severe form of nodulocystic acne, acne fulminans, can produce severe systemic symptoms, including fever, arthralgia, and myalgia and requires urgent intervention.

Demographics and natural history of the disease

Acne vulgaris is the commonest skin condition to affect man. It is principally a disease of adolescence and it has been estimated to affect over 80% of those between 12 and 25. Although widely thought to be an adolescent disease, 3% of men and 12% of women will continue to have acne until their mid-forties.

Approach to diagnosing the disease

The diagnosis of acne vulgaris is a clinical one. Non-inflammatory acne is characterized by the presence of open (blackheads) and closed (whiteheads) comedones. Closed comedones are skin-coloured papules and are easily distinguished from the often black, discoloured, dilated follicular openings of the open comedone. When comedones become inflamed, they expand to develop pustules, inflammatory papules, nodules, and cysts. All of these lesions can result in scarring.

Acne fulminans is the most severe form of nodulocystic acne and is characterized by the abrupt onset of nodulocystic acne in association with systemic features, including fever, arthralgia, and myalgia. Severe eruptive nodulocystic acne without systemic features is known as acne conglobata.

Other diagnoses that should be considered

Although the diagnosis of acne vulgaris in adolescents is usually not difficult, in other age groups or when atypical features are present, other diagnoses may be considered. Rosacea is the most common differential diagnosis to acne vulgaris. Patients with rosacea often complain of both redness and spots. Important clues from the history are that sufferers often notice an exacerbation of their symptoms with alcohol, exercise, spicy foods, and emotion. They often also report easy flushing in their youth. Clinically, patients with rosacea have evidence of erythema, telangiectasia, and inflammatory papules and pustules. There may also be evidence of sebaceous hyperplasia, which can result in enlargement of the nose. A significant proportion of sufferers have ocular involvement, with blepharitis and conjunctivitis.

Another cause of a red face is seborrhoeic dermatitis, which presents as a red, often scaly face, especially in the distribution of the nose and eyebrows, the so-called T-zone of the face. They usually also report scaling of the scalp; however, inflammatory pustules and papules are not usually present.

Table 248.1 summarizes possible differential diagnoses.

'Gold-standard' diagnostic test

There is no 'gold-standard' diagnostic test for acne vulgaris. It is a clinical diagnosis and it is therefore essential to perform a thorough history and examination of the patient. From the history, it is important to ascertain the use of all over-the-counter preparations as well as comedogenic cosmetics, including pomades as well as topical steroids. In females, a menstrual and oral contraceptive history is important to evaluate the hormonal influence on the acne. It is important to establish the severity (using validated scoring system), the type of lesions (inflammatory or comedonal), and the presence of scarring.

Other relevant investigations

Usually no investigations are required; however, a skin swab from a pustule can provide sensitivities of *P. acnes* and hence can help tailor therapy. Skin and nasal swabs can also help to exclude a gram-negative folliculitis. In certain patients where a hormone abnormality is suspected (i.e. very irregular menstrual cycle, significant hirsutism), a sex hormone profile including testosterone, sex hormone-binding

Table 248.1 Differential diagnoses of acne vulgaris

Comedonal acne	Inflammatory acne
Milia	Rosacea
Sebaceous hyperplasia	Perioral dermatitis
Miliaria rubra	Contact dermatitis
Syringomas	Folliculitis
Trichoepitheliomas	Keratosis pilaris
	SLE
	Steroid-induced acne

globulin, prolactin, follicular-stimulating hormone, and luteinizing hormone can be measured. In rare circumstances when a diagnosis of late-onset congenital adrenal hyperplasia is suspected, the 17- α -hydroxyprogesterone levels can be measured.

Treatment and its effectiveness

The treatment of acne is directed towards the four main areas in the pathogenesis of the disease. A summary of the treatments for acne vulgaris is shown in Table 248.2.

Topical treatments

Topical retinoids

Retinoids (e.g. adapalene, tazarotene, tretinoin) work by normalizing follicular keratinization and hence have comedonal properties. They also have significant anti-inflammatory effects and hence can be used as first-line treatments for both mild inflammatory and comedonal acne. Topical retinoids can be used as monotherapy or in combination with benzoyl peroxide or antibiotics. They can cause local drying, irritation of the skin, and thinning of the outer layer of the epidermis (stratum corneum). Some are also unstable in the sun; therefore, patients should be advised to apply them in the evening. Female patients should be advised not to become pregnant while using topical retinoids, as there is a theoretical risk of systemic absorption of this known teratogen.

Benzoyl peroxide

Benzoyl peroxide is a bactericidal agent and acts on the *P. acnes* within the hair follicle. It is available in multiple strengths, from 2.5% to 10%, as washes, soaps, gels, and lotions and in combinations with topical antibiotics. Patients should be warned that benzoyl peroxide can be an irritant as well as bleach clothes and bedding.

Topical antibiotics

Topical antibiotics (e.g. clindamycin, erythromycin, sodium sulfacetamide) should not be used in the long term due to the possibility of the development of bacterial resistance. They are available in combination with benzoyl peroxide or topical retinoids.

Salicylic acid

Salicylic acid has comedolytic and mild anti-inflammatory properties. It is available in strengths up to 2% in gels, creams, and lotions.

Azelaic acid

Azelaic acid is a naturally occurring dicarboxylic acid found in cereal grains. It has both anti-inflammatory effects and comedolytic activity. It also has the added benefit of helping post-inflammatory hyperpigmentation. It also has fewer side effects, compared to topical retinoids.

Oral treatments

Oral antibiotics

Oral antibiotics (e.g. oxytetracycline, tetracycline, doxycycline, lymecycline, minocycline, erythromycin, and trimethoprim) are prescribed for moderate-to-severe inflammatory acne. Their primary mechanism of action is the suppression of growth of *P. acnes* but they also possess intrinsic anti-inflammatory properties. There are increasing reports of resistance to erythromycin and some of the tetracyclines.

Hormonal manipulation

Hormone therapy is an established second-line therapy for female patients suffering from moderate-to-severe acne vulgaris. The oral contraceptive pill works by decreasing the production of both adrenal and ovarian androgens. A number of formulations that combine oestradiol with the anti-androgenic cyproterone acetate are widely used. Other formulations combine oestradiol with a low-androgenic progestin such as drospirenone.

Isotretinoin

Isotretinoin is a retinoid and an isomer of tretinoin. It is used for severe nodulocystic acne, significant acne that has not responded to adequate courses of antibiotic treatment or acne that is causing physical or psychological scarring. Its mechanism of action is not fully understood but it is known to inhibit maturation of the basal cells of the sebaceous gland, resulting in decreased sebum production. It also acts to normalize follicular keratinization as well as having anti-inflammatory and antimicrobial activity. It is the only treatment to target all four of the pathogenic contributors to acne.

Isotretinoin has a number of common side effects, including severe dryness of the skin and mucous membranes, causing nosebleeds, cracking of the lips, and intolerance of contact lenses. As it is teratogenic, it should not be prescribed in women of childbearing years unless they are registered with a pregnancy prevention programme. Therapy can also result in an elevation in serum triglyceride and cholesterol levels as well as abnormalities in liver enzymes.

A causal link between oral isotretinoin and psychological disturbance is not fully proven but it is prudent to get a specialist psychiatric opinion prior to initiating therapy if there are any mood concerns. Therapy should be stopped if there is any significant alteration in mood during therapy.

Surgical treatments

Comedones can be treated with a number of surgical techniques such as electrocautery, or the comedone can simply be expressed with a needle or scalpel blade. Deep, inflamed cystic lesions can be improved with steroid injections with triamcinolone acetonide. Low-concentration chemical peels have also been successful in the treatment of comedones.

Table 248.2 Acne vulgaris treatment algorithm

Acne Treatment Algorithm					
	Mild		Moderate		Severe
	Comedonal (blackheads/whiteheads)	Papular/ Pustular	Papular/ Pustular	Nodular	Nodular/ Conglobate
1st Choice	Topical Retinoid	Topical retinoid + topical antimicrobial	Oral antibiotic +/- topical retinoid +/- benzoyl peroxide	Oral antibiotic +/- topical retinoid +/- benzoyl peroxide	Oral Isotretinoin
Alternatives	Alternative topical retinoid or azelaic acid or salicylic acid.	Alternative topical antimicrobial + alternative topical retinoid or azelaic acid.	Alternative oral antibiotic + alternative topical retinoid +/- benzoyl peroxide	Oral Isotretinoin or alternative oral antibiotic + alternative topical retinoid +/- benzoyl peroxide/ azelaic acid.	High dose oral antibiotic + topical retinoid + benzoyl peroxide
Options for Females	Oral contraceptive/anti-androgen				
Maintenance	Topical retinoid		Topical retinoid +/- benzoyl peroxide

Acne scarring is difficult to treat satisfactorily. Chemical peels may be used to treat scars resulting from acne. Other techniques include dermabrasion and laser resurfacing, which aim to alter the contours of the scars.

249 Psoriasis

Ben Esdaile

Definition of the disease

Psoriasis is a common, chronic inflammatory skin disease that is associated with joint disease in approximately 25% of patients. The most common variant of psoriasis is chronic plaque psoriasis (*psoriasis vulgaris*), which has the hallmark of well-demarcated erythematous plaques covered by silvery scale. There are a number of other variants of psoriasis, including guttate, inverse, palmoplantar, flexural, pustular, and erythrodermic.

Aetiology of the disease

Psoriasis is a polygenic disease. Twin studies have shown a 67% concordance for monozygotic twins versus 18% for dizygotic twins. Several susceptibility loci have so far been identified and the PSOR1 gene (C6p21.3), situated within the major histocompatibility complex (MHC) region of Chromosome 6, has been shown to be involved in around 50% of patients with psoriasis. The association of psoriasis with MHC alleles suggests an important role of T-lymphocytes in the pathogenesis. This has been confirmed as, once the disease is triggered, there appears to be a large recruitment of T-lymphocytes to the dermis and epidermis, resulting in the characteristic plaques. There is a resultant large production of pro-inflammatory mediators, including tumour necrosis factor alpha and interferon gamma, as well as numerous cytokines which have become targets for novel therapies.

Psoriasis can be triggered by external factors such as infection, physical trauma, or sunburn. The development of psoriasis in sites of trauma to the skin is known as the Koebner phenomenon. Other external factors include infections, especially streptococcal upper respiratory tract infections. Several drugs are known to trigger psoriasis, including beta blockers, lithium, and antimalarials.

Typical symptoms of the disease, and less common symptoms

Chronic plaque psoriasis is often asymptomatic but may itch or sting and can bleed easily when scratched (Auspitz sign). Psoriasis can have an enormous psychological impact and can limit normal social and leisure activities. This can be measured using the Dermatology Life Quality Index, which provides a score between 0 and 30. A score of greater than 10 is regarded as a severe impact on a patient's quality of life.

Demographics of the disease

In most reviews, the prevalence of psoriasis worldwide varies between 0.1% and 3%. In the UK, the prevalence is estimated at between 1% and 2%. There are certain parts of the world, such as Canada and the US, where the prevalence has been reported up to 4.7%. In contrast to this, there are some parts of Africa where the prevalence is estimated as low as 0.4%. Psoriasis affects both sexes equally.

Natural history, and complications of the disease

Psoriasis can first appear at any age but there appears to be two main peaks in a person's twenties and fifties; 75% of disease occurs before the age of 40. It tends to run a chronic relapsing and remitting

course. Psoriasis can be complicated by its pustular and erythrodermic variants.

Psoriasis is associated with metabolic syndrome and its components, including diabetes, hypertension, and obesity. The increased risk of myocardial infarction in patient with psoriasis highlights the importance of addressing reversible risk factors.

Approach to diagnosing the disease

The diagnosis of psoriasis is usually made clinically and does not require histological confirmation. A full history is important and can reveal a family history of psoriasis, as well as details of all medications and recent illnesses which may be important triggers for the disease.

The most common variant of psoriasis is chronic plaque psoriasis (*psoriasis vulgaris*). Clinically, the patient presents with well-demarcated 'salmon-pink' symmetrical scaly plaques with an overlying silvery scale. The plaques classically present on extensor surfaces and can vary in size (from tiny papules to extremely large plaques). There are certain sites of predilection that can give clues to the diagnosis, such as the sacrum, the umbilicus, the nape of neck, the hairline of the scalp, and extensor surfaces. Approximately 50% will have nail changes such as pitting, onycholysis, and subungual hyperkeratosis. Plaques can occur in the flexures, in which case the condition is termed flexural psoriasis. When this is the only site of involvement, the term 'inverse' psoriasis is often used. The severity of chronic plaque psoriasis can be quantified using a scoring system known as the Psoriasis Area and Severity Index score.

Other variants of psoriasis include guttate psoriasis, which is common in children and young adults, with often an antecedent history of an upper respiratory tract infection. Clinically, patients present with a scattered 'rain-drop' appearance of small papules/plaques over the body.

Psoriasis can present with a pustular variant that is either localized (palmoplantar pustulosis/acrodermatitis of Hallopeau) or generalized. The generalized variant presents as multiple sterile pustules on an erythematous background. Importantly, this can be induced by the rapid cessation of oral steroids or the inappropriate use of topical steroids. Psoriasis is one of the causes of erythroderma, and patients can present with generalized erythema and desquamation from their psoriasis.

Other diagnoses that should be considered

The diagnosis of psoriasis is classical but differentials that may be considered are outlined in Table 249.1.

'Gold-standard' diagnostic test

The gold-standard diagnostic test for the diagnosis of psoriasis is a skin biopsy. In chronic plaque psoriasis, there is epidermal hyperplasia

Table 249.1 Differential diagnoses for chronic plaque psoriasis

Single plaque	Multiple plaques
Lichen simplex chronicus	Eczema
Bowen's disease (squamous cell carcinoma in situ)	Cutaneous T-cell lymphoma
Lichen planus	Lichen planus
Tinea corporis/capitis	Tinea corporis

(acanthosis), with flattening of the rete ridges and loss of the granular cell layer with cells in the stratum corneum still possessing flattened nuclei (parakeratosis). There are often neutrophils found in the epidermis in so-called Munro microabscesses.

Acceptable diagnostic alternatives to the gold standard

The diagnosis of psoriasis is usually made clinically without the need for histological confirmation or further investigations.

Other relevant investigations

Skins swabs can provide clues for potential triggers of flares of psoriasis. Patients who are commenced on systemic therapies need regular blood test monitoring that will be outlined in 'Systemic treatments'. The association of psoriasis and metabolic syndrome means that it is worth measuring lipids and other cardiovascular risk factors.

Prognosis, and how to estimate it

Chronic plaque psoriasis is a chronic disease that usually runs a relapsing and remitting course.

Treatment and its effectiveness

There are many factors that influence the choice of therapy in the management of psoriasis including patient choice, disease extent, lifestyle, and comorbidities. The different therapy choices available are detailed in this chapter.

Topical treatments

Vitamin D analogues

Vitamin D₃ analogues (e.g. calcipotriol, calcitriol, tacalcitol) act by inhibiting the proliferation of keratinocytes and inducing normal differentiation. They can have an effect on calcium homeostasis and so a maximum weekly dose of 100 g is recommended. They can also be combined with topical corticosteroids. They are used as monotherapy or in combination as a first-line agent for mild-to-moderate chronic plaque psoriasis.

Coal tar

The mechanism of action of coal tar is not understood but it has a range of anti-inflammatory properties. There are a number of preparations of tar used in creams, lotions, shampoos, gels, and ointments. It is also used in its crude form for special inpatient topical regimens. It is often combined with other products including salicylic acid, coconut oil, and corticosteroids. It is also occasionally used in combination with UV light.

Glucocorticoids

Topical corticosteroids have become one of the major first-line therapies for chronic plaque psoriasis. This is mainly due to their cosmetic acceptance and relative ease of use. Inappropriate use of topical steroids can not only lead to relapses and flares but can also induce pustular psoriasis. The topical corticosteroids are important in flexural disease due to their lack of irritancy.

Topical retinoids

Tazarotene is an acetylic retinoid which has an antiproliferative effect on the keratinocytes. Its use is limited by both efficacy and irritation.

Dithranol

Dithranol (anthralin) is derived from the bark of the araroba tree, which is indigenous to South America. It has a marked antiproliferative effect on the epidermis. It can cause burning and erythema to normal skin as well as stain clothes and bath enamel. It is rarely used on the flexures or face due to irritation. It is often used as part of an inpatient regimen but there are now some more 'short-contact' non-staining preparations that can be used in the day setting or even at home.

Phototherapy

It is well described that a number of patients note an improvement in their psoriasis after exposure to the sun. Phototherapy with UVA and UVB radiation is one of the mainstays of treatment of moderate-to-severe psoriasis. Phototherapy with broadband UVB has largely been replaced with narrow band UVB produced by TLO1 bulbs. UVA radiation is used in combination with photosensitizers 8-methoxypsoralen and 5-methoxypsoralen either orally or topically. Phototherapy does have side effects, with dose-dependent burning, photoageing, and the increased risk of skin carcinogenesis with cumulative doses.

Systemic treatments

When disease control fails with topical or light therapy, patients are often offered a systemic therapy. These drugs all have side effects and so the choice of agent is made after a balanced discussion between doctor and patient. Patients require careful monitoring.

Methotrexate

Methotrexate is the most commonly used systemic therapy for psoriasis in the UK. It is a derivative of folic acid and acts as an antimetabolite by inhibiting the enzyme dihydrofolate reductase and hence cell division. The drug also has anti-inflammatory properties on lymphocytes and neutrophils. Methotrexate is usually started at a dose of 5 mg weekly and a full blood count is recorded after 7 days to check for an idiosyncratic reaction of myelosuppression. The dose can then be increased, usually to a maximum of 15–25 mg weekly. Monitoring of liver tests, renal tests, and full blood counts takes place weekly for 2 weeks after any dose change and then 2–3 monthly once the dose is stable. Specific markers for liver fibrosis are the serum pro-collagen III N-terminal peptides levels, which are measured on a 3-monthly basis where available. This test has now superseded the previous invasive liver biopsies that were routinely performed before and after a cumulative 1.5 g dose. The co-administration of 5 mg of folic acid is said to help reduce the main side effect of nausea.

Ciclosporin

Ciclosporin acts as a calcineurin inhibitor and prevents T-lymphocyte activation. It was originally used to prevent organ rejection in transplant patients. Ciclosporin is a highly effective drug in the treatment of psoriasis but its use is limited by its inevitable side effects. The major side effect is that of nephrotoxicity, which usually limits the therapy to short courses of 3–4 months. The usual starting dose is 2.5 mg/kg per day and can be increased up to a maximum of 4 mg/kg per day. Close monitoring of blood pressure and renal function is required during therapy.

Acitretin

Vitamin A (retinol) is an essential epithelial growth factor whose precise mode of action is not fully understood. A deficiency in vitamin A leads to reversible dry skin and squamous metaplasia. Acitretin is given in doses usually ranging from 10 mg to 50 mg daily. It is often combined with UVB therapy. Acitretin is useful in all forms of psoriasis but is especially in erythrodermic and pustular variants. The most important side effect is that of teratogenicity and it is therefore not usually used in women of childbearing age. It is important to monitor liver function and lipid metabolism during therapy.

Other systemic therapies

Other systemic therapies include the fumaric acid esters and hydroxyurea.

Biological therapy

Biologic therapies for psoriasis target specific molecules involved in the inflammatory cascade of psoriasis. There are now a number of licensed drugs which have transformed the lives of patients with psoriasis. Many of the biologics specifically target tumour necrosis factor and include infliximab, etanercept, and adalimumab. There are some newer monoclonal antibodies against other interleukins in the inflammatory cascade, such as ustekinumab, which targets interleukins 12 and 23. The long-term safety of these drugs is not proven, with potential long-term side effects including malignancy (e.g. lymphomas and skin cancers) and opportunistic infections (e.g. tuberculosis).

250 Eczema

Ben Esdaile

Definition of the disease

Eczema is a descriptive term for a set of symptoms and signs which usually involve itchy inflammation of the skin, and is subcategorized into many different forms. Atopic eczema (atopic dermatitis) is the most common chronic inflammatory disease amongst children. Other types of eczema include seborrhoeic eczema, discoid eczema, asteatotic eczema, contact allergic eczema, contact irritant eczema, pompholyx eczema, venous eczema, juvenile plantar dermatosis, and lichen simplex. In this chapter, we will cover atopic eczema, which is called 'atopic' due to its association with other atopic disorders such as asthma and allergic rhinitis.

Aetiology of the disease

The aetiology of atopic eczema has yet to be fully understood but it is known to have both genetic and environmental factors. A gene encoding a protein called filaggrin, which is involved in keratin aggregation, has been shown to be mutated in 20%–50% of children with the disease. The rising prevalence over the last few decades, with the simultaneous increasing levels of hygiene, led to the 'hygiene theory' that children who were exposed to more antigens were less likely to develop atopy. Factors that are known to exacerbate eczema include sweating, irritants such as detergents and solvents, infection, stress, and, in some cases, contact allergens, including aeroallergens.

Typical symptoms of the disease, and less common symptoms

The main symptom of atopic eczema is pruritus. Patients develop further symptoms from the sequelae of scratching (e.g. infection). Virtually all patients with atopic eczema have constitutional dry skin known as xerosis.

Demographics of the disease

Atopic eczema has an estimated prevalence of between 10% and 20% in Northern Europe and the US, with lower rates in Africa. It is slightly more common in girls. In the UK, it is associated with an estimated cost of over £500 million per year.

Natural history, and complications of the disease

The majority of patients with atopic eczema first develop their disease in early infancy, usually after 2 months. Many children with atopic eczema improve by the age of 3. Over 50% are disease-free by the age of 6, and up to 80% by the age of 14. Some may relapse in early adult life but most recover by their thirties. A small proportion will go on to suffer from lifelong disease.

Eczema can be complicated by infection, with bacteria being the most common offending agents. Secondary infection with herpes simplex virus can lead to eczema herpeticum with a characteristic (bullet-spray) appearance of punched-out erosions and vesicles. Patients can become systemically unwell, as well as have ophthalmic involvement. Eczema herpeticum can be life-threatening.

Patients with severe eczema can develop a generalized exfoliative erythroderma. This is a dermatological emergency, as patients can develop problems with temperature regulation, sepsis, and even cardiac failure.

Approach to diagnosing the disease

A diagnosis of atopic eczema is usually readily made from a history and clinical examination. The rash of atopic eczema is usually symmetrical, with ill-defined patches of erythema and scale and with serous exudate and vesiculation seen in acute states (the eczema usually starts on the face and then extends to involve the trunk and limbs). In infants, the face and extensor surfaces are mostly affected but, as children mature, it tends to involve the flexural areas, especially the antecubital fossae, the popliteal fossae, the wrists, and the neck. Chronic eczema leads to thickening of areas of scratching (lichenification) and post-inflammatory hyper- or hypopigmentation.

The decrease in epithelial/skin barrier function can result in secondary infection, with the classical yellow overlying crust of impetiginized eczema. Patients with eczema also appear to be more susceptible to viral infections, with higher incidences of molluscum contagiosum, warts, and herpes simplex viral infections (eczema herpeticum).

Other diagnoses that should be considered

In infancy, the main differential is seborrhoeic dermatitis. Seborrhoeic dermatitis is not usually pruritic and there is usually no associated family history of atopy. The main clue is the distribution, with seborrhoeic eczema being more prominent on the scalp (cradle cap), face, and nappy areas. In older children and adults, a diagnosis of scabies should always be considered in any itchy rash. When a patient presents with no family or personal history of eczema, one should always consider the possibility of an allergic contact dermatitis. Cutaneous T-cell lymphoma can mimic chronic eczema. It is sometimes difficult to differentiate eczema and psoriasis, especially when a patient presents with a hand/foot dermatitis.

'Gold-standard' diagnostic test

The diagnosis of atopic eczema is a clinical one and there is no 'gold-standard' diagnostic test. A skin biopsy is, therefore, rarely needed but the histological features of eczema will depend on the stage of the eczema. In acute eczema, there is oedema between the epidermal cells, known as spongiosis. In more chronic eczema, there is thickening of the epidermis with epidermal hyperplasia.

Acceptable diagnostic alternatives to the gold standard

As mentioned previously, the diagnosis of atopic eczema is a clinical one and rarely needs a skin biopsy. Patch testing is used to investigate any extrinsic allergens exacerbating the atopic eczema.

Other relevant investigations

Elevation of serum IgE levels and eosinophilia are often found in atopics, but approximately 25% will have normal levels. Total IgE levels are often elevated in atopic eczema patients but the usefulness of the detection of specific IgE-directed antibodies against certain allergens (radioallergosorbent testing (RAST)) in finding triggers of disease is controversial. RAST and skin prick testing can potentially provide some useful information about allergen avoidance but careful patient selection, based on their history, is advised (e.g. flares in exposed sites and associations with house dust mite allergy).

Prognosis, and how to estimate it

Prognosis is difficult to predict in atopic eczema but severe disease in infancy and disease on the extensor surfaces of the elbows and knees are poor prognostic markers.

Treatment and its effectiveness

Education plays a vital role in the management of eczema. A reduction of trigger factors such as harsh chemicals, the use of soaps, and avoidance of house dust mite are all beneficial. Cotton clothing appears to be less irritating to the skin than clothing made of other material. The importance of treating the xerosis of the skin and breaking the itch–scratch cycle is vital.

Topical treatments

Emollients

Emollients are an essential aspect of the treatment of atopic eczema. The xerosis and impaired barrier function are vital targets for therapy. There are numerous commercially available different emollients with varying ingredients, usually containing paraffin. The greasier the emollient, the more effective it will be but, usually, the less acceptable it will be to the patient. Emollients should be generously applied as many times a day as practical. They should also be applied after bathing, to damp skin.

Soap substitutes and bath additives

Soaps are irritating to the skin and so it is important to avoid them and use a soap substitute for washing. There are, again, a number of soap substitutes available, including *ones with emulsifying ointment and aqueous cream. In fact, many emollients can be used as a soap substitute. There are now a number of bath additives and shower gels designed for patients with eczema. Some are now combined with an antiseptic agent that can be useful in patients with recurrent infective exacerbations.

Topical corticosteroids

Topical glucocorticosteroids are the mainstay of treatment for atopic eczema. The choice of steroid is dependent on the age of the patient and the site and stage of the eczema. In general, low-potency steroids such as hydrocortisone and clobetasone butyrate are used on the face. Moderately potent steroids are used in the flexures. It is advised that a potent steroid is used at first to gain control, prior to reducing its strength. The vehicle of the active ingredient is important, as ointments lead to better absorption, compared to creams.

Inappropriate chronic daily use of topical corticosteroids can lead to complications of skin atrophy, telangiectasias, and striae. There is also a risk of cataract development if potent steroids are used near the eye for a prolonged duration.

A table summarizing the potency of some of the commonly used steroids is shown in Table 250.1.

Topical pimecrolimus and tacrolimus

Pimecrolimus and tacrolimus are licensed for mild-to-moderate and moderate-to-severe atopic eczema, respectively. They are steroid-sparing immunosuppressants that act via inhibition of the T-cell activator calcineurin. They have an important role in the long-term management of eczema (especially on the face) to reduce the use

of topical steroids. They can cause stinging when first used but this effect fades after a number of applications.

Occlusive bandaging

Occlusive bandaging of the limbs can be extremely useful in the treatment of atopic eczema affecting the limbs. Steroids can be applied underneath the bandages, which can contain antipruritic substances such as zinc and ichthammol. The process of 'wet wrapping', a two-layer bandaging technique where the inner layer is soaked in warm water, is also useful in the paediatric setting.

Antihistamines

The sedating antihistamines do have a role in the treatment of atopic eczema. Their sedative properties can help break the itch–scratch cycle, especially at night. (It is the sedative properties that are useful.)

UV phototherapy

UVB TLO1

There are a number of different phototherapy regimens that have been used with success in treating eczema but narrow-band UVB seems to be the safest and appears effective in some, but not, all patients.

Oral treatments

Systemic treatments are reserved for patients in whom optimal topical therapy does not result in disease control.

Oral corticosteroids

Systemic corticosteroids are used for acute severe flares of atopic eczema that fails to respond to topical therapy. Their use in protracted courses can result in systemic side effects.

Azathioprine

Azathioprine is an immunosuppressive corticosteroid-sparing agent that is an antimetabolite thought to inhibit the proliferation of lymphocytes. Note, however, that there is a genetic polymorphism for an enzyme called thiopurine methyltransferase (TPMT), which is important in the metabolism of azathioprine; although >1% of the population is homozygous for an allele of low activity of TPMT, they are at risk of profound myelosuppression at standard doses. For this reason, patients should have their TPMT levels checked prior to starting therapy.

Ciclosporin

Ciclosporin acts as a calcineurin inhibitor and prevents T-lymphocyte activation. It was originally used to prevent organ rejection in transplant patients. The major side effect is that of nephrotoxicity which usually limits the therapy to short courses. The usual starting dose is 2.5 mg/kg per day but can be increased up to a maximum of 4 mg/kg per day. Close monitoring of blood pressure and renal function is required during therapy.

Other systemics

There are many other agents that have been used with variable success in the long-term control of atopic eczema, including methotrexate and mycophenolate mofetil.

Table 250.1 The potency of some of the commonly used steroids

Generic name (brand names)	Potency
Hydrocortisone 0.5%–2.5%	Mild
Clobetasone butyrate 0.05%	Moderate
Betamethasone valerate 0.1%	Potent
Mometasone furoate 0.1%	Potent
Clobetasol propionate 0.05%	Very potent

251 Urticaria

Sarah Wakelin

Definition of the disease

Urticaria is an inflammatory complaint characterized by short-lived skin swellings termed 'weals' or 'hives'. It can be divided into acute urticaria, where the disease is short-lived and chronic urticaria, where weals occur on a regular basis for more than 6 weeks. Inducible or physical urticaria is a subgroup of chronic urticaria where an underlying external/physical trigger can be identified. Contact urticaria is a localized weal or swelling of the skin or mucosa following contact with a chemical substance.

Angioedema represents a similar process affecting the deeper dermal tissue and has a predilection for the skin around the eyes and mouth. It may occur in association with urticaria or as an isolated complaint.

Aetiology of the disease

The primary event is degranulation of activated dermal mast cells and release of pro-inflammatory mediators including histamine. These cause vasodilation and increased vascular permeability leading to leakage of plasma proteins and leukocytes into the perivascular tissue. Mast cell degranulation may occur in response to cross-linking of surface high-affinity IgE receptors by allergens or IgG autoantibodies or it can be directly triggered by non-immunological agents such as opiates, neuropeptides, and C5a anaphylatoxin.

An underlying cause may be identified in approximately 50% of patients with acute urticaria. In most cases, this is infective. Food allergy may need investigating if there is a temporal relationship. A detailed drug history is also mandatory. In chronic spontaneous urticaria, (CSU) some patients have evidence of underlying autoimmunity especially autoimmune thyroid disease. It is seldom related to food allergy which can be excluded by taking a careful history. Parasite infection such as strongyloidiasis rarely causes urticaria in developed countries, but may be more significant in tropical regions.

Causes of inducible urticaria include friction (symptomatic dermographism), heat and sweating (cholinergic), stress (adrenergic), UV radiation (solar), pressure, and cold. Contact urticaria is usually mild and localized and may be caused by a range of environmental chemicals and proteins. Immunological contact urticaria (e.g. natural rubber latex allergy) is a manifestation of IgE-mediated, immediate-type hypersensitivity, and atopic individuals are predisposed to develop this complaint the aetiology of non-immunologic contact urticaria is not clear, but prostaglandins and other inflammatory mediators have been implicated.

Typical symptoms of the disease, and less common symptoms

Weals vary in size from a few millimetres to many centimetres (giant urticaria) and are raised, smooth red areas of skin, sometimes surrounded by pallor (see Figure 251.1). They are usually itchy and uncomfortable, and symptoms are aggravated by heat, sweating, and tight clothing. Weals of CSU are often round or annular, while those of symptomatic dermographism are typically linear and occur at sites of friction. Weal duration may be short-lived, as in contact urticaria and most forms of physical urticaria, where resolution usually occurs within an hour. However, in delayed pressure urticaria and delayed dermographism, the onset of weals is delayed for several hours and they can persist for over

Figure 251.1 Widespread ordinary urticaria; the smooth erythematous papules and plaques may expand into annular shapes. Please see colour plate section.

Reproduced from Burge, S., Wallis, D. Oxford Handbook of Medical Dermatology (Copyright Oxford University Press 2010).

24 hours. Persistent, painful weals lasting for over 24 hours with residual bruising are a feature of urticarial vasculitis.

Exercise-induced (cholinergic) urticaria and immunological contact urticaria may, on rare occasions, progress to anaphylaxis with symptoms of hypotension and collapse.

Demographics of the disease

Statistics on the incidence of urticaria vary widely, depending on the age group studied and subtypes. The lifetime prevalence for all types of urticaria is around 10%, making this one of the commoner inflammatory dermatoses. Urticaria may affect all ages and races. Allergic urticaria is associated with atopy in childhood. CSU is commoner in women than men (2:1), while some forms of inducible urticaria such as delayed pressure urticaria are commoner in men.

Natural history, and complications of the disease

If acute urticaria and angioedema are caused by an underlying immediate-type hypersensitivity reaction, there may be associated systemic features, including bronchospasm and hypotension. CSU often coexists with a inducible urticaria, and both complaints are associated with a significant impairment in quality of life. NSAIDs and dietary pseudoallergens may exacerbate chronic urticaria.

Approach to diagnosing the disease

A careful history should be taken in patients with acute urticaria to identify any possible infective, dietary, or drug trigger. This may include over-the-counter medication. In chronic urticaria, enquiry about physical triggers and the duration of individual wheals is

Table 251.1 Typical duration of individual wheals in urticaria

Type of urticaria	Typical duration of individual wheals
Physical urticaria	From minutes up to 2 hours
Delayed pressure urticaria (delay of 30 min to 12 hours)	From >24 hours to several days
Chronic spontaneous (idiopathic) urticaria	From 2 hours to 12 hours
Urticarial vasculitis	From 24 hours to several days

essential, as this will help distinguish the different types of urticaria (see Table 251.1).

Dermographism can be easily demonstrated as an exaggerated and pruritic wheal-and-flare response by firmly stroking the skin with a blunt, fine-tipped object such as an orange stick.

Other diagnoses that should be considered

Other intensely pruritic skin complaints include eczema, scabies, and insect bites. In these conditions, individual lesions persist for days to weeks and are usually excoriated. Bullous pemphigoid should be considered in elderly patients who present with fixed urticaria-like plaques and in pregnant women with an urticarial rash over the abdomen. Drug rashes may resemble urticaria, but lesions are typically polymorphic and persistent. A characteristic feature of acute eczema/dermatitis is that inflamed skin takes days to settle and resolves with surface changes of dryness and flaking.

Urticarial vasculitis is characterized by tender, long-lasting wheals that leave bruising. Recurrent non-pruritic wheals with arthralgia, fever, and a raised erythrocyte sedimentation rate are features of auto-inflammatory disease such as Schnitzler's syndrome, which is associated with an underlying IgM gammopathy.

Angioedema without urticaria may be a feature of hereditary or acquired C1-esterase inhibitor deficiency. It may also be induced by angiotensin-converting-enzyme inhibitors and can present many months after commencing the drug.

'Gold-standard' diagnostic test

Diagnostic tests are not usually required for urticaria, as the appearance is characteristic. In atypical cases, a skin biopsy can be helpful, especially to exclude urticarial vasculitis. Provocative testing can be carried out for inducible urticaria, for example the ice cube test for cold urticaria, and solar simulator exposure for solar urticaria.

Other relevant investigations

For inducible urticaria, no specific tests are required, with the exception of cold-urticaria, where underlying viral infections and coagulopathy should be excluded.

The routine investigations for CSU are full blood count, erythrocyte sedimentation rate, thyroid function tests, and thyroid autoantibodies.

In patients with a suspected underlying immediate-type allergy, further investigation with serological tests to measure antigen-specific IgE levels or with skin prick testing is indicated.

Prognosis, and how to estimate it

The prognosis depends on the underlying cause. Acute urticaria is usually an isolated and short-lived event, unless there is an unidentified allergen which is not avoided, in which case recurrent exposure can lead to further intermittent attacks.

The prognosis for CSU is variable. Studies have shown complete resolution in about a third of patients within 1–5 years, and partial improvement in another third. Patients who are under the age of 30 and have more severe symptoms and physical triggers fare less well. Associated angioedema is also a marker of chronicity.

Treatment and its effectiveness

Patients with acute urticaria and anaphylaxis require emergency management of this condition (see Chapter 75). Acute urticaria without systemic symptoms should be treated with oral antihistamines. Second-generation oral H1 antihistamines are the treatment of choice for CSU and inducible urticaria, as they are generally non-sedating at standard dosages, due to improved receptor selectivity and poor permeability across the blood–brain barrier. They are usually effective at reducing wheal duration and pruritus. The aim is symptom control and they can be prescribed at increased doses in refractory cases. Simple advice includes wearing loose soft clothing, keeping cool, and avoiding alcohol because of its vasodilatory effects. Disease severity should be quantified for example with the UAS7 score and the dermatology life quality index. In patients with uncontrolled disease, addition of oral H2 antihistamines or leukotriene-receptor antagonists have been advocated but evidence for their effectiveness is limited. In a minority of patients, chronic urticaria runs a severe, recalcitrant course and may justify additional treatment with immunosuppressive drugs such as ciclosporin or methotrexate or the anti-IgE biological drug omalizumab which is licensed for severe CSU in patients aged 12 years and older. Corticosteroids, while effective for acute disease control, should be avoided for long-term treatment because of their adverse effects.

Low-salicylate or additive(pseudoallergen)-free diets have been advocated for chronic ordinary urticaria and may help a minority of individuals.

252 Bullous disorders

Emily Davies

Introduction

This chapter focuses on immunobullous diseases. Please refer to Chapter 69 for all other causes of bullous disorders.

Definition of the disease

The immunobullous disorders are a group of diseases in which pathogenic autoantibodies bind to target antigens either in intra-epidermal desmosomes (intercellular adhesion junctions) or in part of the basement membrane zone, resulting in loss of adhesion, and blister formation. The immunobullous disorders can be categorized by the level of blister formation (see Table 252.1).

This chapter will mainly focus on the following disorders: pemphigus vulgaris and pemphigus foliaceus; bullous pemphigoid; linear IgA disease and chronic bullous disease of childhood (CBCD); and dermatitis herpetiformis; it will also make mention of mucous membrane pemphigoid, pemphigoid gestationis, and epidermolysis bullosa acquisita.

Demographics of the disease

Pemphigus vulgaris and pemphigus foliaceus

Pemphigus is a chronic, blistering disorder affecting people of middle age (40–60 years). It has an equal sex distribution and affects all races, but pemphigus vulgaris is commonest in those of Jewish ancestry. Pemphigus foliaceus is very rare in the UK. Endemic pemphigus foliaceus (Fogo Selvagem) is common in parts of Brazil. It can be induced by some drugs.

Bullous pemphigoid

Bullous pemphigoid is a chronic, blistering disease affecting elderly people, usually with onset after the age of 60. Children can occasionally be affected. It is slightly commoner in men. Studies have found a higher frequency of neurological conditions such as multiple sclerosis in patients with bullous pemphigoid. It is the commonest immunobullous disease in Western Europe (2 per 100,000). Occasionally, it can be drug induced.

Linear IgA disease and CBCD

Linear IgA disease and CBCD are chronic, blistering diseases of adults and children, respectively. They are rare (1 per 2 million), with

a slight female predominance. They typically present in old age and in preschool children, respectively.

Dermatitis herpetiformis

Dermatitis herpetiformis is a rare, chronic, recurrent blistering disorder (1 per 15 000 in the UK). It affects all ages and has an equal sex distribution. Ireland has the highest incidence, with 600 per million people affected. It may be associated with coeliac disease.

Aetiology of the disease

The autoantibodies in patients with these disorders play a pathogenic role in inducing blister formation. The target antigens for many of these conditions have now been identified (see Table 252.2).

Typical symptoms of the disease, and less common symptoms

Pemphigus vulgaris and pemphigus foliaceus

Pemphigus vulgaris usually presents with painful erosions of the oral mucosa. Over 50% of patients also have cutaneous involvement with widespread flaccid blisters and erosions. The nasal and genital mucosae, the conjunctivae, and the oesophagus may also be involved.

Pemphigus foliaceus tends to be less severe than pemphigus vulgaris with a more insidious onset. Patients present with crusted, scaly lesions affecting the face, scalp, and upper trunk. Blisters are not usually seen as they are small and flaccid and easily rupture. There is no mucous membrane involvement, and the lesions heal without scarring.

Bullous pemphigoid

Bullous pemphigoid often presents with a prodrome of pruritus (may last for months), followed by development of urticarial papules and plaques, and then tense bullae, on either erythematous or normal skin. Blisters most frequently appear on the central abdomen and limbs, often favouring the flexures. There may be mucosal involvement (usually the mouth), with blisters and erosions. The patient is systemically well.

Linear IgA disease and CBCD

In children, there is often an abrupt onset of CBCD. The rash affects the perineum, vulva, face, trunk, and limbs. The rash consists of annular polycyclic lesions with blistering around the edge, termed the 'string of pearls' sign.

The onset of linear IgA disease in adults may be insidious, but is usually abrupt. The trunk is always involved, but the limbs, face, and scalp are also commonly affected. The characteristic 'string of pearls' appearance is less common.

Pruritus in both age groups varies considerably. Blisters may arise from normal skin, and mucosal involvement is frequently seen.

Dermatitis herpetiformis

Dermatitis herpetiformis is an intensely pruritic, recurrent disease with a symmetrical distribution, and predilection for the extensor surfaces of knees, elbows, shoulders, and buttocks. Upon examination, only erosions may be seen. All patients have an underlying gluten-sensitive enteropathy, but this may be asymptomatic.

Table 252.1 Classification of immunobullous disorders by the level at which blisters form

Level of blister	Disease
Intra-epidermal	Pemphigus vulgaris (and foliaceus) IgA pemphigus Drug-induced pemphigus
Sub-epidermal	Bullous pemphigoid Linear IgA disease, and chronic bullous disease of childhood Dermatitis herpetiformis Mucous membrane pemphigoid Pemphigoid gestationis Epidermolysis bullosa acquisita Drug induced

Table 252.2 The target antigens in immunobullous disorders

Disease	Blister	Target antigen	Direct immunofluorescence	Indirect immunofluorescence
Pemphigus vulgaris	Intra-epidermal	Desmoglein 3 +/- 1	Intercellular deposition of IgG +/- C3	Positive
Pemphigus foliaceus	Subcorneal	Desmoglein 1	Intercellular deposition of IgG +/- C3	Positive
Bullous pemphigoid	Sub-epidermal	BP180 BP230	Linear deposition of IgG +/- C3	Positive
Linear IgA disease, and chronic bullous disease of childhood	Sub-epidermal	LAD285 BP180 BP230 Collagen VII	Linear deposition of IgA	Positive
Dermatitis herpetiformis	Sub-epidermal	Tissue transglutaminase	Granular deposition of IgA	Negative

Natural history, complications of the disease, and prognosis

The severity and disease duration of pemphigus vulgaris is variable. Disease activity usually decreases with time. The mortality is between 5% and 15%. This is related to disease severity, dose of prednisolone used for treatment, and comorbidities. The mortality rate was much higher before the use of corticosteroids. Pemphigus foliaceus is a much more benign, chronic disease. It responds well to treatment and may remit.

Bullous pemphigoid is a chronic, self-limiting disease with exacerbations and remissions. It is associated with significant morbidity and has a marked impact on a patient's quality of life. There is also an increased mortality rate in elderly patients, probably related to side effects from steroids and immunosuppressive agents.

Most cases of linear IgA disease and CBDC spontaneously remit after 3–6 years. The vast majority of childhood cases resolve by puberty. In contrast, dermatitis herpetiformis is usually a lifelong condition and spontaneous remissions are rare (up to 10%).

In all these disorders, possible complications of cutaneous blistering may occur, such as secondary bacterial infections and scarring. Oral involvement can lead to severe pain and subsequent restriction of dietary intake and poor oral hygiene. The mouth and genital mucosa may become secondarily infected with candida.

Approach to diagnosing the disease

The clinician should take a history, including a detailed enquiry about the blisters, time course, any preceding itch or rash, previous episodes, and areas affected. A past medical history, a detailed drug history, a family history, and a systems enquiry including any gastrointestinal symptoms should be recorded (dermatitis herpetiformis). This should be followed by a thorough examination of the skin, hair, nails, and mucous membranes; look for blisters, excoriations, erosions, and evidence of scarring and/or secondary infection.

Other diagnoses that should be considered

The differential diagnosis for these conditions includes all causes of immunobullous disorders as well as other causes of blistering such as bullous impetigo and bullous erythema multiforme. Patients who have pemphigus but who only have oral involvement should have aphthous ulcers, herpes, mucous membrane pemphigoid, lichen planus, and erythema multiforme excluded. In the non-bullous phase of bullous pemphigoid, conditions such as eczema, scabies, and drug reactions should be considered. CBDC has sometimes been misdiagnosed as sexual abuse in cases with vulval involvement. Bullous drug reactions, as well as drug-induced pemphigus/bullous pemphigoid should be considered.

'Gold-standard' diagnostic test

All patients should have a skin biopsy performed. An incisional skin biopsy should be taken through an intact blister for histopathology. The level of the split (subcorneal, intra-epidermal or suprabasal) will help indicate possible diagnoses. The inflammatory infiltrate should

also be recorded. A sample of perilesional, uninvolved skin should also be taken for direct immunofluorescence to look for deposition of immunoglobulins/complement.

Acceptable diagnostic alternatives to the gold standard

Indirect immunofluorescence is performed on serum or blister fluid and detects circulating immunoglobulins/complement. If a skin biopsy is not appropriate in a particular patient, this test will aid with diagnosis, depending on the pattern and type of immunoglobulin/complement deposition. This test is negative in dermatitis herpetiformis.

Other relevant investigations

All patients should have baseline blood tests performed, including a full blood count to assess for anaemia and evidence of any infection (elevated white-cell count). A swab should be taken if infection is suspected.

Treatment and its effectiveness

The general principle of treating immunobullous disease is to make the patient comfortable with the lowest dose of immunosuppression required. Most morbidity and mortality is from treatment rather than the disease and this has to be weighed up when making management decisions. In some patients, disease can be managed with superpotent topical steroids in combination with anti-inflammatory agents, such as a tetracycline, erythromycin, or nicotinamide. Many cases require oral steroids.

In most cases of bullous pemphigoid, oral prednisolone (0.5–1 mg/kg) will control the disease within a couple of weeks. When control is established, steroids should be tapered very slowly to avoid relapse. In those patients with more resistant disease and who are unable to come off steroids, an additional immunosuppressive agent, such as azathioprine or mycophenolate mofetil, is added.

Pemphigus is often more challenging to treat and therefore more frequently requires the addition of azathioprine or mycophenolate mofetil. Oral disease should be managed with good oral hygiene, topical antiseptics, and topical steroids (sprays/gels/mouthwashes). Any superimposed candida infection should be treated with oral fluconazole.

Treatment of dermatitis herpetiformis is usually with a combination of dapsons and a gluten-free diet. Pruritus is relieved within a couple of days of commencing dapsons, but the lesions will rapidly return if it is stopped. Dapsons has no effect on the enteropathy. Haemolysis and methaemoglobinaemia are present in virtually all patients on dapsons, although these are usually tolerable. Patients on a strict gluten-free diet may be able to reduce their dapsons dose or stop it completely. Sulfapyridine is used as an alternative in those patients who are unable to tolerate dapsons. All patients should be referred to gastroenterology.

Erythromycin is now used as the first-line treatment for CBDC. Those who do not respond require dapsons therapy. Dapsons or sulphapyridine are used to treat linear IgA disease.

Any patient with a suspected immunobullous disorder should be referred to dermatology for specialist investigation and treatment, although long-term management is often with a multidisciplinary team.

Other bullous disorders

Mucous membrane pemphigoid

Mucous membrane pemphigoid is a rare, chronic blistering disease which usually affects middle-aged or elderly people. It is predominantly a mucosal disease, most frequently affecting oral and conjunctival mucosa. Scarring can result in blindness. It runs a varied course and is often very treatment resistant. Patients should be managed by a multidisciplinary team, including ophthalmologists and oral surgeons. Oral and topical corticosteroids in combination with azathioprine or mycophenolate mofetil are used.

Pemphigoid gestationis

Pemphigoid gestationis is a rare blistering disorder, which occurs in association with pregnancy. The average onset is around 21 weeks gestation. The rash initially affects the periumbilicus and then spreads to involve the trunk, palms, and soles. The rash consists of urticated papules, plaques, and blisters. It usually remits after delivery, but can

recur with subsequent pregnancies. Treatment is with topical or oral corticosteroids.

Epidermolysis bullosa acquisita

Epidermolysis bullosa acquisita is an extremely rare chronic blistering disorder with trauma-induced blistering. Scarring and deformities can result and treatment is difficult.

253 Hair disorders

David de Berker

Inflammatory scalp diseases

Definition of inflammatory scalp diseases

Inflammatory diseases of the scalp can affect all epidermal surfaces or focus upon the follicle, with relative sparing of the interfollicular skin. Eczema and psoriasis are examples of the former; they affect the scalp in the manner of affecting skin elsewhere. The process is non-scarring in most instances, unless associated by bacterial infection. Other diseases, such as lichen planopilaris (LPP) or discoid lupus erythematosus (DLE) have a greater propensity to inflame the follicle than to cause inflammation in the surrounding skin. They can cause scarring. Some other follicular diseases, such as the family of diseases based on alopecia areata (alopecia areata (small areas of hair loss), alopecia totalis (whole scalp), and alopecia universalis (whole body)), cause barely visible follicular inflammation which results in hair loss but no scarring.

Aetiology of inflammatory scalp diseases

Eczema and psoriasis are lymphocyte-mediated diseases with significant inherited components. Atopic eczema is closely allied to mutations in the gene for filaggrin, an intermediate filament that contributes to the barrier structure of skin. In addition, there is a link with increased concentration and activity of IgE.

DLE and lichen planus are also lymphocyte mediated, characterized by a histological picture of lymphocytes interacting with the basal layer of the epidermis and causing keratinocyte death. Where this is associated with substantial damage to the basement membrane zone, there may be scarring. In some with DLE, sunlight plays an exacerbating factor.

Alopecia areata and related conditions are characterized by lymphocyte attack on the hair bulb—the deepest component of the hair follicle. Hair follicle function is halted by the attack, and the hair is lost. However, once the attack subsides, hair growth may recommence.

Typical symptoms of inflammatory scalp diseases, and less common symptoms

Eczema and psoriasis may present with itch, where scaling is particularly prominent in the latter. In some psoriatics, scale may build up to large, aggregated clumps of keratin matting the hair. In those with eczema, it is more likely to be exudative, especially if there is substantial itch which attracts scratching and secondary infection. In such instances, there may be regional lymphadenopathy. Scale and itch are less prominent with DLE and LPP, although new areas or disease activity may initially be indicated by slight itch. Symptoms are typically absent from those with alopecia areata, although, when there is rapid onset of severe disease, patients will often describe a preliminary tingling or slight discomfort of the scalp.

All of these diseases may present at other body sites with associated features characteristic of the diagnosis.

Demographics of inflammatory scalp diseases

Atopic eczema is most common in childhood, dropping to about 10% prevalence in adults, with a slight preponderance in women. Psoriasis is slightly more common in women than men, with a peak presentation age in the twenties. It is more common in Caucasians, with a prevalence in Western societies of about 2%. LPP is most common in women between the ages of 40 and 65. DLE is most common between the ages of 20 and 40 and seen twice as often in women as men. There is a slight excess in those

of African origin over other races, with an overall prevalence of approximately 0.02%.

Alopecia areata can occur at any age or race and has no clear gender preference, with a prevalence of 0.1%–0.2%.

Natural history of inflammatory scalp diseases, and complications of these diseases

Eczema wanes with emerging adulthood, but then deteriorates again with senescence and the loss of skin barrier function. Psoriasis is less common with age, but may still present in the elderly. Neither cause scarring and so, with disease fluctuation, the scalp can return to normal during remission. With DLE and LPP, areas of more intense inflammation are associated with scarring, which means that remission leaves areas of permanent alopecia. Treatment aims to abbreviate and diminish the intensity of episodes of inflammation so that follicles are not lost. A single area of alopecia areata is said to have an 80% chance of remission. This is not the same as saying that the disease itself will fully remit, and patients often suffer intermittent periods of variable hair loss. The prognosis of recovery is inversely proportional to the amount of hair lost and the duration of its loss.

Approach to diagnosing inflammatory scalp diseases

Diagnosis is performed by assessing for local signs in the context of the history, and for signs elsewhere on the skin (see Table 253.1).

Other diagnoses that should be considered aside from inflammatory scalp diseases

Fungal scalp infection is the main differential for scalp disease where there is scaling and hair loss. This is most common in children, but can also present in adulthood. Folliculitis decalvans is an alternative scarring alopecia and usually presents with pustules mixed in with foci of hair loss and tufts of residual hair clumped into aggregated follicular opening.

'Gold-standard' diagnostic test for inflammatory scalp diseases

The gold-standard diagnostic test for inflammatory scalp disease is a scalp biopsy; ideally, this should be done using a 'double-punch' technique, where two 4 mm punch biopsies are taken and prepared for sections in the horizontal and vertical axes. Where DLE is suspected, half of a vertically bisected punch should be sent fresh for immunofluorescence.

Acceptable diagnostic alternatives to the gold-standard test for inflammatory scalp diseases

Often, the history and clinical examination provides a fully adequate basis for diagnosis with no histology. In any condition where there is scaling and uncertainty, scalp scale and hair should be sent for mycology. A biopsy of an affected body site may be a substitute in some instances.

Other relevant investigations for inflammatory scalp diseases

DLE can merge with SLE, either at presentation or with time. It is useful to test for autoantibodies (e.g. antinuclear antibodies, anti-double-stranded DNA antibodies, extractable nuclear antigen antibodies) to establish the antibody status at the outset. Where hair shedding accompanies any disease, it is advisable to check the full blood count, ferritin level, and thyroid function. The latter may be

Table 253.1 Diagnosis of inflammatory diseases

Disease	History	Local signs	Signs at other sites
Eczema	Family history common Atopy: asthma, hay fever, contact allergy	Redness Light scale Sometimes crust	Eczema at other sites, particularly the flexures if atopic Skin may be dry if the patient is elderly
Psoriasis	Family history common May have joint problems	Silvery scale that can build up and become matted Rash in patches and within and behind ears	Nail changes and rash on extensor surfaces
Discoid lupus erythematosus	50% have deterioration in bright sunlight Scalp irritation	Discoid red or purplish areas in scalp with prominent follicles as well as some rash between follicles Central zones may have scarring	Similar less follicular discoid patches may be seen at other sites and, in particular, on the head and neck
Lichen planopilaris	Scalp itch Progressive hair loss	Small cuff of redness and slight scale around the follicular openings in a zone of scalp which may be discoid or at a hair margin Pale scarred areas in zones of previous disease	Rarely have lichen planus at other sites, such as mucosae of mouth and genitals, or skin lichen planus on the wrists or other sites
Alopecia areata	History of previous episodes which have spontaneously remitted Family history in 20% of cases	Hair shed from circumscribed area with normal follicular openings May leave white hairs behind in early stages, or demonstrate regrowth of white hairs first with recovery Exclamation mark hairs seen at margins	Other patches of alopecia areata can be found at other body sites, such as the beard area, eyebrows, eyelashes, or limbs Nails can be involved, with pitting or a roughened surface and discoloration Alopecia totalis is the loss of all scalp hair Alopecia universalis is the loss of all body hair

particularly relevant to alopecia areata, as they are both thought to share an autoimmune basis.

Prognosis for inflammatory scalp diseases, and how to estimate it

Scalp eczema and psoriasis are chronic relapsing and partially remitting conditions. They are unlikely to go away completely unless there is systemic treatment. However, they can become well controlled. DLE and LPP both demonstrate the tendency to ‘burn out’ after an unpredictable period of activity, causing irreversible hair loss. It is rare to see either disease progress to the extent that it creates substantial baldness, and wigs are rarely needed. Alopecia areata is thought to be worse if there is an onset in childhood and possibly worse if there is associated atopy. Overall prognosis is dependant on how much hair is lost—such severe disease means a poor prognosis.

Treatment of inflammatory scalp diseases, and its effectiveness

Scalp eczema and psoriasis can be treated with the same products used on the skin elsewhere—typically, a range of steroids and, with psoriasis, calcipotriol. Tar and emollient can be used with both diseases, especially psoriasis, where the emollient can help lift scale. Treatments applied in the evening and retained overnight with a shower cap can be very effective. For cosmetic ease, people may choose a vehicle such as a gel, alcohol liquid, or thin emollient base. These do not mess up the hair as much as the heavier cream or ointment bases. Systemic therapy with immunosuppression can be indicated for very severe disease.

DLE and LPP both respond to some extent to potent topical steroid, usually applied as a cream or gel as, focally, there is no hair to make greasy. Injected triamcinolone acetonide can be useful, and systemic treatment with hydroxychloroquine can help DLE. Systemic prednisolone or ciclosporin are short-term options for LPP.

Topical and injected steroids are the mainstay of treatment for alopecia areata. Systemic steroid is rarely used due to the high relapse rate and the risks of the treatment if used long term.

Hair shedding: Telogen effluvium and pattern hair loss

Definition of hair shedding

Some patients present with hair shedding or change of hair pattern as their primary complaint, with no scalp disease. Patterned loss, when manifest, is characteristic of ageing.

Aetiology of hair shedding

Shedding is continuous and normal in humans and, in most instances, occurs at a rate of 150 hairs a day. When a significant event increases the proportion of hair follicles entering the resting phase (telogen), then more hairs will be shed. This event can be physiological, for example occurring 1–3 months after a fever or haemorrhage, and is termed telogen effluvium. Alternatively, it can be toxicological, as with the ingestion of a poison such as a chemotherapy agent. In some instances, it is where a normal medication may have an adverse effect of impairing follicular function, as occurs with some forms of synthetic vitamin A (retinoids).

Other patients, without conspicuous shedding, present with an altered pattern of scalp hair. This is usually following a period during which the normal rate of shedding has exceeded the rate of regrowth such that there is an overall decline in scalp coverage. This is the basis for patterned hair loss, which is seen in both men and women. Women are more likely than men to seek medical advice to determine whether there is a cause or treatment for the hair loss.

Typical symptoms of hair shedding, and less common symptoms

Hair shedding is noted in the shower and sink and also commented on by social partners. There are rarely any physical associations unless there is a clear recollection of a preceding event or causal medication. Change of hair pattern is usually based on gradual realization.

Demographics of hair shedding

All people and ages appear susceptible to telogen effluvium. Men and women suffer patterned hair loss with age, starting as early as mid-adolescence. There is a strong but ill-defined genetic basis. Those of Chinese origin are thought to have less marked patterned balding than those of other origins.

Natural history of hair shedding, and complications of the disease

Telogen effluvium evolves 1–3 months after the event and may take a further 2–3 months to peak. Return towards normal takes a further 3 months, such that it is common for people to be affected to some extent for a year. Patterned hair loss in men and women may be highlighted by a period of shedding that does not fully reverse. By the age of 70, 70% of men will have significant balding. By menopause, 30% of women will have a degree of male pattern balding with frontal recession. Most of the rest of the women will have some thinning on the crown, but will retain their frontal margin.

Approach to diagnosing hair shedding

A history of shedding is normally clear and substantiated by gently pulling strands of hair on the scalp as part of the examination. If these easily pluck, then it confirms the account. If it does not, it does contradict the account, but may mean that the period of active shedding is passed and regrowth can be anticipated.

Diagnosing patterned hair loss is one of recognizing the pattern and ensuring that there are no other features in the history or examination.

Other diagnoses that should be considered aside from hair shedding

Fungal scalp infection can be considered if there is hair breakage or scalp scaling, but is not common in the age group presenting with these problems. Endocrine problems with masculinization can be relevant with androgen-secreting tumours and will usually present with features such as amenorrhoea, evolution of hirsutism, and altered body habitus. A milder version of this pathology is represented by polycystic ovary syndrome.

'Gold-standard' diagnostic test for hair shedding

In the presence of normal periods and no change in body habitus, the main test for telogen effluvium is the hair pull test. Where multiple hairs come out with the lightest pull, the diagnosis is confirmed.

Patterned hair loss is characterized by miniaturization of the hair follicles and their hairs and can be confirmed by scalp biopsy. This needs to be done with horizontal sections of 4 mm punch biopsies in order that the number, hair cycle status, and bore of the hairs can be determined.

Acceptable diagnostic alternatives to the gold-standard test for hair shedding

Biopsy is rarely needed, and clinical assessment usually provides all that is needed.

Other relevant investigations for hair shedding

Iron deficiency and thyroid disease can be contributory and would normally be checked. Any other investigation would be done on the basis of some relevant part of the history or examination such as a testosterone if there were a degree of hirsutism or altered periods.

Prognosis for hair shedding, and how to estimate it

Telogen effluvium has a good prognosis over a 12-month period. As people age, they may find that the reversal is not complete and

there has been a stepped reduction in the bulk and extent of their hair. Prognosis for those with either male or female pattern hair loss is that it will gradually progress with time. Women do not go bald, although, with advanced age, there can be considerable loss of coverage.

Treatment of hair shedding, and its effectiveness

Any medical abnormalities detected should be addressed. Telogen effluvium is self-limiting. If medication is thought to play a part (e.g. atenolol, oral retinoids, some anticonvulsants, progesterone-containing medication), then alternatives might be sought.

Many argue that ferritin should be maintained significantly above the lower range of normal described by most laboratories, such that it is 70 ng/ml. This may require iron supplementation.

Anti-androgens, such as the oral contraceptive pill with a synthetic progestogen (not norethisterone), cyproterone acetate, or spironolactone, are advocated by some. The potential for iatrogenic disease related to treatment for a normal variant should be considered with these options. Also, the end point of treatment and hence its duration is difficult to determine.

In men, finasteride is licensed for use in male pattern balding and can result in some regrowth for 60% of men within 2 years. Over the subsequent 5 years, this improvement tails off, but probably the person will have some additional retained hair for as long as they take the medication. Data on improvement for women with other anti-androgens (finasteride is not licensed in women) is not so definite.

Topical minoxidil 2% and 5% is available over the counter as a liquid applied twice daily to affected areas for a minimum of 6 months, to be continued as long as any benefit accrued is desired to be maintained. There is technical evidence of increased hair growth in men and women, although the change in front of the mirror is seldom marked.

254 Nail disorders

David de Berker

Definition of the disease

Nail diseases present as alteration of the nail plate, alteration of the periungual tissues, or as a combination of the two. Most commonly, external agents, such as fungus or trauma, affect the nail alone, whereas all inflammatory and neoplastic processes affect the surrounding tissues as a primary process giving rise to secondary nail plate alteration.

Aetiology of the disease

The most common inflammatory diseases of nail are psoriasis, eczema, and lichen planus, which, in turn, are amongst the most common inflammatory disease of the rest of the skin.

The most common infections arise through fungal invasion of the nail plate and the nail bed, which is the skin underlying the nail. Fungi are of two main families, dermatophytes and non-dermatophytes. For dermatophytes, skin is a natural medium for existence, whereas non-dermatophytes are more typically found in the soil, but may rarely become pathological to skin, nail, and hair.

Trauma represents the third most common cause of nail abnormalities, with an increasing prevalence of traumatic disease affecting toenails as people age. Some trauma is directly upon the nail, made vulnerable through its location on the dorsal distal tip of the toe. Other trauma may be related to foot mechanics, which alter with time. Trauma to fingernails is less commonly a cause of significant dystrophy, outside the specific area of self-inflicted damage arising from nail biting or a form of self-mutilation known as onychophagia.

Both benign and malignant neoplasia can present with nail changes. The former cause a space-occupying effect, distorting the position of the nail. If the mass is proximal and pressing on the nail matrix, then it will alter the nail during its creation. More distal or lateral tumours will impinge on the nail following generation and will usually just alter its position. Glomus tumours, subungual exostoses, or periungual fibromas of the type seen in tuberous sclerosis can be found in either location.

Malignancy of the nail unit presents as squamous cell carcinoma or malignant melanoma. The former is typically *in situ* in the first instance and has a very long prodrome before invasion. HPV 16 and 18, seen in genital squamous cell carcinoma, can be present. Malignant melanoma of the nail unit is rare and represents about 2% of all melanoma, with an incidence in the UK of 1 per million population per year. It is diagnosed later than melanoma on other skin sites and, consequently, is usually deeper and has a worse prognosis.

Typical symptoms of the disease, and less common symptoms

All nail disease evolves from minor changes in appearance to more major alterations of nail integrity. Depending on the focus and inflammatory basis of the disease, there may be associated pain and loss of function. Onychomycosis is mainly associated with asymptomatic thickening and white-to-yellow nail discoloration extending from the distal edge.

Less common diseases present with features such as sterile pustulation in psoriasis or chronic ooze from beneath the nail for a squamous cell carcinoma of the nail bed. Malignant melanoma most commonly presents initially as a dark longitudinal streak in the nail in a pale-skinned person. When someone has a single such streak, it warrants close and expert assessment.

An important factor in any presentation of nail disease identifying a pattern. Disease that affects multiple digits is more likely to yield significant clues at other body sites. For psoriasis, the presence of pits in the nail, lifting of the nail (onycholysis), and nail thickening may be corroborated by scaling on the elbow, on the scalp, and in the ears. For eczema, the presence of itching and a typical rash at other body sites may illustrate the disposition. Conversely, if the pathology is limited to a single digit, then neoplasia or infection is more likely and, given that some neoplasias can be malignant, it is important to obtain a clear diagnosis.

Demographics of the disease

Different nail diseases have their own demographic. Eighty percent of patients with psoriasis of the skin will develop nail psoriasis at some point in their lives, but only 30%–40% will have it at any one time. It is not common in childhood and becomes particularly prevalent amongst those patients who have psoriatic arthritis of the distal interphalangeal joints. The demographic for eczema of the nail is only partly related to the peak of atopic manifestation. Whereas the latter occurs mainly in childhood, it is common for irritant and occupational factors to become major factors once people enter the workforce and are subject to repetitive activities, like wet work or building, that disturb periungual skin.

Fungal nail infection (onychomycosis) is mainly a disease of middle age and beyond. It is more common in subgroups where there is a predisposing factor, such as psoriatics, the immunosuppressed, or those with damage to the nail. The accumulation of damage to the nail is a feature of time, so onychomycosis increases in prevalence in the elderly.

Malignancy of the nail primarily is seen in those 40 and older. However, immunosuppression predisposes to squamous cell carcinoma, in which case people may present with malignancy of the nail at an earlier age.

Natural history, and complications of the disease

All the inflammatory diseases are fluctuating, except for those with scarring potential, such as lichen planus, where the nail matrix and, consequently, the nail plate may be permanently lost. Onychomycosis is gradually progressive such that it will usually destroy a nail plate over 20 or more years, or immunity may hold it in check. Malignancy of the nail is slow to progress in most instances, save for where nodular variants present at the outset or evolve on the background of indolent disease. In such instances, the outcome can be fatal, especially for melanoma, where 5-year survival rates are reported at around 50%–70%.

Approach to diagnosing the disease

Diagnosis is by assessment for characteristic signs within the digit, all other digits, and the rest of the skin. Some diseases may give clues through other systems, such as the joints for psoriasis, or asthma for atopic eczema. Where onychomycosis is a potential diagnosis, generous clippings of nail and subungual debris should be obtained for mycological examination and culture. It is only with the results of this that the clinician is equipped to prescribe oral antifungal medication. The presence of fungus does not rule out coexisting disease. Where pathology presents with a single digit, the author would advocate close attention to detail in order to not miss malignancy or some treatable structural abnormality. This objective may entail imaging

with all soft tissue and bone modalities and taking an incisional diagnostic biopsy under local anaesthetic.

Other diagnoses that should be considered

Some nail changes are manifestations of systemic disease. Examples include clubbing, splinter haemorrhages, and paraneoplastic changes within the nail unit. The latter may mimic psoriasis, but come about through internal malignancy. Hence, anyone presenting with a marked inflammatory change in their nails, usually in later life, in the absence of an obvious cause, should be assessed for internal malignancy.

'Gold-standard' diagnostic test

If there were one test that the clinician could do, and no other, then it would be the incisional biopsy. However, usually there is enough information from the clinical examination and history, supplemented by a generous mycology sample, to conclude the diagnosis. In widespread nail disease, when a diagnosis cannot be made, it may be warranted to take a diagnostic biopsy in order to ensure that any proposed systemic therapy is appropriate. Such therapies are usually immunosuppressant and may be intermittently long term with side effects. To give such treatment without a clear diagnosis would be questionable. For diagnosis of the single digit, it is possibly more understandable to resort to biopsy, given the risk of malignancy.

Who does the biopsy, what pattern of biopsy is done, and who interprets the histology make a difference. It is best that such tests are undertaken by those who do them frequently.

Acceptable diagnostic alternatives to the gold standard

Clinical acumen with only marginal confidence may be adequate when balanced against complete confidence. This holds as long as the sequelae of the proposed treatment are not problematic, or as long as the significance of the diagnosis being missed because of a failure to obtain histological certainty is not a grave one. Mycology should be undertaken several times to ensure that fungus is not missed, as laboratory standards acknowledge a false-negative rate for mycology of the nail at around 40%.

Other relevant investigations

Skin biopsy or mycology of abnormal non-nail tissue can sometimes provide enough information to give confidence to the interpretation of the nail problems.

Prognosis and how to estimate it

The prognosis of non-scarring nail disease is that it will progress at approximately the same rate as that of the skin disease at other sites. It will fluctuate and respond well but variably to treatment. Compliance with treatment plans will make a difference and, typically, people tire of prolonged regimens of hand care and topical therapies. The prognosis of scarring nail disease will depend upon the natural aggressiveness of the disease and the intensity of immunosuppression. At times, the consequences of treatment will not be acceptable. Dermatophyte onychomycosis is cured in about 60% of people after systemic treatment but in more like 20% of those who have milder disease eligible for topical therapy. However, topical therapy may hold the disease back and render it manageable. Relapse after systemic therapy is about 20% over 5 years.

Treatment and its effectiveness

Hand and foot care is important in all nail diseases, save possibly malignancy. It entails keeping nails short, using copious amounts of emollient, and wearing gloves during wet work. Where toenails are involved, this may be achieved for the elderly with the help of a podiatrist and carefully fitted footwear.

Topical treatments for psoriasis are calcipotriol ointment with or without betamethasone valerate or dipropionate. This is applied to the affected periungual area; at times, in order to do this, the nail plate may have to be clipped back to expose the nail bed. For eczema, the steroid alone may be sufficient. In resistant cases, it is possible to inject steroid into the nail matrix. Systemic therapy is as for the disease in general, and the most successful for psoriasis has been ciclosporin or biologics such as infliximab and etanercept.

Onychomycosis is usually treated with oral terbinafine, although there is a significant side-effect profile that includes liver failure. Death has been reported. Malignancy is treated with surgery and, in more advanced cases, this may require distal or ray amputation to ensure adequate clearance.

255 Mucosal disease

Kathy Taghipour

Pemphigus vulgaris

Definition of pemphigus vulgaris

Pemphigus vulgaris is an autoimmune disease that affects the skin and the mucosal membranes with blisters and erosions.

Aetiology of pemphigus vulgaris

In pemphigus vulgaris, autoantibodies target components of desmosomes, the structures that provide cell-to-cell adhesion in the skin. An intra-epidermal cleavage results from this immune reaction, leading to blister formation.

Typical symptoms of pemphigus vulgaris, and less common symptoms

In pemphigus vulgaris, flaccid and thin-walled blisters and/or erosions are present on the skin and mucosal membranes, including in the oropharynx and the genital area. The oral lesions often present on buccal and palatal mucosa and are painful.

Demographics of pemphigus vulgaris

Pemphigus vulgaris commonly affects individuals in their middle age. The incidence in the UK is 7 per million per year and both sexes are equally affected. It is more common in Eastern Europe, Middle East, India, and amongst Ashkenazi Jews, and certain HLA associations have been described.

Natural history of pemphigus vulgaris, and complications of the disease

The clinical course of pemphigus vulgaris varies between individuals but, in most cases, immunosuppressive treatment is required for years to control the disease. Painful mouth lesions may lead to malnutrition. Most complications are, however, related to long-term treatment with systemic steroids.

Approach to diagnosing pemphigus vulgaris

A diagnosis of pemphigus should be considered when patients present with painful, non-healing oral or genital erosions. A full skin examination is important in confirming the clinical diagnosis. Pemphigus has a predilection for scalp, face, and flexures, although mucosal erosion may be the only presenting sign. A full history of drug intake should be taken to exclude drug-induced pemphigus.

Other diagnoses that should be considered aside from pemphigus vulgaris

Other diagnoses that should be considered aside from pemphigus vulgaris include erosive lichen planus and mucous membrane pemphigoid. Erosive lichen planus presents with erosions of the oral and/or genital mucosa. It may be associated with a skin rash and white, lacy streaks on buccal mucosa, namely Wickham striae. Mucous membrane pemphigoid is a rare sub-epidermal bullous disease that leads to erosions and gingivitis in the mouth and may affect the genital mucosa, skin, conjunctivae, and gastrointestinal tract, leaving scars on the affected areas. Drug-induced reactions such as Stevens–Johnson syndrome (see ‘Stevens–Johnson syndrome’) should also be considered when the history is suggestive of a recent relevant drug intake, in particular if conjunctivae are involved. Other differential diagnoses include infections and systemic disease (Box 255.1).

Box 255.1 Common disorders that affect mucosal membranes

Infections

Viral

- herpes simplex
- herpes zoster virus
- Coxsackie virus (e.g. hand, foot, and mouth disease)
- HIV

Bacterial

- gram-negative bacteria
- anaerobes

Fungal

- candida

Treponemal

- syphilis

Skin diseases

- erosive/oral lichen planus
- autoimmune bullous diseases (e.g. pemphigus vulgaris, linear IgA disease, mucous membrane pemphigoid)
- erythema multiforme
- Stevens–Johnson syndrome
- Sweet’s syndrome
- lichen sclerosus et atrophicus of vulva

Systemic diseases

Gastrointestinal tract

- inflammatory bowel disease
- coeliac disease

Rheumatology

- SLE
- Behçet’s syndrome
- Reiter’s syndrome

Drug induced

- chemotherapy
- other drugs (e.g. nicorandil, NSAIDs, angiotensin-converting-enzyme inhibitors)

Malignancy

- leukaemia
- squamous cell carcinoma
- other malignancies

Iatrogenic

- radiotherapy

‘Gold-standard’ diagnostic test for pemphigus vulgaris

The gold-standard diagnostic tests for pemphigus vulgaris are immunofluorescence studies on a perilesional skin biopsy (direct immunofluorescence) and on serum (indirect immunofluorescence), to confirm the presence of IgG antibodies in the intercellular space.

Acceptable diagnostic alternatives to the gold-standard test for pemphigus vulgaris

An acceptable diagnostic alternative to the gold-standard test for pemphigus vulgaris is light microscopy of the lesional biopsy, showing

rounding and separation of the keratinocytes (acantholysis) and intra-epidermal cleavage. In addition, circulating antibodies to desmogleins 1 and 3 can be detected with ELISA.

Other relevant investigations for pemphigus vulgaris

In pemphigus vulgaris, it is important to have a haematology and biochemistry workup and a relevant infection and malignancy screen before patients are commenced on immunosuppressive treatment. A baseline bone densitometry scan is useful when long-term oral steroids are considered.

Prognosis for pemphigus vulgaris, and how to estimate it

Prognosis varies amongst individuals but, in general, older patients, patients with extensive disease, and those who require high doses of systemic steroids have poorer prognosis. Relapse and mortality is more common within the first 2–5 years of diagnosis than at other times.

Treatment of pemphigus vulgaris, and its effectiveness

In pemphigus vulgaris, topical treatment with steroids and good oral care is important in providing comfort for patients. Systemic steroids provide the mainstay of treatment and are often required to reach disease control. Adjuvant immunosuppressants are usually used while steroids are tapered, and the most common agents include azathioprine, mycophenolate mofetil, and cyclophosphamide. More recently, an anti-B-cell monoclonal antibody (rituximab) has been used successfully in refractory disease.

Lichen planus

Definition of lichen planus

Lichen planus is a cell-mediated immunological mucocutaneous disease. Oral lichen planus may present with erosions, white streaks, or plaques in the oral cavity.

Aetiology of lichen planus

The exact aetiology of lichen planus is unknown. An association with hepatitis C virus has been documented in patients from Italy and is likely to be related to immunogenetics. Mercury in dental amalgam fillings has been suggested as an immunogenic or irritant factor that may trigger oral lichen planus.

Typical symptoms of lichen planus, and less common symptoms

Oral lichen planus may be asymptomatic, and the onset may be insidious. It may present with rough plaques, sensitivity to acidic or hot food, soreness of the oral cavity and gums, and erosions and ulceration. A pruritic skin rash consisting of violaceous, flat-topped papules may be present, and genitals may be affected. Associated frontal alopecia and nail involvement is less common.

Demographics of lichen planus

There is no significant racial or geographical preponderance of lichen planus. Oral lichen planus is rare in childhood.

Natural history of lichen planus, and complications of the disease

The disease course of lichen planus is chronic, with waxing and waning over years. Stress and anxiety may trigger exacerbation. Squamous cell carcinoma may rarely complicate oral lichen planus.

Approach to diagnosing lichen planus

Asymptomatic oral lichen planus is usually detected by dental practitioners. A detailed drug history is important in differentiating lichen planus from lichenoid drug reactions. Examination of skin, scalp, genital mucosa, and nails should be performed to look for other manifestations of lichen planus.

Other diagnoses that should be considered aside from lichen planus

When considering a diagnosis of lichen planus, important differential diagnoses include oral manifestations of autoimmune bullous diseases, contact dermatitis, oral candidiasis, viral infection, and drug reaction.

'Gold-standard' diagnostic test for lichen planus

The diagnosis of lichen planus is clinical and can be confirmed with a biopsy from the affected area. The hallmark of the histology is a lichenoid (band-like) lymphocytic infiltrate at the dermoepidermal junction, and basal cell layer degeneration. Immunofluorescence studies may help differentiate lichen planus from lupus or autoimmune bullous disease.

Acceptable diagnostic alternatives to the gold-standard test for lichen planus

There are no acceptable diagnostic alternatives to the gold-standard test for lichen planus.

Other relevant investigations for lichen planus

There are no other relevant investigations for lichen planus, aside from the gold-standard test.

Prognosis of lichen planus, and how to estimate it

Oral lesions in lichen planus are slow to heal, and complete remission is rare.

Treatment of lichen planus, and its effectiveness

The treatment of lichen planus aims at symptomatic relief. Good oral hygiene and well-fitting dentures to reduce trauma are important aspects of the treatment. Potent topical steroids and steroid oral rinses accelerate the healing, and anaesthetic mouthwash provides pain relief. Extensive ulceration requires systemic treatment with steroids or other agents such as retinoids and ciclosporin.

Stevens–Johnson syndrome

Definition of Stevens–Johnson syndrome

Stevens–Johnson syndrome is an emergency dermatological condition in which an immunological hypersensitivity causes erosions and inflammation of mucosal membranes and the skin.

Aetiology of Stevens–Johnson syndrome

The main trigger factor for Stevens–Johnson syndrome is drug intake. Antibiotics (e.g. sulpha-group antibiotics and penicillin), NSAIDs, allopurinol, antiepileptics, and some antiretrovirals may cause Stevens–Johnson syndrome. Certain HLA classes are associated with increased risk of developing drug-induced Stevens–Johnson syndrome. Idiopathic and infection-related forms of Stevens–Johnson syndrome are less common.

Typical symptoms of Stevens–Johnson syndrome, and less common symptoms

In Stevens–Johnson syndrome, non-specific symptoms such as flu-like symptoms, fever, and soreness of eyes and throat may precede erosions and blistering of the skin and mucosa. Trunk and face as well as acral skin are most commonly affected, and oral, genital, and conjunctival mucosa are involved. In severe cases, the mucosal lining of the respiratory and gastrointestinal tract are also affected. Detachment of epidermis may be present in <10% of body surface area.

Demographics of Stevens–Johnson syndrome

The incidence of Stevens–Johnson syndrome is estimated at 1–2 per million per year; the disease affects both sexes and all age groups.

Natural history of Stevens–Johnson syndrome, and complications of the disease

In Stevens–Johnson syndrome, the erosions on the skin and mucosa are painful and may be complicated by infection. Pneumonitis, urinary

retention, and renal failure are other complications; however, the most common sequelae is damage to the eyes, including symblepharon, corneal ulcerations, and opacities.

Approach to diagnosing Stevens–Johnson syndrome

The diagnosis of Stevens–Johnson syndrome is based on the clinical picture and a detailed history of any drug intake, including over-the-counter drugs, in the period of 1–3 weeks preceding the symptoms.

Other diagnoses that should be considered aside from Stevens–Johnson syndrome

Toxic epidermal necrolysis should be considered if >30% of the skin is denuded in addition to oral, genital, or respiratory mucosal involvement. It is important to note that Stevens–Johnson syndrome may evolve into toxic epidermal necrolysis. Staphylococcal scalded skin syndrome and some autoimmune bullous diseases such as paraneoplastic pemphigus and linear IgA disease may mimic Stevens–Johnson syndrome.

‘Gold-standard’ diagnostic test for Stevens–Johnson syndrome

In Stevens–Johnson syndrome, a skin biopsy complements the clinical diagnosis.

Acceptable diagnostic alternatives to the gold-standard test for Stevens–Johnson syndrome

There are no acceptable diagnostic alternatives to the gold-standard test for Stevens–Johnson syndrome.

Other relevant investigations for Stevens–Johnson syndrome

In Stevens–Johnson syndrome, in addition to routine haematology and biochemistry tests, skin swabs and blood cultures are useful in

cases of secondary infection and sepsis. Renal function should be monitored for haematuria and renal failure.

Prognosis of Stevens–Johnson syndrome, and how to estimate it

Mortality in Stevens–Johnson syndrome is estimated at 1%–5% and is mainly due to sepsis. Prognosis worsens when erosions and denuded skin involve larger body surface area, and with transition of Stevens–Johnson syndrome to toxic epidermal necrolysis. When epidermal detachment occurs over more than 10% of skin surface area, the prognosis and severity of the condition should be estimated with a validated scoring system (SCORTEN) that evaluates age, malignancy, tachycardia, body surface area involved, serum urea, bicarbonate, and glucose. A patient with a SCORTEN score of 3 or above should be managed in intensive care. The outcome improves with early withdrawal of the culprit drug, although drugs with long half-life are associated with a higher risk of death. The commonest sequelae in survivors of Stevens–Johnson syndrome are ophthalmological complications.

Treatment of Stevens–Johnson syndrome, and its effectiveness

Following discontinuation of the causative drug, patients with Stevens–Johnson syndrome often require admission and symptomatic treatment. There is no specific treatment for Stevens–Johnson syndrome, and supportive treatment should address haemodynamic, respiratory, and infectious complications. Topical care of skin, conjunctivae, and oral mucosa provides further symptom relief.

256 Genital disease

Susan Cooper and Tess McPherson

Definition of the disease

The term 'genital disease' refers to a spectrum of diseases. Certain systemic diseases preferentially affect mucous membranes. Local factors including warmth, occlusion, irritants, and friction are important and contribute to skin disease in this region and increase risk of certain infections. Skin conditions may be difficult to diagnose as they may have atypical appearances. Therefore, the diagnosis of disease in the anogenital region may be complex.

This chapter will focus on the most common genital diseases seen in the dermatology clinic: lichen sclerosus, lichen planus, eczema, genital pain syndromes, and pre-malignant and malignant disease. Other less common dermatological conditions seen in this area will be briefly covered.

Definition and aetiology of the most common diseases

Lichen sclerosus is a chronic inflammatory disease of unknown aetiology, preferentially affecting the anogenital region. There appears to be a genetic component, with a positive family history in some patients and a relationship with certain HLA types. Lichen sclerosus appears to be related to other autoimmune conditions such as vitiligo and thyroid disease.

Lichen planus is a chronic inflammatory disease which affects skin, nails, and mucous membranes. The aetiology is unknown but probably represents T-cell-mediated damage to epidermal cells.

In patients with genital eczema, a mixed picture of both endogenous (e.g. atopic) and exogenous eczema is frequently seen. Atopic eczema may be associated with history of eczema in other sites or other atopic disease (asthma and hay fever). Contact dermatitis can be due to irritants or allergens and is an important contributor to genital eczema. Allergens seen on patch testing include rubber and fragrance. Haemorrhoid creams and medicated toilet paper are also frequent culprits. Lichen simplex chronicus is chronic dermatitis with skin changes caused by itching/rubbing.

Vulvodynia and scrotodynia may be localized (vestibulodynia) or generalized. These both probably represent a regional pain syndrome.

Typical symptoms of the disease, and less common symptoms

There are only a limited number of symptoms in the anogenital area. Therefore, pruritus or itch and pain may be the presenting feature of a wide variety of diseases.

Itch and soreness are presenting features of lichen planus, lichen sclerosus, and vulval eczema. The patient may report an abnormal clinical appearance, and this can be primary or secondary to scratching.

A normal clinical appearance with localized pain or persistent burning is a presenting feature of vulvodynia and scrotodynia. Depression may be a feature of any chronic pain syndrome.

Demographics of the diseases

Lichen sclerosus is more common in females; the female:male ratio is reported to be 6–10:1. It may occur at any age, but two peaks of onset are during childhood and after menopause. In men, it most frequently occurs in the fourth or fifth decades, with an estimated prevalence of 1 in 660.

Like lichen sclerosus, lichen planus is more common in females. It can present any time but is more common in the sixth decade. In the UK, lichen planus accounts for around 1% of referrals to dermatologists.

Dermatitis is an extremely common condition, with a lifetime risk of over 30%.

Natural history, and complications of the disease

Lichen sclerosus, lichen planus, and vulval eczema can be chronic or resolve after a period of time with or without treatment. An important complication of lichen sclerosus and lichen planus is an increased risk of malignancy.

Approach to diagnosing the disease

In diagnosing genital disease, a full history of symptoms and their time course is required. Examination of all skin, as well as the mouth and nails, can lead to a clinical diagnosis and help differentiate between conditions that may present similarly in the genital area. Full examination of the mouth is essential and can show typical features of lichen planus (white lacy streaks on buccal mucosa) or evidence of other conditions, such as autoimmune bullous disorders. The nails and the scalp should be examined for evidence of lichen planus or psoriasis. Additionally, the presence of other autoimmune conditions, such as vitiligo, may be associated with lichen sclerosus. Other areas affected by dermatitis would be relevant.

Lichen sclerosus preferentially affects the genitals and only rarely affects other cutaneous sites. On examination of the anogenital area, clinical findings for lichen sclerosus include pallor, atrophy, fissures, and foci of hyperkeratosis. Scarring may cause loss of architecture.

Genital lichen planus can be seen with or without cutaneous disease; 50% of women with cutaneous lichen planus, and 25% of men with cutaneous lichen planus, have genital involvement. The most frequent finding is the classical violaceous papules and plaques on the labia minora and majora in woman, and on the glans or the shaft of the penis in men. Erosive lichen planus is a distinct subtype characterized by severe, scarring, erosive disease of the vestibule, the introitus, the vagina, and the oral cavity. Lacy white streaks, as seen orally, may be seen in these areas as well. Hypertrophic and lichen planopilaris are the least frequent forms of this disease.

Genital eczema appearances range from mild erythema to extreme thickening and lichenification. Typical sites affected are the labia majora and the mons pubis in women, and the crura and the scrotum in men.

Pain on examination may be feature of vulvodynia. This typically has normal clinical findings but there is overlap of some syndromes, and patients with lichen sclerosus may have vulvodynia.

A skin biopsy of lesional (abnormal) tissue can be very useful in clarifying the clinical diagnosis. In particular, it is useful for distinguishing between an interface dermatosis, such as lichen planus and lichen sclerosus, and a spongiotic dermatitis, such as dermatitis. Histological analysis is also vital to distinguish malignant from inflammatory conditions.

Perilesional skin can be biopsied for immunofluorescence if an autoimmune blistering disorder is suspected.

Swabs may be important for diagnosing candida infection, which can complicate all anogenital pathology.

Other diagnoses that should be considered

If there is any clinical doubt when diagnosing genital disease, a biopsy will help differentiate between diagnoses.

Other causes of pale patches/plaques

Other causes of pale patches/plaques in genital disease include morphea and vitiligo. Morphea presents with hypopigmented atrophic plaques. Vitiligo presents with asymptomatic hypopigmented patches. There may be cutaneous lesions elsewhere.

Other causes of erythematous patches/plaques

Pre-malignant and malignant causes

Vulval intra-epithelial neoplasia and penile intra-epithelial neoplasia

The majority of intra-epithelial neoplasias in genital disease are HPV related or occur in association with lichen sclerosus or lichen planus. The natural history of these conditions is unclear but an increased risk of malignancy would be expected.

Squamous cell carcinoma

Squamous cell carcinoma is the most common vulval tumour and is most frequently seen in elderly patients. It is very rare in circumcised men.

Extra-mammary Paget's disease

Extra-mammary Paget's disease is a rare intra-epithelial adenocarcinoma of apocrine gland-bearing sites. It may be primary or secondary to underlying malignancy. It is seen most commonly in the vulva (in women) or in the perianal region (in men). There may be pruritus/burning, or it may be asymptomatic. A slowly expanding erythematous plaque is typical. Erosions and scale cause a 'strawberries and cream' appearance. Because of the association of this disease with malignancy, if Paget's disease is diagnosed, a systemic evaluation is required.

Inflammatory causes

Psoriasis

Psoriasis presents with erythematous, well-defined plaques with slight scale. It may look different from psoriatic areas on the rest of the body, with the typical silver scale being not present (as in other flexural sites). It is usually confined to hair-bearing areas, so the labia minora are unaffected. Painful fissuring of the perianal and intergluteal clefts is a problem in both sexes. The presence of typical lesions elsewhere can help in the diagnosis of this disease.

Reiter's disease

Reiter's disease may present on the penis with psoriasiform lesions.

Zoon's (plasma cell) balanitis/vulvitis

Zoon's (plasma cell) disorders predominantly affect males. Clinically, the disorders present with erythematous, moist, speckled, discrete plaques. Involvement of adjacent surfaces produces 'kissing lesions' in men. Circumcision is curative.

Causes of blistering

Acquired autoimmune blistering disorders

Bullous pemphigoid

Bullous pemphigoid has a propensity for flexural sites. It presents with tense blisters on urticated plaques. There is mucosal involvement in 50% of patients.

Mucous membrane pemphigoid

Mucous membrane pemphigoid is a scarring, blistering disorder.

Erythema multiforme and Stevens–Johnson syndrome

Both erythema multiforme and Stevens–Johnson syndrome may present as a bullous eruption, particularly in the genital region. An association with herpes simplex virus is important in recurrent disease.

Fixed drug eruption

A fixed drug eruption presents as recurrent, erythematous, blistered or eroded plaques that, upon exposure to the drug, recur at exactly same site.

'Gold-standard' diagnostic test

The gold-standard diagnostic tests for genital disease include clinical findings and skin biopsy.

Acceptable diagnostic alternatives to the gold standard

An acceptable diagnostic alternative to the gold-standard tests for genital disease is a response to an appropriate treatment (e.g. strong topical steroids in lichen planus and lichen sclerosus).

Other relevant investigations

In genital disease, if pruritus is a predominant symptom, a screen for any other underlying causes of pruritus (e.g. systemic disease, such as liver or renal disease) would be relevant. If a diagnosis of lichen sclerosus or lichen planus is suspected, investigations should screen for other autoimmune diseases.

Prognosis, and how to estimate it

The risk of vulval squamous cell carcinoma is increased in both lichen sclerosus and lichen planus. It is estimated at approximately 2%–5% in lichen sclerosus, although the risk has not been quantified in men. There is also thought to be an increased risk of squamous cell carcinoma in lichen planus. The natural history of intra-epithelial neoplasia is not fully understood but an increased risk of squamous cell carcinoma is expected. Therefore, longitudinal evaluation is recommended for lichen sclerosus, lichen planus, and vulval intra-epithelial neoplasia. Self-examination should be taught. Any non-healing ulcers, fissures, or nodules should be biopsied for histological evaluation.

Treatment and its effectiveness

In genital disease amongst women, general care of the vulva can help all conditions. This includes avoidance of irritants and appropriate emollients. Lichen sclerosus responds well to strong topical steroids. Lichen planus tends to be a self-limiting condition and responds to strong topical steroids, although genital disease can be more resistant to treatment than cutaneous disease is. Hypertrophic lichen planus may benefit from interlesional corticosteroids. Erosive lichen planus is more challenging to treat and may need longer maintenance with topical steroids.

Eczema improves with soap/irritant avoidance, and use of emollients and topical steroids for flares. It can be a chronic condition and challenging to manage. Allergic contact dermatitis is investigated by patch testing and managed by avoidance of proven allergens.

Vulval pain improvement can be seen with the use of bland emollients and the avoidance of irritants and fragrance. Topical local anaesthetic agents and tricyclic antidepressants are the mainstays of treatment.

Pre-malignant and malignant conditions require an appropriate biopsy for diagnosis, together with education of the patient, and longitudinal observation for any risk of malignancy.

257 Polymorphic light eruption and actinic prurigo

Jane McGregor

Definition of polymorphic light eruption and actinic prurigo

Polymorphic light eruption (PLE) is an acute photodermatosis affecting approximately 10% of the population, predominantly women. It is almost always itchy and comprises erythema (redness) and papules which appear within a few hours of sufficient sun exposure to trigger the eruption. It usually lasts a few days to a few weeks, when it resolves spontaneously without scarring, unless re-exposure occurs. It is a seasonal eruption in temperate climates between the months of March and September.

Actinic prurigo is a much less common photodermatosis, but is probably related to PLE. It is a more long-lasting, excoriated eruption that can leave scarring.

Aetiology of PLE and actinic prurigo

The aetiology of PLE and actinic prurigo are unknown, but there appears to be a genetic element. A high proportion of patients with systemic and cutaneous lupus present with symptoms of PLE, but transformation of PLE into lupus is uncommon. About 10% of patients with PLE will have mildly elevated antinuclear antibodies, nonetheless.

Typical symptoms of PLE and actinic prurigo, and less common symptoms

PLE typically presents as an acute itchy papular eruption confined to sun-exposed sites, some hours after sufficient exposure. It resolves within a few days, to weeks without sequelae.

Rarely, PLE can present as facial swelling and erythema (redness) or with blistering on sun-exposed sites. Such cases should be investigated thoroughly for systemic lupus.

Actinic prurigo may at first resemble PLE, but then patients develop more widespread itching and excoriation. The eruption may resemble eczema in its more chronic form. It resolves to leave small scars on exposed sites. It more frequently involves the face than PLE does.

Demographics of PLE and actinic prurigo

PLE is the most common of the photodermatoses and accounts for approximately 90% of all cases of photosensitivity (excluding sunburn). It is most common in temperate climates, but can affect all races, irrespective of skin type.

Actinic prurigo is very rare and usually requires a specialist to confirm the diagnosis as it can be difficult to distinguish from PLE in some cases. It can affect all races.

Natural history of PLE and actinic prurigo, and complications of the diseases

PLE and actinic prurigo typically present in young adulthood, but can be seen as early as at a few months of age or present for the first time in elderly patients. Both conditions appear to last several years and then remit, although more persistent forms do occur.

A very small percentage of patients presenting with PLE will go on to develop systemic or cutaneous forms of lupus, and lupus serology should be undertaken at first and then periodically thereafter, particularly if symptoms worsen or change.

Approach to diagnosing of PLE and actinic prurigo

The diagnosis of PLE is clinical, but lupus serology should be undertaken to exclude cutaneous forms of lupus, especially before phototherapy desensitization.

The diagnosis of actinic prurigo is more challenging and must be distinguished from PLE. HLA typing can be helpful in supporting a diagnosis of actinic prurigo, since HLA-DRB1 0407 is prevalent in this population, but rare in those with PLE and in the general population.

Other diagnoses that should be considered aside from PLE and actinic prurigo

Subacute lupus erythematosus, discoid lupus erythematosus, and SLE can all mimic PLE.

Occasionally, it is difficult to distinguish PLE from actinic prurigo.

'Gold-standard' diagnostic test for PLE and actinic prurigo

The gold standard for the diagnosis of PLE and actinic prurigo is clinical; it therefore relies on an experienced clinician.

Prognosis of PLE and actinic prurigo, and how to estimate it

Both PLE and actinic prurigo have a good prognosis if managed well. A tiny percentage (<1%) of patients with PLE will develop cutaneous or systemic lupus.

Actinic prurigo leaves scarring, but this is usually mild and will improve once the disease has remitted, which it usually does within a few years.

Treatment of PLE and actinic prurigo, and its effectiveness

Sun avoidance and sunblock remain mainstays of treatment for PLE and actinic prurigo. Desensitization with low-dose phototherapy in specialist units is advised when simple measures are insufficient. Occasionally, patients with PLE require immunosuppression with agents such as azathioprine or cyclosporin, to control symptoms.

Actinic prurigo is more challenging to treat. Simple measures are usually ineffective and desensitization rarely works sufficiently well as a monotherapy. Thalidomide is the treatment of choice, and is highly effective at doses of between 50 and 100 mg daily. Treatment holidays can occasionally be taken over the winter months. Monitoring for neuropathy by EMG is mandatory.

Sunburn, and sunburn-related disorders

Definition of sunburn

Sunburn is usually a consequence of overexposure of the skin to solar UV light. The sunburn spectrum is within the UVB wavelengths (290–320 nm) of terrestrial solar radiation. Sunburn presents as reddening of the skin at exposed sites.

Aetiology of sunburn and sunburn-related disorders

Sunburn is usually caused by overexposure of the skin to sunlight. The paler the skin type, the more readily sunburn occurs. Darkly pigmented races require much higher doses of sunlight in order to produce erythema (redness) or sunburn.

Easy sunburn, defined as erythema or redness out of proportion to the perceived exposure, is a cause for investigation. The most common cause of disproportionate sunburn is drug phototoxicity. Many drugs, including antibiotics, diuretics, painkillers, and antipsychotics, are phototoxic.

If easy sunburn occurs in a young child, although the most likely cause is straightforward overexposure of unprotected fair skin, a DNA-repair-deficient dermatosis should be considered, namely xeroderma pigmentosum (XP).

Typical symptoms of XP, and less common symptoms

Typical symptoms of XP in a very young, previously unexposed child are of disproportionate sunburn. Later signs include freckling, dryness of the skin, poikiloderma (pigmentation and atrophy), and, in subsequent years, the development of premalignant and malignant skin cancers, including melanoma.

Demographics of XP

XP is very rare but occurs in all races and all skin types.

Natural history of XP, and complications of the disease

XP is a repair-deficient genodermatosis which ultimately leads to the development of multiple skin cancers caused by a failure to repair UV-induced DNA damage. Some patients also develop neurological complications independent of sun exposure.

Approach to diagnosing XP

The most important approach is to consider the diagnosis of XP, since the signs at an early age, where intervention can quite literally

be life-saving, are very subtle. In cases of easy sunburn or freckling in a young child, if in doubt, refer for a specialist opinion.

Other diagnoses that should be considered aside from XP

Easy sunburn occurs in children because their skin has not had the opportunity to harden—this involves keratinization as well as constitutive tanning following sun exposure. Nonetheless, if a child appears to burn easily, XP is an important diagnosis to consider. Distinguishing easy sunburn in a fair-skinned child from potential XP is **very** difficult and requires specialist referral.

Drug phototoxicity should be considered in all cases of easy sunburn. Take a standard and over-the-counter history of drugs. Occasionally, foodstuffs can also cause phototoxicity—celery, for example, contains psoralen and has been documented as causing phototoxicity after a patient ate homemade celery soup!

'Gold-standard' diagnostic test for XP

The gold-standard test for XP is excision-repair testing in ex vivo fibroblasts and so requires a skin biopsy to be performed. This is an expensive and detailed test available in only a handful of centres in the UK.

Prognosis of XP, and how to estimate it

The prognosis for children with XP depends on the complement type that they have inherited (certain XP complements are more severe than others), and the vigilance of their carers and themselves in enforcing sun avoidance.

Most patients with XP, despite best care, will develop skin cancers early in life. Although survival rates have improved, the commonest cause of death is from metastatic skin cancer, sometimes in young adulthood.

Treatment of XP, and its effectiveness

Treatment for XP is complete sun avoidance. UV face shields and UV screening of windows is standard treatment. A recent product, a T4 endonuclease, applied to the skin daily, showed some promise in reducing skin cancer frequency in trials, but its use is not widespread.

258 Disorders of pigmentation

David J. Gawkrödger

Introduction

Skin colour is due to a mixture of the pigments melanin, oxyhaemoglobin (in blood), and carotene (in the stratum corneum and subcutaneous fat). Pigmentary diseases are common and particularly distressing to those with darker skin. Disorders of pigmentation often involve melanocytes. Vitiligo is the commonest disease of reduced pigmentation, and melasma is the commonest of hyperpigmentation.

Vitiligo

Definition of vitiligo

Vitiligo is an acquired idiopathic disorder showing white non-scaly macules.

Aetiology of vitiligo

In vitiligo, melanocytes are absent from affected skin on histology. An autoimmune aetiology is suggested by the association with thyroid disease and Addison's disease in some cases, and the presence of antibodies to melanocytes in the blood.

Typical symptoms of vitiligo, and less common symptoms

In vitiligo, sharply defined, white, often symmetrical macules are seen, often involving the hands, wrists, knees, neck, and areas around the mouth or eyes (see Figure 258.1). Occasionally, vitiligo is segmental (e.g. down an arm), generalized, or universal. In light-skinned individuals, vitiligo may only be discernible in summer, when the non-vitiliginous areas become tanned.

Demographics of vitiligo

Vitiligo affects 1% of the population. It is seen in all races but is most troublesome in those with a dark skin. The sex incidence is equal. The onset is usually between 10 and 30 years of age. About 20% of patients have a family history of vitiligo.

Figure 258.1 Extensive vitiligo of the hands. Please see colour plate section.

Natural history of vitiligo, and complications of the disease

Vitiligo may be precipitated by injury or sunburn. Areas may remain static, spread, or (infrequently) repigment. The condition is usually relentlessly progressive over several years.

Approach to diagnosing vitiligo

In the diagnosis of vitiligo, when taking the history, enquire about any precipitants, any personal history of other autoimmune disease, and any family history of vitiligo or autoimmune disease. Examine the entire skin surface, including with a Wood's light.

Other diagnoses that should be considered aside from vitiligo

Other diagnoses that should be considered aside from vitiligo include inflammatory skin disease, chemical leucoderma, leprosy, albinism, and phenylketonuria (see Table 258.1). Post-inflammatory hypopigmentation may occur with inflammatory skin disease. In chemical leucoderma, a history of exposure to phenolic chemicals should be sought. The hypopigmented macules of leprosy normally are anaesthetic. Albinism is a group of autosomal recessive conditions in which the melanocytes fail to synthesize pigment in the epidermis, hair bulb, and eye due to defects in the enzyme tyrosinase. It is uncommon (1 in 20 000) and usually presents in infancy with white or pink skin, white hair, and eyes that lack pigmentation. Phenylketonuria is an autosomal recessive defect of phenylalanine hydroxylase and is usually detected after birth by a routine screening test (incidence 1 in 10 000). Patients have fair hair and skin, due to impaired melanin synthesis. If phenylketonuria is left untreated, mental retardation and choreoathetosis develop.

'Gold-standard' diagnostic test for vitiligo

The gold-standard diagnostic test for vitiligo is Wood's light, a handheld UVB light source, which can show up areas of vitiligo not visible to the naked eye.

Table 258.1 Other causes of hypopigmentation

Cause	Disease or example
Chemical	Substituted phenols Hydroquinone
Genetic	Albinism Phenylketonuria Tuberous sclerosis Piebaldism
Infection	Leprosy Yaws Pityriasis versicolor
Post inflammatory	Cryotherapy Eczema Psoriasis Morphoea Pityriasis alba
Other	Lichen sclerosus Halo naevus Scarring

Acceptable diagnostic alternatives to the gold-standard test for vitiligo

There are no acceptable diagnostic alternatives to the gold-standard test for vitiligo. The diagnosis is usually clinical.

Other relevant investigations for vitiligo

In vitiligo, it is recommended to perform thyroid function tests.

Prognosis of vitiligo, and how to estimate it

The course of vitiligo is usually relentlessly progressive, with episodes of exacerbation alternating with times of inactivity.

Treatment and its effectiveness

The currently available treatment for vitiligo is unsatisfactory. Camouflage cosmetics are of limited use. Sunscreens help reduce tanning of non-vitiligo skin. Potent topical steroids (e.g. betamethasone valerate) or calcineurin inhibitors (e.g. tacrolimus or pimecrolimus) can induce repigmentation. UVB or photochemotherapy (psoralen and UVA) may induce repigmentation but it may take months. Rarely, depigmentation using hydroquinone derivatives is considered when vitiligo is very extensive.

Melasma

Definition of melasma

Melasma is a common patterned macular facial pigmentation especially occurring with pregnancy and in women on oral contraceptives.

Aetiology of melasma

In melasma, there is an increase in the amount of melanin in the skin from an increased melanin synthesis by melanocytes, often stimulated by hormonal factors.

Typical symptoms of melasma, and less common symptoms

In melasma, the pigmentation is symmetrical and often involves the forehead.

Demographics of melasma

Women are mostly but not exclusively affected by melasma.

Natural history of melasma, and complications of the disease

Melasma usually progresses during the twenties and thirties but may improve spontaneously.

Approach to diagnosing melasma

When diagnosing melasma, determine whether there are any underlying hormonal factors that might be treatable.

Other diagnoses that should be considered aside from melasma

Other diagnoses that should be considered aside from melasma are listed in Table 258.2; they include:

- freckles: small, light-brown macules, typically facial, which darken on sun exposure
- lentigines: brown macules that are scattered and do not darken in the sun; in Peutz–Jeghers syndrome, lentigines are found around the lips, buccal mucosa, and fingers and are associated with small bowel polyps
- Addison's disease: excess adrenocorticotrophic hormone stimulates melanogenesis; Addisonian-like pigmentation is also seen in Cushing's syndrome, hyperthyroidism, and acromegaly

Table 258.2 Other causes of hyperpigmentation

Cause	Disease or example
Drugs	Psoralens Oestrogens Phenothiazines Minocycline Amiodarone
Endocrine	Addison's disease Cushing's syndrome Graves' disease
Genetic	Racial Freckles Neurofibromatosis Peutz–Jeghers syndrome
Metabolic	Biliary cirrhosis Haemochromatosis Porphyria
Nutritional	Carotenaemia Malabsorption Malnutrition Pellagra
Post inflammatory	Eczema Lichen planus Systemic sclerosis Lichen amyloidosis
Other	Malignant melanoma Chronic renal failure Argyria

- drug-induced pigmentation: may be due to stimulation of melanogenesis or deposition of the drug in the skin, but often the mechanism is not well understood.

In addition, sometimes other pigments can colour the skin in a generalized manner, such as iron (with melanin), in haemochromatosis, and carotene (causing an orange discoloration), in carotenaemia (usually due to eating too many carrots).

'Gold-standard' diagnostic test for melasma

There is no gold-standard diagnostic test for melasma.

Other relevant investigations for melasma

Usually, there are no other relevant investigations for melasma, but consider a skin biopsy in atypical cases.

Prognosis of melasma, and how to estimate it

Melasma is usually a persistent condition. It darkens with sun exposure.

Treatment of melasma, and its effectiveness

In melasma, topical tretinoin, azelaic acid, or hydroquinone can reduce pigmentation. Sunscreens and camouflage cosmetics can also help.

259 Skin cancer

Rubeta Matin, Jane McGregor, and Catherine Harwood

Definition of the disease

Skin cancer is very common in the UK, and its incidence is rising rapidly. There are two broad classes of primary skin cancer: non-melanoma and melanoma. Non-melanoma skin cancer is the commonest form (100 000 cases diagnosed annually in the UK), accounting for nine out of ten skin cancers and includes basal cell carcinoma (BCC) and squamous cell carcinoma (SCC). Cutaneous melanoma is less common (10 000 cases diagnosed in the UK annually) but confers a significantly worse prognosis and accounts for 75% of skin cancer related deaths. There are also a number of other, rarer, non-melanoma skin cancers (e.g. appendageal carcinomas, Merkel cell carcinoma, sarcomas, vascular malignancies, and cutaneous lymphomas); however, these account for less than 1% of all skin cancers in the UK and so will not be specifically discussed here.

Cutaneous metastases can occur secondary to any internal cancer or, indeed, to skin cancer (e.g. melanoma). In most cases, cutaneous metastasis occurs after the diagnosis of a primary cancer and usually in late stages of the disease but, in some cases, it may be the first presentation, in which case it should prompt a thorough investigation for the primary malignancy.

Aetiology of the disease

Aetiology of non-melanoma skin cancer

Aetiology of BCC

BCCs are tumours of basal epidermal keratinocytes and occasionally arise from the outer root sheath of a hair follicle, specifically, from hair follicle stem cells residing just below the sebaceous gland duct in an area called the bulge. The most significant etiological factors are exposure to UV radiation, and genetic predisposition. Intense, intermittent sun exposure in childhood is particularly important, and the most commonly involved sites are the head and neck. Increasing age, male sex, fair skin type, a positive family history, immunosuppression, and arsenic exposure are other recognized risk factors. Multiple BCCs are a feature of a rare genodermatosis, basal cell naevus (Gorlin) syndrome. Following development of a BCC, patients are at significantly increased risk (approximately 40%–50%) of developing subsequent BCCs at other sites and are also at increased risk of SCC and melanoma.

Genetic studies have shown somatic mutations in the PTCH gene in 40%–70% sporadic BCCs. These are predominantly UV-signature mutations, supporting the role of UV radiation in the pathogenesis of these skin cancers.

Aetiology of SCC

SCC is a malignant tumour arising from epidermal keratinocytes. Its occurrence is usually related to chronic UV-radiation exposure and is therefore especially common in people with fair, sun-damaged skin, and in UV-sensitive genodermatoses such as oculocutaneous albinism and xeroderma pigmentosum. It may also develop as a result of previous exposure to ionizing radiation or to arsenic, or at sites of chronic inflammation (chronic wounds, scars, burns, ulcers, or sinus tracts). It may arise de novo or against a background of clinically apparent intra-epidermal keratinocyte dysplasia (full thickness intra-epidermal SCC or Bowen's disease; partial thickness intra-epidermal dysplasia or actinic keratosis).

Individuals with impaired immune function, for example those receiving immunosuppressive drugs following allogeneic organ transplantation or for autoimmune or inflammatory diseases, are at significantly increased risk of SCC. In organ transplant recipients, the

risk of SCC increases 65–250-fold and the risk of BCC 10 to 16-fold, compared to that in the non-transplanted population, with consequent reversal of the usual BCC:SCC ratio of 3–4:1. Age, duration of immunosuppression, skin phototype, and a history of high UV exposure are key risk factors in the pathogenesis of post-transplant non-melanoma skin cancer. However, complex genetic factors can determine individual risk. The risk of SCC with the new wave of 'biological' therapies (for inflammatory and haematological disease) has yet to be quantified. Patients with HIV/AIDS or non-Hodgkin lymphoma, specifically chronic lymphocytic leukaemia, may also develop aggressive SCC. Increased cutaneous HPV infection in these immunosuppressed groups, together with the occurrence of SCC in up to 60% patients with the rare genodermatosis epidermodysplasia verruciformis (which is associated with widespread cutaneous HPV infection) indicates a possible association between HPV and SCC.

Aetiology of Kaposi's sarcoma

Kaposi's sarcoma (KS) is a vascular malignancy of spindle-cell origin, thought to be derived from the endothelial cell lineage, which is characterized by mucocutaneous violaceous lesions and oedema. Any organ can be affected. It is caused by human herpesvirus-8. Immunosuppression appears to be a significant cofactor (e.g. in HIV/AIDS (see Chapter 296) and post-organ transplantation). The four main types of KS are detailed in Table 259.1.

Aetiology of cutaneous melanoma

Melanoma arises in genetically susceptible individuals exposed to environmental agents, principally UV radiation. Risk factors for melanoma are detailed in Table 259.2. Major risk factors for melanoma are a past history of melanoma (especially if under the age of 40), a history of eight moles >6 mm diameter, atypical mole syndrome (particularly with a family history of melanoma), large congenital melanocytic naevi (>15 cm in diameter), and the nucleotide excision repair genodermatosis, xeroderma pigmentosum. Mutations in several high-penetrance genes have been identified as influencing melanoma risk: in particular, CDKN2A (chromosomal location: 9p21), which encodes a p16 tumour suppressor protein, and CDK4 (chromosomal location: 12q13). Polymorphisms in low-penetrance genes have also been identified, including the melanoma susceptibility gene, MC1R (chromosome location: 16q24.7).

Typical symptoms of the disease, and less common symptoms

Symptoms of non-melanoma skin cancer

Symptoms of BCC

BCCs usually arise on chronically and intermittently sun-exposed skin of individuals over age 40, but can occur in younger people. Clinicopathological subtypes include nodular, superficial, infiltrating, and morpheic. Nodular BCC accounts for 60%–70% of cases. It is most common on the head and neck and presents as a pearly or translucent papule or plaque with rolled edges and overlying telangiectasia. It may ulcerate centrally and there may be a history of recurrent bleeding or crusting. Some lesions have cystic centres. In darker skin types, BCCs may be pigmented and simulate melanoma.

Superficial BCC accounts for 15% of all BCCs and commonly affect the trunk of younger patients. They present as scaly papules or plaques with a pink to red-brown colour and often have a characteristic thread-like, pearly border. They are often misdiagnosed as patches of eczema, psoriasis, or tinea.

Table 259.1 Typical appearance of common primary skin cancers

BCC	SCC	KS	MM
<p>Nodular: skin-coloured nodule with prominent overlying telangiectasia</p> <p>Soft in consistency</p> <p>Easily damaged by trauma Superficial BCC are scaly erythematous patches/papules with a thin pearly border; they can be mistaken for patches of eczema, psoriasis, or tinea</p> <p>Infiltrative/morphoeic subtypes may present with a scar-like appearance</p>	<p>Indurated, crusted, nodular, or ulcerated lesion arising on sun-damaged skin</p> <p>On lip or genitalia, presents as fissure or non-healing ulcer</p>	<p>Classic KS: affects those of Jewish Ashkenazi/Mediterranean descent</p> <p>African endemic KS: adult male predominance, 1.3%–10% of black Africans affected; lymphadenopathic variant seen</p> <p>KS in immunosuppression: observed in all iatrogenically immunosuppressed individuals, including post-transplantation individuals</p> <p>AIDS-related epidemic KS: high incidence in certain regions of Africa and the Caribbean</p>	<p>Changing or new mole (defined by ABCDE criteria*)</p>

Abbreviations: BCC, basal cell carcinoma; KS, Kaposi's sarcoma; MM, malignant melanoma; SCC, squamous cell carcinoma.

*ABCDE criteria are used to identify early melanomas: **A**symmetry, **B**order irregularity, **C**olour variation, **D**iameter > 6 mm, **E**levation.

Infiltrative/morphoeic subtypes are perhaps the most difficult to diagnose clinically as they may present with a scar-like appearance. Because of their histological characteristics, with cords of tumour cells infiltrating beyond the apparent clinical margins of the BCC, they are the type most likely to recur after surgery.

Symptoms of SCC

SCC commonly arises on chronically sun-exposed skin of elderly Caucasians over the age of 60. The usual sites for SCC are the dorsa of the hands; the forearms; the upper face; the lower lip; and the ears. SCCs most commonly present as indurated, keratotic nodules or plaques, which may ulcerate and are often tender on palpation. They may also present as a fissure or a non-healing indurated ulcer on the lip or genitalia. Regional lymph nodes may be enlarged due to infection/inflammation of the tumour (dermatopathic lymphadenopathy) or as a result of metastases (with harder, irregular, matted nodes).

Symptoms of KS

KS usually begins as macules, which evolve into papules, plaques, nodules, and tumours which may range in colour from violaceous, pink, red, or tan and become purplish-brown. Lesions are usually palpable and firm to hard in consistency. Lesions may originate at a site of trauma and ulcerate or form an overlying crust. Skin lesions may be associated with deeper involvement of the lymphatic system or lymph nodes, resulting in lymphoedema, which common affects the lower limbs. Skin changes secondary to lymphoedema, including

papillomatosis and hyperkeratosis, may then complicate the clinical picture. Mucocutaneous lesions are usually asymptomatic.

Symptoms of cutaneous melanoma

All lesions suspected of being a melanoma should be urgently referred to a clinician trained in their diagnosis and management, usually a dermatologist. There are a number of presenting signs and symptoms for which urgent referral to the local skin cancer multidisciplinary team is indicated:

- a new mole which appears after the onset of puberty and which is changing in shape, colour, or size
- a long-standing mole which is changing in shape, colour, or size
- any mole which has three or more colours or has lost its symmetry
- a mole which is itching or bleeding
- any new persistent skin lesion, especially if growing, pigmented, or vascular in appearance, and if the diagnosis is not clear
- a new pigmented line in a nail, especially where there is associated damage to the nail
- a suspicious lesion growing under a nail

Symptoms of cutaneous metastases

Most skin metastasis occurs in a body region near the primary tumour. The first sign of skin metastasis can be a firm, round or oval, mobile, non-painful nodule. The nodules are rubbery, firm, or hard in texture and can vary in size. These may be skin-coloured,

Table 259.2 Risk factors for the common skin cancers

Risk factor	RR for developing BCC*	RR for developing SCC*	RR for developing melanoma*
UV exposure: history of blistering sunburn	+	1.9	2.5
Fitzpatrick skin type I (burns without tanning) [†]	+	2	1.7
Keratotic lesions >50	4	12.1	
Multiple benign naevi	NA	NA	11
Multiple atypical naevi	NA	NA	11
Strong family history of melanoma [‡]	NA	NA	35–70
Previous history of melanoma	NA	NA	8.5
Previous history of non-melanoma skin cancer (BCC and/or SCC)	10	10	2.9
Immunosuppression:			
• HIV		+	1.5
• Transplant recipients	10-fold	50–100-fold	2–17
Ionizing radiation	3.6	2.94	?+
Tanning beds	1.5	2.5	2.86–4.44
Arsenic exposure	+	+	
Tobacco smoking		+	
Photosensitizing drugs, e.g. fluoroquinolones, voriconazole	+	+	

Abbreviations: BCC, basal cell carcinoma; RR, relative risk; SCC, squamous cell carcinoma.

*Where quantifiable relative risk is not available, + confirms evidence of increased relative risk.

[†]Fitzpatrick skin types: I: always burns/never tans; II: usually burns/sometimes tans; III: usually tans/sometimes burns; IV: always tans/rarely burns; V: Asian; VI: Black African and Afro-Caribbean.

[‡]Defined as ≥3 family members affected.

Table 259.3 Commonest primary tumours giving rise to skin metastases

Primary tumour	Demographics	Common sites affected	Features
Breast	Commonest primary cancer in females of all ages	Trunk/scalp	Firm, scar-like area May appear as inflammatory plaques with well-demarcated elevated margin
Colon/stomach	Males > females	Abdomen/pelvis	Nodule at umbilicus (Sister Mary Joseph nodule) is a sign of extensive colorectal carcinoma
Melanoma	Males (<40 years) > Females (>40 years)	Trunk and extremities (males) Lower limbs (females)	Pigmented papules and dermal nodules
Lung	Commonest primary cancer in males (>40 years)	Trunk	Firm, erythematous nodules which tend to follow intercostal vessels when on the chest
Squamous cell carcinoma oral cavity/larynx	Males > 40 years	Head and neck	

red, or, in the case of melanoma, blue or black. Sometimes, multiple nodules appear rapidly. The skin metastases may break down and ulcerate through the skin. Depending on the location of the primary tumour, skin metastases display certain characteristic features (see Table 259.3). More unusual patterns of cutaneous involvement by metastases include:

- carcinoma erysipeloides: sharply demarcated red patches that occur when the local spread of a primary cancer blocks lymphatic blood vessels in the adjacent skin
- en cuirasse or sclerodermoid carcinoma: indurated, fibrous, scar-like plaques due to cancer cells infiltrating collagen in the skin
- carcinoma telangiectoides: red patches with telangiectasia or lymphatic vessels (lymphangioma-like)

Demographics of the disease

Demographics of non-melanoma skin cancer

In 2007 more than 84 000 cases of non-melanoma skin cancer were registered, but it is estimated that the actual number of new cases each year is at least 100 000, a figure which is steadily increasing. By 2030, the number of cases presenting to dermatologists could increase by an estimated 50%. The incidence of non-melanoma skin cancer increases with age, and 80% of cases occur in people over the age of 60 years. In addition, the incidence is higher in men than in women.

Demographics of BCC

BCC is the most common cancer in Europe, Australia, and the US and is showing a worldwide increase in incidence. Poor BCC data collection by many tumour registries means that accurate figures for the incidence of BCC in the UK are difficult to obtain.

Demographics of SCC

SCC is the second most common skin cancer and, in many countries, its incidence is rising. It accounts for the majority of non-melanoma skin cancer-related deaths. The BCC:SCC ratio is approximately 3–4:1 in most countries, but is often reversed in immunosuppressed populations.

Demographics of KS

Classic KS was first described as a slow-growing endothelial cell tumour in elderly men of Mediterranean or Eastern European descent; subsequently, a slightly more aggressive form of the disease (so-called endemic KS) was recognized at higher rates in African populations. With the onset of the AIDS epidemic, the worldwide incidence of this cancer has increased dramatically in the past 25 years, and a much more aggressive form of KS is now the commonest tumour amongst HIV-infected people in Africa (>10/100 000 males). KS became common amongst a subset of HIV patients in the West, but the incidence is now falling with the introduction of effective anti-HIV drug therapy. An increased incidence of KS is also observed in organ transplant recipients and other iatrogenically immunosuppressed individuals.

Demographics of cutaneous melanoma

The incidence of cutaneous melanoma is rising faster than for any other major cancer, and rates are set to treble over the next 30 years.

More than 10 400 cases of melanoma are diagnosed annually in the UK, with over 2000 deaths attributable to melanoma. In 2006, melanoma was more common in females than males, with a male:female ratio of 4:5. Although the incidence of melanoma rises with age, a disproportionately high incidence of melanoma is observed amongst young people; almost a third of cases (31%) occur in people aged <50 years and it is the commonest cancer amongst 15–34 year olds. For females, it is the sixth most common cancer and, for males, it is the eighth. The current lifetime risk for males in the UK is about 1:91; for females, it is 1:77.

Demographics of cutaneous metastases

The incidence of skin metastases is 3%–10% for all primary cancers. Although most cancers can metastasize to the skin, some cancers are more likely than others and this is also dependent on gender and age of the individual (see Table 259.3).

Natural history and complications of the disease

Natural history of non-melanoma skin cancer, and complications of the disease

Although non-melanoma skin cancer is very common, in the vast majority of cases it is not life-threatening.

Natural history of BCC, and complications of the disease

BCC is a slow-growing, locally invasive, malignant epidermal skin tumour predominantly affecting Caucasians. Metastasis is extremely rare, and morbidity results from local tissue invasion and destruction particularly to the face, head, and neck (giving rise to the lay term of 'rodent ulcer').

Natural history of SCC, and complications of the disease

SCCs are also locally invasive but, unlike BCCs, have the potential to metastasize to lymph nodes and other organs. Patients with impaired immune function are at higher risk of metastasis. Spread by bloodstream is uncommon. The risk of metastasis is also associated with the size of the tumour (>2 cm), the depth of invasion (>6 mm confers a 16% risk of metastasis), differentiation state (poor differentiated tumours fare worse), the rate of growth, and the anatomical location: tumours on the ear and lip have a worse prognosis than tumours elsewhere. Mucosal SCCs have a greater tendency to recur and metastasize than SCCs located on the glabrous sun-exposed skin. Tumours arising in actinic keratoses on the dorsa of hands are indolent and late in metastasizing. Lesions in sun-exposed areas have a better prognosis than those arising from non-sun-exposed areas. There is an increased risk of a second primary SCC within 5 years after therapy for the first malignancy; this risk is approximately 30% for the general population, but up to 75% in immunosuppressed individuals.

Natural history of KS, and complications of the disease

Although the skin is the most frequent organ of involvement, internal lesions of KS are commonly seen (e.g. affecting the lungs, abdominal viscera, or lymph nodes). Overall mean survival is 10–15 years.

Classic or European KS is typically slowly progressive. African endemic KS has been described in two age groups: young adults (mean age 35) with generally benign cutaneous nodular disease, and young children (mean age 3) with fulminant lymphadenopathic disease, which is fatal within 3 years.

Natural history of cutaneous melanoma, and complications of the disease

Cutaneous melanoma arises from epidermal melanocytes. It is one of the most aggressive skin cancers, occurring in all ages but predominantly affecting adults. Prognosis is closely related to the depth of the tumour (Breslow thickness), as well as tumour ulceration, mitotic rate, and nodal status (see Table 259.4). It accounts for 75% of all skin cancer-related deaths. It is assumed that most melanomas increase in size with time and that early recognition and excision provides the greatest opportunity for cure. Moreover, melanoma is notoriously chemoresistant and often proves to be radiotherapy resistant. Over the last 30 years, there have been no new therapeutic approaches that have improved overall survival rates in metastatic disease but there are recent indications that new targeted and immunotherapy-based therapeutic interventions (e.g. BRAF-targeted therapy and PDL-1 inhibition) may improve this dismal situation.

Approach to diagnosing the disease

Take a thorough history

The following features must be established and can help with diagnosis:

- duration of the lesion: BCCs are usually slow-growing; SCCs often have a more rapid growth pattern
- change in size: a pigmented lesion which is growing or changing in shape or colour is likely to be evolving and could be an early sign of malignant change
- change in colour
- change in shape
- symptoms: itchiness or bleeding in long-standing melanocytic naevi may be suggestive of malignant change, particularly if associated with changes in size, colour, or shape

Assess risk factors

Skin phototype and a UV-exposure history should be established. Individuals deemed to have had high UV exposure would be those with an outdoor occupation for >5 years, those who have lived in a sunny climate for >6 months, or 'sun worshippers' who have actively sought a suntan for >2 weeks per year for >10 years and/or have ever used sunbeds. Conversely, a low-UV-exposure category would include individuals with indoor occupations, those who have

not lived in sunny climates, and those who avoid the sun or do not actively sunbathe. Intermediate UV exposure falls between these two categories.

Patients with a history of long-standing ulcers or wounds (e.g. burns), previous radiotherapy, UV therapy (e.g. psoralen and UVA therapy, for psoriasis), chronic immunosuppressive therapy, or arsenic ingestion are also more likely to develop skin cancers.

Physical examination

Examination of the individual lesion should be undertaken, detailing the following:

- site: this can influence treatment options and prognosis
- size (maximum diameter): this is important to determine further treatment based on surgical margins
- colour (flesh-coloured, erythematous, pigmented); variability of colour should also be noted
- elevation (palpable, nodular)
- margins/border (regular, irregular)
- surface (smooth, scaling, roughened, crusted, ulcerated, bleeding)

When skin cancer is suspected, regional lymph nodes should also be examined to determine any nodal spread. A complete examination of the entire skin should also be undertaken to identify any other pre-malignant or malignant lesions.

Other diagnoses that should be considered

Common differential diagnoses for skin cancers according to type are detailed in Table 259.5.

'Gold-standard' diagnostic test

'Gold-standard' diagnostic test for BCC and SCC

The gold-standard diagnostic test for all skin cancers is histological assessment. There are now well-defined criteria for reporting of histological features to confirm the diagnosis and to determine the prognosis. For smaller tumours, primary excision may be both diagnostic and therapeutic. For larger lesions and for those in cosmetically sensitive sites, an initial diagnostic biopsy (incision or punch biopsy) may be required to confirm the diagnosis and histological subtype (e.g. superficial vs infiltrative BCC; well-differentiated vs poorly differentiated SCC) before planning definitive treatment.

'Gold-standard' diagnostic test for KS

The diagnosis of KS is usually confirmed on skin biopsy.

Stage	Characteristics	5 year survival
1a	Melanoma cells confined to the epidermis	95% +
1b	<1 mm thick Not ulcerated No spread elsewhere	
2a	1–2 mm and ulcerated, or 2–4 mm and not ulcerated No spread elsewhere	Men 80% Women 90%
2b	2–4 mm + ulcerated or >4 mm and no ulceration	Prognosis worsens with higher-grade tumour (i.e. worse for 2c than for 2a)
2c	> 4 mm and ulcerated, confined to skin, and no spread	
3a	Spread into up to three lymph nodes near the primary, only detectable microscopically Melanoma not ulcerated	Men 50% Women more than 50%
3b	Ulcerated melanoma + 1–3 microscopic lymph node spread or non-ulcerated melanoma + 1–3 lymph nodes, which are enlarged, or non-ulcerated melanoma + local skin spread but no lymph node involvement	Prognosis worsens with higher-grade tumour (i.e. worse for 3c than for 3a)
3c	Melanoma in lymph nodes + local skin or spread to 1–3 lymph nodes which are enlarged or spread to 4+ nearby lymph nodes or spread to lymph nodes which have joined together	
4	Spread away from origin and local lymph nodes	Men 10% Women 25%

Table 259.5 Common differential diagnoses for skin cancers according to type

Non-melanoma skin cancer	Cutaneous melanoma
<p>Actinic keratoses:</p> <ul style="list-style-type: none"> rough, scaly erythematous papules on chronically sun-exposed skin if hyperkeratotic, may simulate an early SCC <p>Bowen's disease (intra-epidermal squamous cell carcinoma):</p> <ul style="list-style-type: none"> fixed, erythematous, scaly plaque which gradually expands usually on sun-exposed skin but characteristically on the lower legs may be difficult to differentiate from a superficial BCC, although BCCs often has a thread-like rolled edge <p>Benign intradermal naevus:</p> <ul style="list-style-type: none"> usually very long history of a stable lesion may simulate nodular BCC <p>Keratoacanthoma:</p> <ul style="list-style-type: none"> usually very rapidly growing nodule on sun-exposed skin with symmetrical configuration, 'shouldered' erythematous/translucent margins, and a central keratotic plug SCCs tend to be more irregular in shape and slower growing and do not regress spontaneously 	<p>Melanocytic naevi:</p> <ul style="list-style-type: none"> benign or dysplastic any naevus in which there is a history of change or which is clinically suspicious should be excised for histological examination <p>Seborrhoeic keratosis (basal cell papillomas):</p> <ul style="list-style-type: none"> can mimic many of the features suggestive of melanoma but have a 'stuck-on appearance', and patients often have multiple similar lesions on the body dermoscopy can be a useful adjunct to diagnosis <p>Dermatofibroma:</p> <ul style="list-style-type: none"> usually a firm nodule which may be pigmented often on limbs a history of insect bite may be given <p>Vascular lesions:</p> <ul style="list-style-type: none"> may simulate melanoma, e.g. angiokeratomas (dark red/black scaly papules), pyogenic granuloma (rapidly growing, bright red/purple ulcerated, rounded nodule, surrounding skin is normal)

Abbreviations: BCC, basal cell carcinoma; SCC, squamous cell carcinoma.

'Gold-standard' diagnostic test for cutaneous melanoma

A lesion suspected to be a melanoma should be photographed and then excised completely by a trained specialist. The axis of excision should be orientated to facilitate possible subsequent wide local excision. The excision biopsy should include the whole tumour, with a clinical margin of 2 mm around normal skin, and a cuff of fat. This allows for examination of the entire lesion, such that subsequent definitive treatment can be based on Breslow thickness. With few exceptions, diagnostic shave biopsies or partial removal of lesions must be avoided, as these can lead to incorrect diagnosis due to sampling error.

Acceptable diagnostic alternatives to the gold-standard tests

Although complete excision is the gold standard for diagnosis of melanoma, in a few circumstances, incisional biopsies may be acceptable (e.g. for large lesions on cosmetically sensitive sites). It should be emphasized that, while this approach may assist in confirming whether a lesion is indeed a melanoma, it cannot provide an accurate Breslow thickness, which is required for planning definitive surgical excision, and, occasionally, false negatives may arise from sampling error.

Other relevant investigations

Dermoscopy

Experienced specialists can make a clinical diagnosis of BCC in many cases. Diagnostic accuracy is enhanced by good lighting and magnification, and the dermatoscope can be helpful in some cases. The dermatoscope allows a closer examination of the surface of pigmented lesions with 10× magnification, and a glass plate/oil interface or polarized light to minimize reflection from the surface. A dermatoscopic score takes into account features such as asymmetry, number of colours, pigment structure, and irregular border; this scoring can be correlated with risk of malignancy. Dermoscopy is a specialized tool, usually most successfully used by trained and experienced dermatologists.

Radiological imaging

Imaging is not routinely indicated to aid diagnosis of non-melanoma skin cancers or cutaneous melanoma. However, it may be required to establish involvement of underlying structures (e.g. bony involvement), prior to planning definitive treatment. For melanoma, no routine imaging is recommended unless the disease is Stage IIC/III or above; in these circumstances, staging should be determined using

whole-body CT or CT-PET scans. Ultrasound or CT scanning is indicated for patients with a diagnosis of KS, to exclude visceral or lymphatic involvement.

Investigation of suspicious lymph nodes

Sentinel lymph node biopsy

Sentinel lymph node biopsy (SLNB) was developed as a means to identify the first lymph node draining the skin in which a melanoma arises. This investigation is usually performed at the same time as definitive wider excision of a primary melanoma. It is usually considered as a staging procedure for melanomas for which the Breslow thickness is between 1 mm and 4 mm, as sentinel node positivity is associated with a worse prognosis in such melanomas. As yet, there is no therapeutic value associated with the procedure. Patients with a positive SLNB usually proceed to complete lymphadenectomy. The procedure is associated with 5% morbidity and, in 5% of cases, it is not possible to identify the sentinel lymph node.

As an alternative to SLNB, ultrasound surveillance of lymph node basins can be used but it is only available in specialist centres. Nodes clinically suspicious for metastatic disease should be sampled using fine-needle aspiration cytology or ultrasound-guided biopsy. Prior to lymph node dissection, staging CT scan should be performed.

Prognosis, and how to estimate it

Prognosis of non-melanoma skin cancer

There are a number of well-defined prognostic factors, which affect the outcome of non-melanoma skin cancers (see Table 259.6).

Prognosis of BCC

The histological subtype of BCC may influence the prognosis: morphoeic/infiltrative, micronodular, and basosquamous variants are associated with aggressive tissue invasion and destruction. Perivascular or perineural invasion are features associated with increased aggression and recurrence. Metastasis is extremely rare (1:50 000), but may occur in the setting of tumours exceeding 5 cm in diameter.

Prognosis of SCC

Most patients with primary cutaneous SCC have a very good prognosis. Conversely, metastatic disease has a poor long-term prognosis; patients with regional lymphadenopathy have a <20% 10-year survival rate, and patients with distant metastases have <10% 10-year survival rate. Factors predicting metastatic potential include anatomical site, size, tumour thickness, level of invasion, rate of growth, aetiology, degree of histological differentiation, and host immunosuppression.

Table 259.6 Factors influencing prognosis of non-melanoma skin cancer

Feature	Effect on prognosis of BCC	Effect on prognosis of SCC
Tumour site	Lesions on central face, especially around eyes, nose, lips, and ears are at higher risk of recurrence	SCC arising in areas of radiation or thermal injury, chronic ulcers or pre-malignant lesions > in non-sun-exposed sites > ear > lip (increasing metastatic potential)
Tumour size	Increasing size confers higher risk of recurrence	Tumours >2 cm are twice more likely to recur locally and 3× more likely to metastasize
Tumour depth	–	Tumours <2 mm virtually never metastasize Tumours >6 mm in depth or extending into or beyond the subcutis are more likely to recur and metastasize (risk 16%)
Defined clinical margins	Poorly defined lesions are at higher risk of recurrence	
Histological subtype	Morphoeic, micronodular, infiltrative, and basosquamous histological subtypes confer higher risk of recurrence	Poorly differentiated tumours have a worse prognosis, with >2× local recurrence rates and 3× metastatic rate compared with well-differentiated tumours Certain subtypes (e.g. desmoplastic SCC) have a 24% risk of local recurrence vs 1% for non-desmoplastic SCC
Perivascular or perineural invasion	Confers higher risk of recurrence	More likely to recur and to metastasize (rates up to 50%)
Failure of previous treatments	Recurrent lesions have increased risk of further recurrence Local recurrence is lower with Mohs micrographic surgery	Locally recurrent disease is a risk factor for metastatic disease
Host immunosuppression	Tenfold increased incidence risk	Worse prognosis, increased risk approximately 100-fold, increased risk of metastasis 5%–7%

Abbreviations: BCC, basal cell carcinoma; SCC, squamous cell carcinoma.

Prognosis of cutaneous melanoma

The prognosis of melanoma is dependent on several factors:

- Breslow thickness (the deepest contiguous point of the tumour in millimetres)
- mitotic count (the number of mitoses per square millimetre)
- ulceration status (ulcerated tumours have a worse prognosis)
- nodal involvement (the prognosis of tumours is dependent on the presence and number of involved nodes)
- LDH level
- host immunosuppression
- site of melanoma (limb melanomas have a better prognosis than truncal melanomas do)
- age (younger patients have a better prognosis than older patients)
- gender (males fare worse than females)

Factors (a)–(e) have a significant effect when determining prognosis and are included in the seventh edition of the American Joint Committee on Cancer (AJCC) classification for prognostic staging of melanoma (summarized in Table 259.4). More recently, a website has been set up that provides a tool for predicting the clinical outcome of an individual patient with localized or regional cutaneous melanoma (<http://www.melanomaprognosis.net>). The prediction tools can be used to predict the 1-, 2-, 5-, and 10-year survival rates from initial diagnosis (with a 95% confidence interval) for an individual patient, based on his/her relevant clinical and pathological information. The predictive models were developed and validated using a combined database (n = 28 047) from 11 major institutions and study groups participating in the development of the AJCC Melanoma Staging System.

Treatment and its effectiveness

Treatment of non-melanoma skin cancer

Although surgical excision remains the gold standard for the treatment of non-melanoma skin cancer, there are a range of other surgical and non-surgical management options for selected non-melanoma skin cancers (see Table 259.7). The choice offered to the patient will depend on the anatomical location of the cancer, its size,

its clinical appearance, the histological diagnosis, and the availability of the options.

Treatment of BCC

The range of possible treatments for BCC is listed in Table 259.7.

Treatment of SCC

Prevention of SCC

Individuals at risk of SCC should be given advice regarding photo-protection (e.g. use of protective clothing and effective sunscreens), as this may reduce the incidence of both actinic keratoses and SCC. Although there is good evidence linking SCCs with chronic actinic damage, there is no definite evidence that the treatment of actinic keratosis prevents the development of SCC.

These measures are particularly important for immunosuppressed individuals and those individuals who have rare genodermatoses and so are at increased risk of developing SCC. Education on self-skin surveillance for early detection and treatment should be part of routine care. Topical agents such as imiquimod may have a useful role in preventing the development of skin dysplasia in high-risk renal transplant recipients but substantive evidence is awaited.

Management of SCC

Management of SCC entails surgical excision with a margin of normal skin removed from around the tumour. For clinically well-defined, low-risk tumours (<2 cm in diameter), surgical excision with a minimum 4 mm margin around the tumour border is advised. Narrower margins of excision are more likely to leave residual tumour. In order to maintain the same degree of confidence of adequate excision, high-risk tumours (e.g. tumours >2 cm in diameter; tumours classified as moderately differentiated, poorly differentiated, or undifferentiated; tumours extending into the subcutaneous tissue; tumours on the ear, lip, scalp, eyelids, or nose) should be removed with a wider margin (≥6 mm), and the tissue margins examined histologically or with Mohs micrographic surgery. In cases where the margins of the tumour are ill-defined (e.g. in poorly differentiated SCCs), tumour extent may not be accurately predicted. After excision of high-risk SCCs, patients should be kept under regular review for at least 2 years, with particular attention to the possibility of recurrence at

Table 259.7 Summary of treatments of skin cancers

Treatment	BCC	SCC	KS	Melanoma	Cutaneous metastases
Surgical excision	Nodular ++ Morphoeic ++ Superficial +	Well++ Moderate ++ Poor ++	+	Primary cutaneous, recurrent, and metastatic disease	+
Curettage/shave excision	Superficial subtype ++	Well differentiated +	–	–	–
Cryotherapy /cryosurgery	Superficial+	In situ (Bowen's disease)+	+	–	+
Mohs micrographic surgery*	Morphoeic, cosmetically sensitive sites, recurrent BCC ++	High-risk SCCs (SCC of lip/ear, recurrent SCC, SCC arising in non-sun-exposed sites or in chronic ulcers/inflammation)	–	Lentigo maligna	–
Radiotherapy	Primary treatment for BCCs not amenable to surgery or as an adjunctive therapy, e.g. after incomplete surgical excision	Adjunctive for tumours with perineural invasion or where surgical excision is inadequate/impossible	+	Metastatic disease	+
Topical 5-fluorouracil	Superficial	Actinic keratosis, Bowen's disease	–	–	–
Topical imiquimod	Superficial	Actinic keratosis	–	Small lentigo maligna (in the context of a clinical trial)	+
Photodynamic therapy	Superficial BCCs and some nodular subtypes	Actinic keratosis and Bowen's disease	–	–	+

Abbreviations: BCC, basal cell carcinoma; KS, Kaposi's sarcoma; SCC, squamous cell carcinoma.

*Mohs micrographic surgery is a surgical technique used to treat skin cancers which allows precise microscopic margin control by using horizontal frozen sections. The advantages are superior cure rates, maximal tissue conservation, ability to trace perineural or infiltrating tumours histologically, and negligible risk of anaesthetic complications because of the almost exclusive use of local anaesthesia.

the original site and in the draining lymph nodes. Lower-risk tumours may not require such prolonged follow-up, but all patients should be educated about the risk of further SCCs and the importance of self-skin surveillance and photoprotection.

In immunologically or genetically predisposed individuals (e.g. organ transplant recipients and patients with xeroderma pigmentosa) who have multiple SCCs, making surgical management difficult, systemic retinoids (acitretin) or nicotinamide may reduce the rate of development of new lesions. Where appropriate, reduction of immunosuppression or switching to mTOR inhibitor-based immunosuppression may also reduce SCC risk.

Treatment of KS

The aim of treatment of KS is to control the symptoms of the disease, as it is not 'curable'. Various modalities have been used and are detailed in Table 259.7. In addition, intra-lesional and systemic chemotherapies are also used (e.g. bleomycin, vinblastine, doxorubicin, etoposide). In the setting of iatrogenic KS, reduction of immunosuppression and switching from calcineurin inhibitors to mTOR-based immunosuppression (e.g. rapamycin) are additional therapeutic strategies.

Treatment of cutaneous melanoma

Prevention of cutaneous melanoma

The role of photoprotection in melanoma prevention was recently confirmed in a randomized controlled trial in Australia. This demonstrated that, amongst adults aged 25–75, regular application of SPF15+ sunscreen in a 5-year period appeared to reduce the incidence of a new primary melanoma (as well as of SCC) for up to 10 years.

Management of cutaneous melanoma

Management of primary cutaneous melanoma

Surgery is the only curative treatment for primary melanoma. Following excision for diagnosis and for measurement of microscopic Breslow thickness, a wider and deeper margin is taken to ensure complete removal of the primary lesion, and to remove any micro-metastases. Lateral surgical excision margins for invasive melanoma depend on Breslow thickness and are based on five randomized clinical trials including about 3300 patients, and a National Institutes of Health Consensus Panel (see Table 259.8).

Table 259.8 Recommended lateral surgical excision margins for cutaneous melanoma

Tumour thickness	Surgical excision margins (cm)
In situ	0.5
<1.00 mm	1.0
1.01–2.00 mm	1.0–2.0
2.01–4.00 mm	2.0–3.0
>4.00 mm	2.0–3.0

Management of lymph node basins in melanoma patients should be carried out by specialist skin cancer multidisciplinary teams so that surgical treatment planning and investigations can be run in parallel. Clinically node-negative patients can be investigated using ultrasound or SLNB in specialist centres in the UK. Patients should have access to a skin cancer nurse specialist. There is no evidence of a survival benefit for adjuvant chemotherapy in patients with melanoma.

Management of secondary cutaneous melanoma

Surgery is the treatment of choice for single local or regional metastases. Excision should be clinically and histologically clear but a wide margin is not required. The treatment of locoregional recurrence in a limb is palliative. Multiple small dermal lesions may be treated surgically; CO₂ laser and electrochemotherapy with bleomycin may also be useful palliative strategies. Regional chemotherapy with isolated limb infusion (melphalan and dactinomycin D) should be considered for dermal disease which is progressing despite surgery or laser, and for subcutaneous/deeper limb metastases. Isolated limb perfusion may be suitable for larger volume disease. Surgery should be considered for oligometastatic disease at sites such as the skin, the brain, or the bowel or to prevent ulceration. Radiotherapy may have a palliative role in the treatment of metastases.

Patients with Stage IV melanoma should be considered for entry into clinical trials. Due to a better understanding of melanoma cell signalling and immunological response first line agents include immunotherapies either as monotherapy (PD1 inhibitors) or in combination with anti-CTLA4 antibodies. Targeted therapies are second line agents also as monotherapy (BRAF inhibitors) or in combination with MEK inhibitors. Over the next decade, it is likely that further developments will change the face of managing locoregional and metastatic disease.

Treatment of cutaneous metastases

In the case of cutaneous metastases, the underlying primary tumour should be treated but, in most cases when skin metastases have developed, the cancer is usually widespread and only palliative care is appropriate. Treatment options include debridement or palliation by debulking or removing symptomatic/ulcerative lesions and radiotherapy (see Table 259.7).

260 Skin markers of internal medicine

Charles M. G. Archer and Clive B. Archer

Introduction

Some of the most interesting aspects of dermatology are seen when internal medicine and dermatology overlap. Skin lesions may be part of a systemic disease, as occurs in sarcoidosis or SLE, or may be a manifestation or 'marker' of an underlying disease or process, as seen in acanthosis nigricans. Here, we will focus on the diagnosis and treatment of selected skin markers of internal medicine.

Erythema nodosum

Erythema nodosum (Figure 260.1) is a form of septal panniculitis in which the inflammatory changes also involve the overlying dermis. There are usually painful bruise-like lesions on the shins. Erythema nodosum may be provoked by a number of stimuli, including streptococcal infection, drugs (including oral contraceptives and sulphonamides), sarcoidosis, and tuberculosis, although often a cause is not found. The patient may be unwell with fever and arthralgia, and the lesions usually resolve in a few weeks.

Granuloma annulare and necrobiosis lipoidica

The non-infectious granulomatous disorders include granuloma annulare and necrobiosis lipoidica, as well as sarcoidosis.

Figure 260.1 Erythema nodosum, with painful bruise-like lesions on the shins. Please see colour plate section.

From: *Ethnic Dermatology: Clinical Problems and Skin Pigmentation*, Archer CB, Copyright 2008, Informa Healthcare, reproduced by permission of Taylor & Francis Books UK.

Granuloma annulare

Granuloma annulare (see Figure 260.2) is a reaction pattern in the skin, with a well-established morphology and natural history, although the aetiology and pathogenesis are unclear. A number of potential antigenic trigger factors have been suggested. There is an association between granuloma annulare and diabetes mellitus but this is seen uncommonly. Granuloma annulare can occur at any age but most patients are under 30 years old, and women are affected more frequently than men.

Localized granuloma annulare is the commonest form of granuloma annulare and presents as reddish collections of papules which form annular lesions with palpable edges, often over the knuckles and on the elbows. Other areas of the skin may be involved, and a diffuse or generalized pattern occurs uncommonly. In the generalized pattern, there are numerous skin-coloured or erythematous, slightly palpable, coalescing papules, arranged symmetrically on the trunk and limbs. Annular lesions may be violaceous in colour, and itching is often a feature of the generalized form. Perforating (referring to extrusion of material through the epidermis) and subcutaneous granuloma annulare are uncommon patterns, with the latter sometimes being difficult to distinguish from rheumatoid nodules.

It is reasonable to exclude diabetes mellitus in patients with granuloma annulare but this probably occurs in only about 5% cases of localized granuloma annulare, rising to up to 20% in the generalized form. The association of granuloma annulare with diabetes mellitus is debatable, however, and some relatively small studies have not shown a definite association. The distinction from necrobiosis lipoidica, which is more strongly associated with diabetes mellitus, is usually made histologically but granuloma annulare and necrobiosis lipoidica can occur in the same patient.

The sporadic occurrence of granuloma annulare and its tendency to remit spontaneously makes it difficult to assess the efficacy

Figure 260.2 Granuloma annulare, showing an annular dermal lesion on the dorsum of the hand. Please see colour plate section.

From: *Ethnic Dermatology: Clinical Problems and Skin Pigmentation*, Archer CB, Copyright 2008, Informa Healthcare, reproduced by permission of Taylor & Francis Books UK.

of treatment; in addition, in many cases, no treatment is needed. Spontaneous remission occurs in about 50% of patients within 2 years but recurrence, usually at the same sites, occurs in 40%.

Treatment of granuloma annulare, and its effectiveness

Potent topical corticosteroids may hasten resolution of localized granuloma annulare, and intra-lesional triamcinolone can be effective if treatment is required. Cryotherapy has also been used. Psoralen plus UVA (PUVA) therapy seems to be effective for generalized granuloma annulare. Other treatments reported to be of benefit include retinoids, ciclosporin, local injections of low-dose recombinant interferon gamma, and topical imiquimod or tacrolimus. However, better clinical studies are required in what is a sporadic disorder. In one clinical trial of generalized granuloma annulare treated with oral potassium iodide, the active drug had no advantage over placebo.

Necrobiosis lipoidica

The precise pathogenesis of necrobiosis lipoidica (see Figure 260.3) is unknown but impaired vascularity of the microcirculation is considered to play a role. The occurrence of diabetes mellitus in up to 60% of patients who have necrobiosis lipoidica was probably over-estimated previously in tertiary referral populations. Necrobiosis lipoidica may precede the development of diabetes in about one in ten individuals. However, it does not occur exclusively in diabetes, and the term necrobiosis lipoidica diabetorum is no longer used. It can occur at any age but usually develops in young adults and in early middle age. There is a female to male ratio of 3:1. Only about 0.3% of patients with diabetes mellitus will have necrobiosis lipoidica.

Necrobiosis lipoidica occurs as reddish-yellow shiny plaques on the shins, with atrophy and telangiectasia, but early lesions are less obvious. Lesions may ulcerate and a chronic course is usual. In most cases, lesions are bilateral, and they are similar in appearance whether occurring in diabetic or non-diabetic patients.

The differential diagnosis includes granuloma annulare, in which there is less necrobiosis on histology. The yellowish appearance may resemble xanthomatous lesions but this will be distinguished on histology.

Figure 260.3 Necrobiosis lipoidica, showing atrophic plaques on the shins. Please see colour plate section.

From: *Ethnic Dermatology: Clinical Problems and Skin Pigmentation*, Archer CB, Copyright 2008, Informa Healthcare, reproduced by permission of Taylor & Francis Books UK.

Treatment of necrobiosis lipoidica, and its effectiveness

Treatment with a super-potent topical corticosteroid under polythene occlusion is effective in settling the active inflammatory process of necrobiosis lipoidica but the chronic atrophic changes are not reversible and the lesions persist. Early treatment is therefore recommended. Intra-lesional triamcinolone has been used with good effect, and some dermatologists use perilesional triamcinolone to prevent extension of the process centrifugally. Short courses of prednisolone have been reported to arrest the process but are usually not required.

PUVA using a topical psoralen has been beneficial, as has excision and grafting in severe cases. Other treatments which have been tried in the past with limited success include nicotinamide, clofazamine, pentoxifylline, ciclosporin, mycophenolate mofetil, and, more recently, infliximab.

Other skin disorders in diabetes mellitus

Skin disorders in diabetes mellitus include diabetic dermopathy, which is the commonest skin disorder associated with diabetes; cutaneous infections which occur as a consequence of diabetic neuropathy; acanthosis nigricans (related to insulin resistance); and, as discussed in 'Granuloma annulare and necrobiosis lipoidica', necrobiosis lipoidica and probably generalized granuloma annulare. Anogenital pruritus in diabetes mellitus may be caused by candidiasis or streptococcal infection but diabetes is not a proven cause of generalized pruritus.

Diabetic dermopathy (diabetic shin spots)

Diabetic dermopathy occurs in about half of the patients with diabetes, with men being more commonly affected than women. Diabetic dermopathy is thought to be due to microangiopathy and possible neuropathy. Reddish oval macules and slightly scaly plaques are seen on the shins, forearms, and thighs and over bony prominences, later evolving into brownish atrophic scars, where the brown pigment is due to haemosiderin deposition. The presence of these lesions has been suggested to correlate with other internal complications of diabetes, including retinopathy, nephropathy, and neuropathy.

Acanthosis nigricans and insulin resistance

Acanthosis nigricans (Figure 260.4), in which there is hyperpigmentation and hyperkeratosis of the flexures (e.g. a velvety appearance in the axillae), exists in two forms. In the absence of obesity, acanthosis nigricans may be an important clinical sign of an underlying

Figure 260.4 Acanthosis nigricans, showing hyperpigmentation and hyperkeratosis of the axillary skin. Please see colour plate section.

From: *Ethnic Dermatology: Clinical Problems and Skin Pigmentation*, Archer CB, Copyright 2008, Informa Healthcare, reproduced by permission of Taylor & Francis Books UK.

adenocarcinoma (e.g. carcinoma of the stomach). The changes of acanthosis nigricans in younger obese patients, in whom the nape of neck and the antecubital fossae are often involved, are associated with insulin resistance (hyperinsulinaemia) and sometimes overt diabetes mellitus. There are considered to be two syndromes of insulin resistance: type A, which occurs in hyperandrogenic women due to a genetic defect affecting insulin receptor function, and type B, which occurs in older women with signs of immunological dysfunction.

Xanthomata

There are different forms of xanthoma. Eruptive xanthomata of the skin, often on the buttocks and limbs, may develop in patients with hyperlipoproteinaemia in association with diabetes mellitus. Control of the hyperlipoproteinaemia and diabetes usually leads to resolution of the yellowish papules.

Skin markers of liver diseases

Pruritus in liver disease

Generalized pruritus is the most common symptom associated with liver disease. It may precede the onset of jaundice and may be a feature of hepatitis. Itching is most prominent in primary biliary cholangitis, sclerosing cholangitis, and other forms of biliary tract obstruction, being less of a problem in alcoholic cirrhosis, autoimmune chronic active hepatitis, and haemochromatosis. Improvement in hepatic itching by drugs which block the action of opiates suggests that endogenous opiates may be important in the mechanism of itching.

Treatment of pruritus, and its effectiveness

Treatment of pruritus is directed at the underlying cause (e.g. drug withdrawal, in drug-induced cholestasis; surgery, for mechanical biliary obstruction). Antihistamines are usually ineffective. Other approaches have included colestyramine, rifampicin, and various forms of phototherapy.

Pigmentary changes in liver disease

Jaundice is first seen in the sclerae before it becomes generalized. Carotenaemia and drugs, including mepacrine, can also cause yellowing of the skin.

A grey hyperpigmentation may occur in chronic liver disease of any cause. There may be a yellowish tinge due to associated jaundice. The pigmentation is usually more prominent on sun-exposed sites, including the face, with perioral and periorbital accentuation. Pigmentation sometimes localizes to the palmar creases, and men sometimes have increased pigmentation of the areola in association with gynaecomastia.

Vascular changes in liver disease

Some of the recognized vascular changes in liver disease are non-specific, including spider naevi (spider telangiectasias/spider angiomas) and palmar erythema. Finger clubbing, thought to be due to increased digital pulp blood flow and dilation of arteriovenous anastomoses, occurs in about 15% of patients with cirrhosis.

Hair, nail, and collagen changes in liver disease

The body hair is often thinned and men tend to develop a female pubic-hair pattern, due to increased production and decreased metabolism of oestrogens and associated with decreased production and increased metabolism of testosterone. Extensive loss of scalp hair may be due to zinc deficiency.

Nail colour changes include diffuse white colour; proximal white colour and distal reddish-pink colour; and white bands. Nail plate changes include clubbing, flattened nails, or koilonychia, associated with poor nutrition or altered iron metabolism.

Porphyria cutanea tarda

Porphyria cutanea tarda is associated with chronic liver disease. In this form of porphyria, there is photosensitivity with blisters, scarring, milia (small epidermal cysts), and hyperpigmentation on sun-exposed

areas (e.g. backs of hands and forearms) and hypertrichosis of the face (e.g. the temples).

Skin markers of chronic renal failure

Uraemic pruritus

Generalized severe pruritus occurs in about one-third of patients with renal failure (chronic kidney disease), particularly in patients on haemodialysis, with many more patients experiencing less troublesome pruritus. There seems to be a correlation between pruritus and pre-dialysis plasma urea levels, but a less obvious relationship between itching and dry skin (xerosis) and secondary hyperparathyroidism. The mechanism of pruritus is complicated, since a reduction in uraemia often does not improve the itching, and pruritus is unusual in acute renal failure. Uraemic neuropathy affects about 60% of patients with renal failure or on long-term haemodialysis and may play a role in uraemic pruritus.

The incidence of uraemic pruritus has been reported to be decreasing, which in part may be due to the use of more sophisticated techniques and equipment for dialysis.

Treatment of uraemic pruritus, and its effectiveness

In dialysis, lowering the magnesium concentration of the dialysate has been reported to be helpful. In intractable itching, emollients and UVB radiation are reported to be the most effective therapy. Other treatments have included UVA (without psoralen), colestyramine, activated charcoal, and erythropoietin therapy.

Pigmentary changes in chronic renal failure

Anaemia presenting as pallor is an early and common sign of chronic renal failure, resulting from reduced haemopoiesis and increased haemolysis. A greyish-brown discolouration develops in many cases, due to deposition of melanin. Increased nail pigmentation usually confined to the distal nail occurs in a proportion of patients. This distal brown or reddish colour, combined with a proximal white appearance, gives rise to the term 'half-and-half nails', a distinctive pattern seen in about 10% of patients with renal failure.

Purpura due to mild thrombocytopenia or more marked platelet dysfunction is common and may be partly corrected by dialysis.

Calcific arteriopathy (calciophylaxis)

Calcific arteriopathy (sometimes called 'calciophylaxis' or 'calcific uraemic arteriopathy') is a disorder in which patients, usually with renal failure, develop large painful areas of ulceration.

Recent studies have shown that the calcification seen in this condition is not the same as that seen in patients with skin necrosis, so the term 'calciophylaxis' is now considered inaccurate. The term 'calcific uraemic arteriopathy' indicates the site of the calcification and the usual clinical state of the patients. However, a similar type of arteriopathy has been reported in patients with minimal or no renal failure, hence our preferred use of the term 'calcific arteriopathy'.

In addition to renal failure, the other major risk factors include female gender, white race, diabetes mellitus, obesity, warfarin use, and clotting disorders such as protein C and protein S deficiency. It has also been shown that the use of calcium salts and vitamin D in chronic renal failure is a risk factor. There does not seem to be a direct role of hyperparathyroidism in the development of calcific arteriopathy, the disease having been described in the presence of normal parathormone levels.

The usual presentation of calcific arteriopathy is of areas of ulceration on the legs, buttocks, abdomen, or breasts; these areas are painful and may be extensive. Livedo reticularis around the ulcers may be present. Acral ulceration can also occur, causing autoamputation. The differential diagnosis is any cause of ulceration, and especially vasculitis, in which livedo reticularis may also be present. Increasing awareness of the condition is allowing the diagnosis of calcific arteriopathy at an earlier, non-ulcerative stage, before the subcutaneous indurated plaques develop into ulcers.

The diagnosis of calcific arteriopathy is usually by biopsy, with the histology showing calcification of the media of small arterioles

in the skin. The outcome is poor, with a mortality of about 60% for proximal disease and about 20% for distal disease, usually from overwhelming sepsis.

Treatment of calcific arteriopathy, and its effectiveness

Since there is such a high mortality in calcific arteriopathy, the approach should be to aim for prevention. The control of the hyperphosphataemia is thought to be fundamental to this. Phosphate binders are used, with some evidence showing that the non-calcium-containing binders are better. Parathyroidectomy has been found to be useful in the control of calcific arteriopathy in some series but not in others.

Nephrogenic fibrosing dermopathy

Nephrogenic fibrosing dermopathy (NFD) is a fibrotic disease occurring in patients with renal disease. NFD was initially reported in patients with established renal failure, either on dialysis or having had a transplant, but it has since been reported in patients with chronic renal insufficiency not requiring renal replacement therapy. An association with the IV injection of gadolinium-based radiopaque contrast media (particularly containing gadodiamide) has been suggested.

The clinical presentation of this rare disorder is of plaques of indurated skin on the extensor surfaces of the limbs, and scleral involvement has been described. The limbs are affected in a symmetrical manner with skin-coloured papules coalescing to form brawny plaques with a 'peau d'orange' appearance, occasionally with swelling of the hands and feet. Patients may complain of pain, pruritus, and causalgia. Most patients do not have systemic involvement but, when this is present, the disease may be rapidly fatal.

Treatment of NFD, and its effectiveness

The mainstay of treatment of NFD is improvement of the renal function but transplantation is not guaranteed to cure the disease.

Addison's disease

The autoimmune diseases include Addison's disease (adrenal insufficiency), in which one sees melanin pigmentation of the buccal mucosa and skin, particularly the palmar creases. This may be associated with vitiligo, alopecia areata, and other autoimmune diseases, including pernicious anaemia and thyroiditis.

Thyroid disease and the skin

There are a number of cutaneous manifestations of both hypothyroidism and hyperthyroidism. Skin features associated with hypothyroidism include pale and cold extremities; absence of sweating; puffy oedema of the hands and the face; eczema craquelé and pruritus; xanthomatosis (secondary to hyperlipoproteinaemia); coarse sparse hair; brittle/striated nails; purpura/ecchymoses; punctuate telangiectasia on arms and fingertips; and delayed wound healing. Features associated with hyperthyroidism include soft and dry skin, palmar erythema, flushing, increased sweating, fast nail growth, pruritus, urticaria, pretibial myxoedema (see Figure 260.5), acropachy, and diffuse Addisonian hyperpigmentation.

Figure 260.5 Pretibial myxoedema associated with hyperthyroidism. Please see colour plate section.

From: *Ethnic Dermatology: Clinical Problems and Skin Pigmentation*, Archer CB, Copyright 2008, Informa Healthcare, reproduced by permission of Taylor & Francis Books UK.

Pruritus without a rash

Individuals presenting with itch in the absence of skin disease should be carefully assessed. It can sometimes be difficult to distinguish secondary changes associated with excoriation from primary skin disease. However, a detailed history (including drug history) and a thorough systemic examination are crucial. Routine initial investigations might include renal function tests, a full blood count with differential and haematinics, thyroid function tests, and liver function tests, with consideration of other investigations, such as a chest X-ray, HIV testing, and screening for malignancy, dependent on the clinical findings.

261 Drug-induced skin disease

Muthu Sivaramakrishnan

Introduction

Drug-induced skin disease is one of the commonest dermatological presentations in both hospitalized and ambulatory patients. It affects 2%–3% of hospitalized patients and it is estimated that 1 in 1000 hospitalized patients has a serious cutaneous drug reaction. The clinical presentation can mimic any skin disease and should be considered in the differential diagnosis of any acute-onset symmetrical skin eruption. It is important to make a correct diagnosis, as removal of the offending drug results in clinical resolution in most instances.

Etiopathogenesis

Cutaneous drug reactions can be caused by both immunological and non-immunological mechanisms. The immunological mechanism can be due to the various types of hypersensitivity reactions classified by Gell and Coombs. Non-immunological mechanisms include irritant reactions caused by topical agents, dose-dependent toxic reactions, phototoxic reactions, and idiosyncratic reactions.

Clinical features

Cutaneous drug reactions can mimic any form of skin disease. Most of the reactions are mild and often settle after removing the offending drug. The commonest clinical presentations are exanthematous reactions; urticaria and angioedema; erythema multiforme; lichenoid eruptions; bullous eruptions; and drug hypersensitivity syndrome. Bullous eruptions present in various forms, including fixed drug eruptions, drug-induced vasculitis, Stevens–Johnson syndrome, toxic epidermal necrolysis, drug-induced porphyrias, pseudoporphyria, pemphigus, and pemphigoid. Severe drug reactions can be recognized from their cutaneous and systemic features.

Features of severe cutaneous drug reactions include skin and systemic manifestations. For the skin, extensive reddening, facial swelling, pain, palpable purpura, blisters (especially if extensive), involvement of mucous membranes, and a swollen tongue may be seen. Systemic features include a high temperature; swollen lymph nodes (indicating extensive skin inflammation); joint pains or swelling; respiratory symptoms (particularly breathlessness); and, ominously, low blood pressure.

Individual types of drug-induced skin disease

Common drugs causing cutaneous drug reactions are listed in Table 261.1.

Fixed drug eruption

A fixed drug eruption is characterized by the occurrence of one or more erythematous patches, plaques, bullae, or erosions that are present at the same site and were caused by the ingestion of a drug.

Causes of a fixed drug eruption

The following agents can cause a fixed drug eruption:

- antibacterial agents (e.g. sulfonamides, tetracyclines, penicillin, quinine)
- barbiturates
- NSAIDs
- oral contraceptives
- food substitutes

Table 261.1 Common drugs causing cutaneous drug reactions

Drug reaction	Drugs
Fixed drug eruption	Sulfonamides Tetracyclines Penicillin Quinine Barbiturates NSAIDs
Erythema multiforme	Cephalosporin Sulfonamides Penicillin Rifampicin Barbiturates Carbamazepine Phenothiazines Thiazide diuretics
Stevens–Johnson syndrome and toxic epidermal necrolysis	Sulfonamides Penicillin Ethambutol Rifampicin Tetracyclines NSAIDs Barbiturates Carbamazepine Lamotrigine Phenytoin Terbinafine Griseofulvin
Exanthematous drug eruption	Penicillin Ampicillin Co-amoxiclav Sulfonamides Phenytoin Carbamazepine
Drug hypersensitivity syndrome	Anticonvulsants Co-trimoxazole Minocycline Allopurinol Terbinafine Dapsone
Urticaria and angioedema	Antibiotics Antifungal agents Angiotensin-converting enzyme inhibitors NSAIDs Muscle relaxants Food additives
Lichenoid drug eruption	Gold salts Antimalarials Penicillamine Frusemide Thiazides Sulfasalazine

Clinical features of a fixed drug eruption

Lesions are usually single on the limbs but can be multiple and can occur at any site, including mucous membranes. The initial lesion is an erythematous macule developing then into a patch, plaque, or bulla with erosion. The lesions heal with post-inflammatory pigmentation.

Diagnosis of a fixed drug eruption

Diagnosis is usually done by clinical signs but, occasionally, a skin biopsy may be necessary.

Management of a fixed drug eruption

With a fixed drug eruption, stopping the offending drug will help the lesions heal in few weeks. Potent topical steroids will be helpful for localized lesions, but systemic steroids may be essential for generalized and painful mucosal lesions.

Erythema multiforme

Erythema multiforme is characterized by multiple macules, papules, or urticarial lesions, along with target lesions mainly affecting the distal extremities. It is more often by caused by viral infections (e.g. by herpes simplex virus) but can occasionally be caused by the ingestion of a drug.

Causes of erythema multiforme

The following agents can cause erythema multiforme:

- antimicrobials (e.g. cephalosporin, sulfonamides, penicillin, rifampin)
- barbiturates
- carbamazepine
- phenothiazines
- thiazide diuretics

Clinical features of erythema multiforme

In erythema multiforme, the characteristic lesion is a target lesion which is less than 3 cm in diameter, is round in shape, and has three zones: a central area of erythema or purpura, which is surrounded by a pale zone of oedema, which in turn is surrounded by well-defined erythema. Other lesions may be in the form of macules, papules, or urticarial lesions. The commonest site of involvement is the distal extremities, with rare involvement of mucous membranes (erythema multiforme minor). However, some patients may have a prodromal illness with severe generalized disease and mucous membrane involvement (erythema multiforme major).

Diagnosis of erythema multiforme

The diagnosis of erythema multiforme is usually made with clinical signs but a skin biopsy may be necessary on occasion. The cutaneous biopsy may show vacuolar degeneration of lower epidermis, individual necrotic epidermal cells, and dermal, perivascular lymphohistiocytic infiltrate.

Treatment of erythema multiforme

When treating erythema multiforme, it is important to stop the offending drug. Ocular involvement requires urgent help from an ophthalmologist. Good skin nursing care is essential in severe cases. Potent topical steroids may be helpful in localized lesions. The use of systemic steroids is debated, although they can help in the relief of systemic symptoms and in severe cases. Thalidomide, dapsone, azathioprine, and ciclosporin may be helpful in recurrent cases.

Stevens–Johnson syndrome and toxic epidermal necrolysis

Stevens–Johnson syndrome is a severe, acute-onset disease characterized by a prodromal illness, erythema multiforme of the trunk, and skin blisters involving less than 10% of the body's surface area. Toxic epidermal necrolysis is also a severe, acute-onset illness but is characterized by a prodromal illness, sheets of erythema, and skin peeling involving more than 30% of the body's surface area.

Causes of Stevens–Johnson syndrome and toxic epidermal necrolysis

The following agents can cause Stevens–Johnson syndrome and/or toxic epidermal necrolysis:

- antibiotics (e.g. sulfonamides, penicillin, ethambutol, rifampicin, tetracyclines, thioacetazone)
- NSAIDs
- anticonvulsants (e.g. barbiturates, carbamazepine, lamotrigine, phenytoin)
- antiretroviral agents
- antifungal agents (e.g. terbinafine and griseofulvin)
- others (e.g. allopurinol, thiazide diuretics, gold, vaccines)

Clinical features of Stevens–Johnson syndrome and toxic epidermal necrolysis

In Stevens–Johnson syndrome, patients usually have a severe prodromal illness with fever, myalgia, and arthralgia, following which they develop extensive erythema multiforme lesions on the trunk. They also develop blisters and erosions both on the skin and on mucosal areas. The oral mucosa is commonly involved, followed by the mucosae in the eyes and the genitalia, but any mucosal membrane can be affected. Involvement of lungs and kidneys has been reported. The mortality rate is 5%–15% in untreated patients, due to renal damage, infection, and toxæmia. In treated patients, the eruption usually heals well but permanent damage can be caused to mucous membranes, particularly in the eyes.

In toxic epidermal necrolysis, patients have a severe prodromal flu-like illness followed by sheets of erythema leading to painful erosions involving the skin and mucous membrane. Mucous membranes are involved in all patients; the oral mucosa is particularly involved, but any mucosal areas can be affected. Acute complications include sepsis, renal failure, induction of a hypercatabolic state, and pneumonitis. Chronic complications are mainly due to permanent damage to mucous membranes. The mortality rate is around 30%–40% in untreated cases.

Diagnosis of Stevens–Johnson syndrome and toxic epidermal necrolysis

Skin biopsy and histopathology of toxic epidermal necrolysis will reveal full thickness necrosis of skin in established lesions with perivascular mononuclear cells in the dermis. The histology of Stevens–Johnson syndrome more often resembles erythema multiforme.

Management of Stevens–Johnson syndrome and toxic epidermal necrolysis

In Stevens–Johnson syndrome and toxic epidermal necrolysis, early diagnosis and stopping the offending drug are the most important steps in management. Patients are best managed in specialized dermatology unit or burns unit (particularly patients with toxic epidermal necrolysis).

Fluid and electrolyte replacement and maintaining body temperature is important, as often these patients can develop renal failure and hypothermia. Specialist involvement should be sought early if mucosal areas are involved to prevent complications.

Good skin care with emollients and topical antibacterial agents is necessary. Systemic steroids in high doses and early in the disease might be helpful but their use is controversial. IV immunoglobulins early in the disease might help further progression. Appropriate early treatment of complications (like sepsis) is essential.

Exanthematous drug eruptions

Exanthematous drug eruptions are the most common of all cutaneous drug reactions (about 75% of all drug rashes) and can occur between 3 days to 2 weeks of ingesting a drug. An exanthematous drug eruption is characterized by an erythematous maculopapular eruption and scaly patches commonly affecting the trunk and extremities. Purpuric lesions of the legs and erosive stomatitis can occur in some patients. Some patients may have fever, itching, and peripheral eosinophilia.

The commonly implicated drugs are penicillin, ampicillin, co-amoxiclav, sulfonamides phenytoin, and carbamazepine. Removal of the offending agent, together with the use of moderately potent to

potent topical steroids and antihistamines, will usually help to resolve the situation.

Drug hypersensitivity syndrome

Drug hypersensitivity syndrome, also known as DRESS syndrome (drug rash with eosinophilia and systemic symptoms), consists of fever, lymphadenopathy, organ involvement (e.g. hepatitis, nephritis, pneumonitis, and encephalitis), haematological abnormalities, and a cutaneous rash. The skin eruption is usually in the form of papules or a papulopustular or exanthematous rash leading to erythroderma. Haematological abnormalities include eosinophilia and atypical lymphocytes.

This condition is usually caused by anticonvulsants but can also be caused by co-trimoxazole, minocycline, allopurinol, terbinafine, and dapsone. Treatment includes stopping the offending drug and administering systemic corticosteroids.

Urticaria and angioedema

Urticaria is characterized by itchy, transient, oedematous papules, and plaques. These lesions are called 'wheals' and are caused by superficial oedema in the papillary dermis. Angioedema involves oedema of the deeper tissues, including the dermis and subcutaneous tissue.

The common causative drugs in urticaria and angioedema are antibiotics, antifungal agents, angiotensin-converting enzyme inhibitors, NSAIDs, muscle relaxants, and food additives. Management involves

stopping the offending drug and administering antihistamines and systemic corticosteroids (in severe cases).

Lichenoid drug eruption

A lichenoid drug eruption is characterized by scaly violaceous papules and plaques on the trunk and extremities, sometimes leading to erythroderma. Mucosal involvement is uncommon in a lichenoid drug eruption, unlike the case with lichen planus. The common causative drugs include gold salts, antimalarials, penicillamine, furosemide, thiazides, and sulfasalazine. Quinine and tetracyclines can cause such eruptions on the photo-exposed areas of the skin. Management involves stopping the offending drug and administering potent topical steroids and systemic corticosteroids (in severe cases).

262 Psychocutaneous medicine

Anthony Bewley

Introduction

The links between the mind and the skin have long been recognized. The skin has been described as the mirror of the mind, and so it is not surprising that the interface between dermatology and psychiatry ('psychocutaneous medicine' or 'psychodermatology') is emerging as a specific subspeciality of dermatology. Psychodermatological conditions can be classified as either primarily psychiatric disorders which manifest via skin disease, for example delusional infestation, or primarily dermatological disorders, for example psoriasis, which may be caused by, or associated with profound psychiatric morbidity (e.g. anxiety, depression; see Table 262.1).

Delusional infestation

Delusional infestation is a well-recognized uncommon condition in which patients hold a fixed belief that they are infested with organisms (parasites, bacteria, viruses) or fibres. When referred to a purely psychiatric clinic, patients with delusional infestation often default their appointments, but they are also difficult to manage in a standard dermatology clinics. Older terms such as 'delusional parasitosis' and 'acaraphobie' have been replaced by the term 'delusional infestation'. Delusional infestation can be classified into primary and secondary disorders. Primary delusional infestation is classified by DSM-IV as 'delusional disorder of somatic type', and in ICD-10 as 'persistent delusional disorder'. It is uncommon (about 20 new cases per million population); the female-to-male ratio under the age of 50 years is similar, but that for those over 50 is 2:1. There is a bimodal distribution with respect to age, with one peak occurring between 20 and 30 years of age, and then another at over 50, and there are frequent reports of the delusions being shared with a relative or close friend (folie-a-deux; 8%–12% of cases), and occasionally more than one person (folie-a-trois).

Secondary delusional infestation may follow a real infestation, be associated with recreational drug use (alcohol, cannabis, etc.), be a precursor to dementia, and be associated with other organic disease. But also delusional infestation may be secondary to 'functional' psychiatric diseases (such as schizophrenia). It is therefore essential that

a full medical history (including a dermatological history, a history of substance abuse, and a psychiatric history) and a physical examination are undertaken to identify potential organic disease and make an accurate diagnosis.

Many patients bring containers with samples of 'infested material' (the 'matchbox sign') to the doctor. Patients may take extreme measures to eradicate the organisms from their bodies, and frequently cause severe damage to their skin through applying noxious substances or even burning the skin.

Patients with delusional infestation are notoriously difficult to manage due to their lack of insight and resistance to psychiatric referral. Joint working between psychiatrists and dermatologists is therefore vital. Exclusion of organic cause is mandatory. This may include a pruritus screen (thyroid, renal, and liver function tests, blood count, vitamin B₁₂, folate, and syphilis serology). But clinical assessment will inform whether these or other investigations may be relevant.

It is important **not** to confront the patient with the falsity of their delusional belief, as this leads to loss of any therapeutic alliance, and the patient will simply move to find someone who will take their concern 'seriously'. All samples should be sent for analysis, first, to support the patient, second, to provide a template for discussions about why treatment with antimicrobials is inappropriate, and, last, to exclude genuine infestation. Empathizing with patients is crucial. Patients with delusional infestation have usually seen a large number of doctors, are often frustrated with the perceived lack of help they have received, and are frequently hostile. But it is important not to collude with patients, too. Instead, letting patients know that you understand the seriousness of their condition, and that there are effective therapeutic options for their symptoms, is often enough to engage the patient in a clinical dialogue.

Conventional antipsychotics are probably effective. Pimozide was considered the treatment of choice; however, in view of its cardiotoxic side effects, atypical antipsychotics are now considered a better choice. There are no random controlled trials but case reports, case series, and clinical experience suggest that atypical agents such as risperidone, olanzapine, quetiapine, and amlisulpride are effective. Typically, patients respond to smaller doses (e.g. 0.5 mg risperidone twice daily, increasing if necessary to 1 mg twice daily). The prognosis of delusional infestation is highly dependent on the clinical environment. In joint dermatology–psychiatry clinics, successful treatment of delusional infestation can be expected in over 75% of patients.

Body dysmorphic disorder

Body dysmorphic disorder (BDD; also, inaccurately, called dysmorphophobia) is characterized by a preoccupation with a perceived or real visible difference in which the patient's concern is out of proportion to the 'defect'. There is a spectrum from patients with overvalued ideas to those whose beliefs are held with delusional conviction (in DSM IV, 'delusional disorder-somatic type'; in ICD 10, 'other persistent delusional disorders').

BDD is common, affecting 1%–2% of the population (although many of us have a lesser degree of dissatisfaction with our bodies), especially in adolescence, and is known to be associated with mood disorders, obsessive compulsive disease, and social phobia. The condition is extremely disabling for patients and their relatives, as the 'defect' may seem, objectively, to be minor and the reaction to the 'defect', extreme. Many patients spend long periods in front of mirrors, while others have extensive rituals simply to build enough confidence to look in a mirror. Many become socially isolated, and many seek repeated aesthetic surgery, only to be dissatisfied with the results, or to find another perceived 'defect'.

Table 262.1 Psychocutaneous medicine

Primary psychiatric disorders which present with skin disease	Primary dermatological disorders caused by or associated with psychiatric comorbidity
Delusional infestation	Psoriasis
Body dysmorphic disorder	Eczema
Dermatitis artefacta	Alopecia (e.g. areata)
OCD (e.g. repeated handwashing)	Acne
Trichotillomania	Rosacea
Neurotic excoriation	Urticaria
Others	Vitiligo
	Visible differences (disfigurements)
	Inherited skin conditions (e.g. ichthyosis)
	May be caused, exacerbated by, or associated with:
	<ul style="list-style-type: none">• depression• anxiety• body image disorder• social anxiety

Treatment may be tricky, as most patients lack insight and will not accept psychiatric treatment or referral. Affected individuals are therefore best seen in a joint psychodermatology clinic, where they can be supported, and gradually encouraged to accept psychological interventions. Their surgery-seeking behaviour can also be contained. The limited evidence base indicates that serotonergic antidepressants (fluoxetine, citalopram, fluvoxamine) may be effective, particularly in higher doses and for longer periods. Importantly, CBT can be effective in BDD patients, and may be pivotal in allowing the patient to regain a healthier perspective of their 'defect'. Untreated, the condition tends to be chronic, and there is a high suicide risk.

Dermatitis artefacta

Dermatitis artefacta (DA) describes the condition whereby a patient creates skin lesions but denies knowledge of self-infliction (as opposed to deliberate self-harm, where the patient will be able to acknowledge the self-infliction, and will usually indicate that 'cutting' gives the individual a sense of control over their body, and/or relieves some emotional tension). In DA, patients produce their artefacts secretly, deny complicity, and may be unaware of their psychological motivations. They and their relatives are often puzzled about the aetiology of their skin lesions, and may be angry with doctors' inability to diagnose and treat the mysterious problem. The skin lesions, themselves, may be very varied in character (e.g. linear tears, bruises, cuts, non-healing ulcers) and in severity (minor erosions to widespread, severe, deep ulceration).

DA is probably common and under-reported. It is more common in women (at least 3:1), and the incidence is greatest in the late teens or early twenties. Often, there is a connection between the patient or their family and some aspect of healthcare (such as a recent illness). In addition, studies suggest an association with physical or sexual abuse in some patients.

The first rule of managing patients with DA is to be absolutely certain that the diagnosis of DA is accurate and that non-self-induced disease has been comprehensively excluded. A non-confrontational approach is essential. Focusing on how the skin lesions are generated is of less importance than finding out why they are there. Although DA is primarily a dermatological diagnosis, management should involve close cooperation with specialists in mental health. Management is of the skin as well as the underlying psychological issues. General measures such as emollients and topical antibacterials can all be used, depending on the presenting lesions. Occlusion has been used as a diagnostic and therapeutic tool with variable success. Psychological and psychopharmacological approaches are started at the same time as the dermatological treatments. CBT and psychotherapy are probably pivotal, but there is a wide range of efficacy. Patients are often unwilling to accept the psychiatric nature of the disorder and lack the awareness of their circumstances that trigger the drive to produce the lesions. In such circumstances, dermatology/liaison psychiatry clinics may be beneficial. Often, it is important to simply wait until the patient has enough confidence to relate the underlying psychological issues (there is almost always an underlying issue; this may be relatively minor, such as pressure from examinations, or may be

Box 262.1 Management of the psychosocial aspects of chronic skin disease

- 1. Listen to the patient.** This is by far the easiest and most important aspect of psychosocial care. It is easily overlooked.
- 2. Engage patients with support groups:**
 - <http://vitiligosociety.org.uk>
 - <http://www.psoriasis-association.org.uk>
 - <http://www.changingfaces.org.uk>
- 3. Assess any suicidal ideation.**
- 4. Consider a referral to a 'psychodermatology clinic'.** Unfortunately, these are few and far between, but local dermatology units may have either someone with psychodermatological experience, or will be able to refer to a local (usually liaison) psychiatrist.
- 5. Discuss the possibility of CBT.** This may be invaluable for some patients. Person-centred psychotherapy is probably the most appropriate, as it may focus on thought and behaviour patterns which are unhelpful.
- 6. Consider psychotropic medication.** Sometimes medication for affective disorders may be a useful part of the patient's holistic care. SSRIs (e.g. citalopram) are usually the medication of choice.

devastating, such as sexual abuse). SSRIs can be used where there is an underlying or associated affective disorder. The prognosis of this condition is probably much, much better when patients are engaged with their healthcare professional team.

Psychological comorbidities of chronic skin disease

Psychological comorbidities of chronic skin disease are often underestimated by healthcare professionals. The anxiety, disempowerment, and frustration felt by patients with, for example, psoriasis and vitiligo is only beginning to be recognized. The commonest psychological implication of cutaneous disease is impaired self-esteem, to the extent that some patients will even consider suicide.

Inclusive management of the dermatology patient's psychosocial comorbidities (Box 262.1) is a newer, under-recognized and emerging area of holistic care.

PART 12

Disorders of the musculoskeletal system

263 Normal function of the musculoskeletal system

Shireen Shaffu and James Taylor

Introduction

The musculoskeletal system consists of specialized connective tissue whose primary function is to allow locomotion. The tissues of the musculoskeletal system are bones, muscles, tendons, and ligaments. In particular, the bony skeleton also has the task of protecting vital internal organs, contains the bone marrow, and is an intrinsic part of the metabolic pathways involved in calcium homeostasis. Motion is allowed by specialized articulating structures, the joints. This chapter contains a brief description of all the components.

Bone

Bone is a collagen-rich connective tissue matrix (mainly collagen type I) that is calcified to provide rigidity. Some bones are laid down as a matrix that then calcifies, in a process called **membranous ossification** (e.g. skull, collarbone), but the majority are laid down as a cartilage model which then gets remodelled and replaced by bone in a process called **endochondral ossification** (e.g. long tubular bones of the limbs). Initially, the shaft diaphysis calcifies, but the ends of the bones maintain a cartilage architecture which allows further elongation of the bone, resulting in linear growth. These cartilaginous growth plates (epiphyses) eventually calcify as the skeleton matures, so further longitudinal growth ceases.

Bone is not an inert tissue; it is in a constant cycle of resorption and formation to allow microarchitectural repair of bone. Bone contains most of the body stores of calcium and therefore is an integral part of calcium homeostasis, which is principally under the control of parathyroid hormone and vitamin D. These hormones control intestinal absorption of calcium, calcium exchange with the principal body stores in bone, and renal excretion of calcium. Abnormalities of these hormone systems can therefore have substantial impacts on the calcified bone matrix and, therefore, the overall bone strength.

There are many genetic disorders which affect bone growth and structure and which result in short stature, disproportionate growth, or deformity (e.g. achondroplasia). Genetic alteration of the collagen 1 production results in very low bone mass prone to fracture, a condition known as osteogenesis imperfecta. The common acquired diseases affecting bone metabolism are:

- **osteoporosis**, which is an idiopathic reduction in bone mass which becomes increasingly prevalent with age; risk factors for premature osteoporosis include early menopause, chronic steroid use, rheumatoid arthritis, thyroid/parathyroid and adrenal disorders, and malabsorption syndromes of any cause
- **osteomalacia**, which is defined as a failure to calcify the connective tissue matrix of bone due to reduced availability of calcium or phosphorus, most usually as a result of vitamin D deficiency

Cartilage

Cartilage is a specialized and largely avascular connective tissue, rich in collagen type II, which in the adult skeleton covers the articulating surfaces of bone of synovial joints. Cartilage is rich in highly charged hydrophilic molecules (glycosaminoglycans) attached to a large hyaluronic acid molecule, which allows cartilage to maintain a high water content. In the growing skeleton, cartilage also forms a matrix scaffold of future long bones, which are further remodelled by endochondral

ossification into mature bone. Some structures in the body remain as cartilage (e.g. the pinna of the ear and the nasal septum). Idiopathic inflammation of cartilage structures is the hallmark of the rare disease **relapsing polychondritis**. More commonly in degenerative arthritis (**osteoarthritis**), there is degeneration of cartilage within the joint; this progresses from fibrillation of the surface to fissuring of cartilage and eventual thinning of the cartilage layer, resulting in exposed bone.

Muscle

Muscle is a specialized connective tissue that is able to contract. This is a metabolically active process directed by a neurological signal. Acetylcholine released at the nerve ending crosses the neuromuscular junction and engages a receptor to trigger calcium-dependent actin/myosin interactions which allow the muscle fibres to shorten. Further requirements are a supply of oxygen, a source of fuel, such as glycogen, and a well-maintained balance of potassium and calcium, all of which are essential for normal muscle function. **Voluntary muscle** (sometimes referred to as **striated muscle** due to its appearance under the microscope) requires an intact neurological supply and neuromuscular junction to initiate movement. This type of muscle is made up of two principal types of muscle fibre cell: type 1, fast-twitch muscle fibres, and type 2, slow-twitch muscle fibres. Some muscles are not under voluntary control. These **involuntary muscles** (sometimes referred to as **smooth muscle** due to their appearance under the microscope) are largely controlled by the autonomic nervous system and are generally found in the muscular walls of some arterial, bronchial, and intestinal tissues, as well as tissues of the urogenital tract. Some specialized muscles (e.g. **cardiac muscle**) are able to contract autonomously but still require some neuronal control for appropriate function.

Alterations in muscle function are caused by deprivation of oxygen or by metabolic abnormalities that alter the metabolism or availability of the muscle's fuel sources. Biochemical imbalances and neurological disease also result in impaired muscle function. Genetic abnormalities can result in muscular dystrophies or myotonic syndromes. However, the principal manifestation of muscle disorders in rheumatology are due to direct tissue injury by an inflammatory process, **myositis**.

Tendons

Tendons are non-calcified collagen-rich connective tissues that attach muscle to bone. Tendons transmit the force generated by muscles to the moving parts of the skeleton through a specialized attachment called an enthesis. Inflammation of these attachment points, **enthesitis**, is a common feature of the inflammatory spondyloarthritides. The tendon itself can become inflamed, resulting in a condition known as **tendonitis**, as part of a more general inflammatory disorder, or as a specific localized event. Tendons sometimes have a sheath which can also become inflamed; this condition is referred to as **tenosynovitis**. However, the principal cause of localized tendon damage is usually secondary to mechanical loading which exceeds the capabilities of the tendon and commonly results in a degenerative process referred to as **tendinosis** but occasionally progresses to catastrophic failure: tendon rupture.

Ligaments

Ligaments are non-calcified connective tissues attaching adjoining bones together across a joint. By providing constraints, ligaments can define congruency of adjoining joint surfaces and the number of possible planes of movement. Ligament strains are frequent causes of pain following injury. Ligament rupture often results in instability, and the abnormal motion can accelerate cartilage degradation in the joint due to the alteration in joint biomechanics.

Disorders which affect the connective tissue components of tendons and ligament frequently result in **hypermobility** and, in extreme cases, recurrent dislocation of joints is sometimes associated with arterial fragility and rupture (e.g. **Ehlos-Danlos syndrome**—of which there are many types).

Joints

Synovial joints allow significant movement between two adjacent bones. The joint is enclosed by a capsule lined by **synovium** on its inner surface. Ligaments reinforce the capsule and hold the bones which make up the joint together. The ligaments and the articulating surfaces define the planes of movement possible at that joint. Movement is facilitated by a reduction in friction of the joint surfaces due to the formation of a cartilage cap at the end of each bone, thus allowing cartilage–cartilage articulation. The **synovium** is a layer of specialized connective which secretes joint fluid, which in small quantities is present in all joint spaces. Joint fluid provides a boundary fluid layer which further helps to reduce the coefficient of friction between cartilage surfaces. As well as secreting joint fluid, the cells of the synovium also take part in the immune response by taking on tissue macrophage roles and allowing the generation of germinal centres if required. In inflammatory arthritides, the synovium is the target for the inflammatory process which results in **synovitis**.

In synovitis, the synovium thickens due to the accumulation of chronic inflammatory cells involved in the immune response and

the generation of inflammation. The synovitic tissue can have locally invasive effects eroding into the cartilage of the joint; this mass of synovial tissue in contact with cartilage and bone within the joint is often referred to as a **pannus**. Synovial lining cells also secrete large quantities of joint fluid which can result in a **joint effusion**.

Arthritis is said to exist if the joint is swollen and tender on palpation and if there is limitation of movement on examination. In inflammatory synovitis, the joint will, in addition, often be warm to the touch and, in acute onset, may have overlying skin colour changes (particularly if the joint is close to the skin surface).

Ageing and the musculoskeletal system

Any discussion of normal musculoskeletal function should include an understanding of how the normal ageing process affects both normal homeostatic mechanisms for normal musculoskeletal function, and the types of diseases one is likely to encounter at different ages. Our genes programme development in utero and affect the growth and development of the skeleton into the mid-twenties. Some tissues retain the capability to repair (e.g. soft tissue, bone) and some do not or only retain a limited capacity to repair (e.g. cartilage). In general, genes determine our maximum capacity to develop traits (e.g. bone mineralization, muscle strength/endurance). Whether or not an individual achieves this maximum capacity predetermined by our genes depends on subsequent nurture and avoidance of disease (e.g. a child affected by inflammatory arthritis through pre-teen and teenage life will struggle to achieve maximum bone mineralization and will therefore be at higher risk of osteoporosis in later life).

264 Diagnosis in suspected rheumatological disease

Rachel Jeffery

Introduction

Musculoskeletal symptoms may be the sole presenting complaint of a rheumatological disease or may be a minor part of a presenting symptom complex. Determining whether or not these symptoms reflect serious pathology requiring specialist management relies on careful history taking and a thorough examination. The majority of rheumatic conditions are chronic, and a holistic approach to patient management is required to establish how the illness affects the physical and psychological functioning of the patient, and to explore how symptoms may be managed.

In assessing the patient with musculoskeletal symptoms, you must consider the following questions:

- are the symptoms due to an inflammatory process or a non-inflammatory process?
- do the symptoms reflect a primary rheumatological disease or are they secondary to another pathology (e.g. infection or malignancy)?
- are the symptoms a complication of the disease or a complication of treatment?
- is there evidence of non-articular disease, which may be relevant to diagnosis or management?

This chapter focuses on how elements of the history and examination can help answer these questions. Investigation, dealt with in Chapter 265, provides additional information on diagnosis and prognosis.

History taking

When the history is being taken, the age, gender, and ethnicity of the patient should be noted, as well as whether the patient is pregnant, whether the patient smokes, and the presence of any psychosocial factors that may have an impact. Symptoms should be recorded and a history of preceding symptoms, a travel history, a sexual history, and a family history should be taken.

Age

When diagnosing rheumatological disease, the following age-related factors should be taken into consideration:

- most autoimmune rheumatic disease can present at any age, although peak incidence varies with condition
- osteoarthritis is uncommon below the age of 45, unless there has been specific trauma or congenital deformity at one site
- calcium pyrophosphate crystal arthropathy (pseudogout) is rare in patients under the age of 60, unless there is a familial association
- malignancy as cause of musculoskeletal or systemic symptoms is more common in those over the age of 65
- polymyalgia rheumatica and giant cell arteritis rarely occur in those <50
- the onset of ankylosing spondylitis typically occurs before the age of 40
- the juvenile onset of rheumatic disease (occurring before the age of 16) has separate classification criteria
- Kawasaki disease is an acute vasculitis predominantly affecting infants and young children
- the incidence of primary systemic vasculitis in adults increases with age (peak onset at ages 65–74)

- the risk of complications varies less with age than with duration of disease (e.g. in diffuse systemic sclerosis, the highest risk of pulmonary hypertension and renal crisis is in the first 5 years; with rheumatoid arthritis, early diagnosis and treatment is associated with better functional outcome)
- in lupus, the pattern of disease may differ with age; there is some evidence that, when onset occurs over the age of 55, the disease is more insidious, with less renal and neurological disease but more interstitial lung disease, serositis, and overlap syndromes
- polypharmacy is more common in older age and can be associated with a higher risk of drug interactions and side effects, with implications for the treatment and cause of symptoms (e.g. statins and toxic myopathy)
- osteoporosis risk factors, for patients on long-term corticosteroids or with falls risk, should be considered in all age groups; the risk is highest for postmenopausal women

Gender

When diagnosing rheumatological disease, the following gender-related factors should be taken into consideration:

- there is a female predominance in SLE, rheumatoid arthritis (which occurs less frequently in older age groups), polymyalgia rheumatica, giant cell arteritis (which occurs mainly in older Caucasians), Takayasu's arteritis (which occurs mainly in young Asians), systemic sclerosis (although there is less sex difference with the diffuse subtype), Sjögren's syndrome, and fibromyalgia
- gout may be the most common inflammatory arthritis in men and is associated with obesity, family history, alcohol, renal insufficiency, and hypertension; its onset in men occurs at a younger age than it does in females, where it is rare prior to menopause
- men tend to develop rheumatoid arthritis at a later age than females do; in addition, while more men are seropositive (a feature associated with extra-articular disease), with more rheumatoid nodules, more lung, large joint and proximal joint involvement, and more secondary vasculitis, women tend to have more sicca symptoms and worse joint disease activity and functional scores
- male survival with diffuse systemic sclerosis is worse than female survival, and pulmonary fibrosis is more common in men than in women
- ankylosing spondylitis is more prevalent in men than in women, and occurs with more spinal fusion; however, peripheral joint involvement is more common in women
- primary systemic vasculitis of medium vessels is more common in men than in women
- Behçet's syndrome has an equal sex distribution but tends to run a more severe course in men than in women
- osteoarthritis has female predilection in the hands and knees

Ethnicity

When diagnosing rheumatological disease, the following ethnicity-related factors should be taken into consideration:

- rheumatoid arthritis has higher prevalence in Northern Europe than in Southern Europe; in the UK, it seems less common in those of Afro-Caribbean descent than in other ethnic groups
- while SLE is more prevalent in those of Asian descent than it is in those of Caucasian descent, it is most prevalent in those of Afro-Caribbean descent; in addition, renal disease is associated with a worse outcome in those of Afro-Caribbean descent, and this

group responds less well to certain drug therapies (e.g. IV cyclophosphamide, angiotensin-converting-enzyme inhibitors)

- cultural factors may influence use of health resources

Pregnancy

When diagnosing rheumatological disease, the following pregnancy-related factors should be taken into consideration:

- musculoskeletal pain (back pain, symphysis pubis pain, sacroiliac pain) is common in pregnancy, particularly during the third trimester
- vitamin D sufficiency is important, as insufficiency fractures can occur
- pregnancy influences the drugs that can be used
- autoimmune disease can present in pregnancy (especially lupus)
- lupus can deteriorate during pregnancy, with renal complications being particularly serious
- early and diffuse systemic sclerosis is associated with an increased risk of renal crisis
- renal involvement from connective tissue disease can be hard to distinguish from pre-eclampsia
- anti-Ro and anti-La antibodies can cause fetal heart block or neonatal lupus and can be the first presentation of rheumatological disease; if these antibodies are known to be present, fetal cardiac monitoring should be arranged
- pregnancy loss, intrauterine growth retardation, thrombosis, pre-eclampsia, and premature delivery occur in higher incidence with SLE and antiphospholipid syndrome (anticardiolipin antibody or lupus anticoagulant positive); specialist obstetrics advice should be sought
- rheumatoid arthritis often improves symptomatically during pregnancy but can relapse in the post-partum period

Cigarette smoking

When diagnosing rheumatological disease, if the patient smokes, the following should be taken into consideration:

- smokers have an increased risk of developing autoimmune disease (e.g. the risk of developing rheumatoid arthritis is doubled)
- smokers have a poorer prognosis for rheumatoid arthritis:
 - they have an increased risk of being seropositive (which is associated with erosive and extra-articular disease)
 - they have a reduced response to some drugs (e.g. methotrexate, hydroxychloroquine, anti-tumour necrosis factor therapy)
- they have an increased risk of cardiovascular disease, which occurs at a higher incidence in autoimmune rheumatic disease

Psychosocial factors

Psychosocial factors, such as employment, depression, relationships, and coping strategies, impact on outcome and disability; in addition, there is a two-way interaction, as disease impacts on psychosocial factors. Obtaining information in the history is important in anticipating these issues.

Employment

Manual workers are less likely to retain employment than those in professional or managerial roles. Length of time off work (>6 weeks) reduces the likelihood of returning to work. Financial problems predict depression, disability, and relationship problems.

Depression

Depression is common in chronic rheumatologic conditions and is often missed. It is predicted by level of disability rather than severity of disease. Deformity, negative self-image, loss of independence, and control also contribute.

Relationships

Social support from family, friends, healthcare workers, and patient groups is associated with lower levels of depression. Problems arise when there are reduced opportunity for social contacts; increased isolation and dependence; sexual problems; mood changes; and loss of income.

Table 264.1 Features suggesting inflammatory versus non-inflammatory causes

Inflammatory	Non-inflammatory
Pain improves with activity	Pain worse on activity
Pain worse with rest	Pain better with rest
Early morning stiffness >30 min	Early morning stiffness <30 mins
Stiffness improves with exercise, worse with rest	Stiffness less responsive to exercise and rest

Coping strategies

The belief of self-control over pain is associated with higher well-being and lower disability scores. In contrast, catastrophizing, fear-avoidance behaviour, and reduced levels of activity are associated with lower psychological well-being and higher disability scores.

Symptoms

Determining the presence of specific symptom complexes helps to narrow the differential diagnosis and classification and will guide decisions on further investigations and management. Classification criteria for rheumatic disease should not be confused with diagnostic criteria. Once information about pain and stiffness has been obtained, it should be possible to decide whether the condition is more likely to be inflammatory or non-inflammatory (mechanical; see Table 264.1).

This distinction is important, as it will influence the rest of the history taking. For inflammatory conditions, systemic and extra-articular features, as well as clues as to classification of the condition, will be looked for in both the history and the examination. For non-inflammatory conditions, aggravating factors and ways of managing the symptoms within the patient's lifestyle will be considered. In addition, 'red flags', which would indicate the need for urgent further investigation to exclude infection and malignancy, need to be excluded (see Box 264.1).

Pain

Pain is the most common rheumatological symptom. Several patterns of pain are recognizable:

- pain which is worse with or following movement and which is often worse later in the day is suggestive of a mechanical process, such as degenerative arthritis
- pain which is worse in the early morning, is often associated with prolonged early morning stiffness, is worse after rest, and is relieved by exercise is suggestive of an inflammatory process
- pain associated with neurological symptoms suggests a neuropathic element; radicular pain that is sharp, electric-shock-like, and often aggravated by cough (due to raised intrathecal pressure) suggests nerve root entrapment; pain associated with significant neurological dysfunction suggests neural injury and is often worse at night-time
- well-localized bone pain suggests an injury and, if severe at rest or at night, may be indicative of a malignancy
- poorly defined pain localized to a single area but not affected by movement of that area suggests referred pain (e.g. right shoulder pain in cholecystitis; left arm pain in acute coronary syndrome)
- musculoskeletal pain associated with systemic/constitutional symptoms should prompt a search for infection, malignancy, or features of connective tissue disease or vasculitis

Box 264.1 'Red flags'

- pain worse at night
- associated systemic features (fever, sweats)
- unexplained weight loss
- new neurological symptoms
- previous history of malignancy
- immunocompromise
- extremes of age (<16 years, >70 years)

- increasing muscle pain during the use of a limb suggests vascular claudication and, when in unusual locations (upper limb or jaw), could suggest a vasculitis
- hyperalgesia (more pain than expected from a noxious stimulus) and allodynia (pain from a non-noxious stimulus) suggests a more complex central pain-processing problem; this can be generalized pain in fibromyalgia, or localized pain in complex regional pain syndrome

Stiffness

Stiffness is another common symptom of rheumatological disease, but it can be difficult to characterize precisely, as patients will often equate it with pain. Significant stiffness, particularly early morning stiffness of more than 30 minutes duration, is more in keeping with inflammatory disease and will usually improve with activity through the day.

Mechanical disorders can cause stiffness but this is often short-lived, start-up pain/stiffness.

Some neurological conditions cause stiffness following upper motor neuron lesions (e.g. cervical cord compression) or extrapyramidal disease (e.g. parkinsonism).

Swelling

Swelling is often reported but must be corroborated by examination (e.g. patients with areas of numbness often report a feeling of swelling). When swelling of a joint is fixed and bony, this suggests osteoarthritis. When swelling of a joint is soft and boggy, it may be inflammatory. When swelling of a limb occurs with pitting on pressure, this suggests oedema.

Colour changes

Redness (erythema) associated with a joint or bursa should be considered a sign of infection until proven otherwise. Non-specific skin redness of a limb should be considered a possible sign of cellulitis. Once infection has been excluded, other possible causes include crystal arthropathy, seronegative spondyloarthropathy, erythema nodosum, ruptured Baker's cyst, and DVT. Palmar erythema can be seen in rheumatoid arthritis and vasculitis, although other non-rheumatological causes need to be considered.

Vascular changes in Raynaud's disease typically follow a triphasic colour change of white (the initial vasoconstrictive phase), blue (deoxygenated blood flow), and red (erythralgia, usually painful, as compensatory vasodilatation occurs). Raynaud's disease is more likely to be primary if it is of young onset (age <20), occurs in female patients with low BMI, and is triggered in cold environment and recovers quickly on warming, without associated skin changes. It will be aggravated by smoking and some drugs (e.g. beta blockers). Chilblains can occur. Secondary Raynaud's disease is more likely with older onset (age >40), digital ulceration, persistence even in a warm environment, and systemic symptoms. Unilateral Raynaud's disease or vascular changes should prompt a search for occlusive causes (extravascular, mural, or intravascular).

Livedo reticularis, producing a characteristic purple criss-cross pattern over the skin, is more commonly pathological if the upper limbs are involved and if it persists in warm environment. This can be associated with vasculitis or antiphospholipid syndrome.

Joint range of movement

Joint range of movement is not a particularly helpful feature of the history, as movement may be restricted by pain from any area of the limb. This feature is more useful and specific on examination.

Fatigue

Fatigue is a very common symptom in association with chronic rheumatologic conditions, both inflammatory and non-inflammatory (reported in up to 90% of patients). The aetiology is multifactorial and often there is a history of sleep disturbance either in the duration or the quality of sleep. This is not always associated with pain and often does not respond to treatment of the underlying condition. Fatigue can affect pain experience, mood, and coping ability and impact on functional outcome.

Systemic symptoms

Systemic symptoms of fever, sweats, or unexplained weight loss can occur with severe inflammatory arthritides and systemic autoimmune rheumatic disease, but infection and malignancy must be excluded.

Generalized myalgia (pain in the muscles) and arthralgia (pain in the joints) can occur with systemic illness and fever, due to systemic cytokine release, without the musculoskeletal system being the primary location of inflammation, as in response to a viral 'flu-like' illness. A history of associated and preceding symptoms as well as the duration of the symptoms will provide pointers to possible infectious aetiology.

Preceding symptoms, travel, and sexual history

A history of upper or lower respiratory tract infection, acute gastroenteritis, genitourinary symptoms, or risk of exposure to sexually transmitted disease may help identify a reactive arthritis (likely if multiple joints involved) or secondary septic arthritis (essential to consider, particularly if only one joint is involved). In addition, note that an individual who already has one autoimmune disease has a 1 in 5 risk of developing a second one.

The spectrum of infectious agents considered will be influenced by the travel history, for example travel to areas endemic for Lyme disease (e.g. New Forest and Norfolk in the UK; Germany; northern parts of North America). HIV infection can be associated with autoimmune disease presentation at seroconversion, as part of the AIDS complex of symptoms and during immune reconstitution on antiretroviral treatment. Diffuse infiltrative lymphocytosis syndrome (DILS), presenting with Sjögren's type glandular swelling, should not be missed. Psoriasis and spondyloarthropathies can present in HIV infection, and there is a higher risk of septic arthritis.

Family history

The following factors should be taken into consideration when taking the family history:

- there is a 20% increased risk of autoimmune disease if the patient has a first-degree relative with an autoimmune disease; the impact of this will depend on the incidence of the disease
- in spondyloarthropathies, there is a strong dominant association with HLA-B27:
 - of Caucasian patients with ankylosing spondylitis, >90% are positive for HLA-B27 (the percentage is less for non-Caucasians)
 - of patients with reactive arthritis with sacroiliitis, 80% are positive for HLA-B27
 - of patients with peripheral arthritis without sacroiliitis, 25–40% are positive for HLA-B27
- there is a familial association for early onset gout without traditional associated risk factors
- periodic syndromes (acute remitting attacks of fever and serositis) have strong family associations
- benign joint hypermobility and pathological hypermobility associated with specific syndromes (e.g. Marfan syndrome and Ehlers–Danlos syndrome) usually present in familial clusters
- in osteogenesis imperfecta, the most common types (Types I and IV) are usually inherited in an autosomal dominant fashion, whereas the more severe forms (including Types II and III) usually occur as the result of sporadic mutations, with no family history
- polyarticular generalized nodal osteoarthritis is increasingly recognized as having familial associations

The penetrance of phenotype may vary between individuals.

Examination

The history will establish whether the symptoms are likely to have an inflammatory or non-inflammatory cause. The musculoskeletal system is then examined with this in mind, looking for features to confirm or refute the suspected diagnosis. These findings then inform the general examination.

Examination of the musculoskeletal system

Inspect the joints and limbs, looking for:

- swelling, its localization to the joint or surrounding tissue/bursa and whether it arises from one compartment or arises more diffusely in the limb
- the pattern of joint swelling: whether it occurs in one joint or multiple joints, and the symmetry and size of joint involvement (see Figure 264.1)

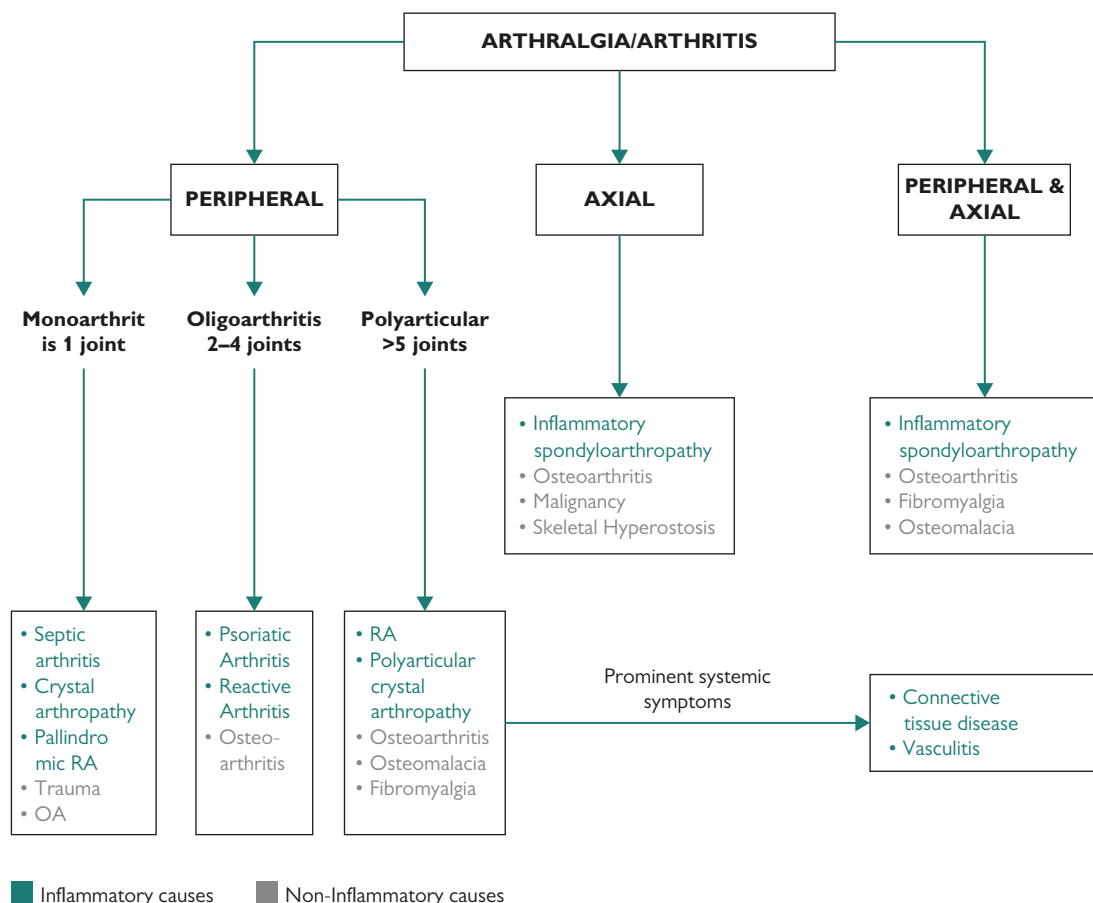

Figure 264.1 Approach to the diagnosis of joint pain; OA, osteoarthritis; RA, rheumatoid arthritis.

- deformity: bone distortion (post fracture, osteophytes, remodeling in Paget's or osteomalacia), subluxation (joint failure due to soft tissue damage), and/or Boutonniere (fixed flexion of the proximal interphalangeal joint, with hyperextension of the distal interphalangeal joint) or swan neck (fixed flexion of the distal interphalangeal joint, with hyperextension of the proximal interphalangeal joint) deformities of fingers (characteristic of chronic rheumatoid arthritis)
- local skin changes or trauma
- muscle changes (e.g. wasting, indicating disuse)

Palpate the joints and muscles, looking for:

- tenderness and the site of tenderness:
 - tenderness at the joint line is more specific for joint disease
 - tenderness over entheses occurs in spondyloarthropathies but also with generalized chronic pain syndrome (fibromyalgia)
 - tenderness over muscles; identify the pattern and localization (see Chapter 63)
- specific bony tenderness at one site (suggests a local bone problem)
- the nature of the swelling:
 - is it bony?
 - is it boggy (suggesting inflammation)?
 - is there fluid within the joint (fluctuance; e.g. test with a patella tap) and/or in the surrounding soft tissue (pitting oedema)?
- the temperature of the overlying skin: (e.g. is it raised, due to inflammation, or cold, due to reduced circulation?)

Examine the movement of the joints and muscles:

- compare the range of movement on both sides and in similarly sized joints, as the exact flexibility will vary between individuals and between joints and will usually reduce with age
- mild hyperextension is normal for most joints in children and young adults but is classified as hypermobility when this is more marked

- inability to achieve a normal range of movement is considered restricted movement

In addition, confirm the nature of deformity and identify any restrictions. Observing both passive and active ranges of movement makes it possible to distinguish between fixed deformities and restrictions (arising from bone and cartilage changes within the joint, from restrictions from soft tissue surrounding the joint, or from skin restrictions), and reversible deformities (arising from altered muscle balance—primary to the muscle or secondary to neurological disease—or from tendon rupture or subluxation)

General examination

Specific further local and systemic examination will be determined by the findings from the examination of the musculoskeletal system and by features from the history. If systemic/inflammatory causes are a possibility, then a full systems examination is mandatory. Looking for localizing signs of infection or malignancy is essential.

Neurological system

When examining the neurological system, look for the following features:

- muscle weakness, which can present as inability to move a joint; this necessitates neurological examination of the limb
- numbness or neuropathic pain; if present, a full neurological assessment is indicated
- new-onset headache (unusual for the patient), which is unilateral, involving temple, jaw claudication, visual symptoms (partial or complete loss of vision), with associated systemic symptoms; this suggests giant cell arteritis and requires immediate corticosteroids and further investigation

- headaches with features of meningitis or encephalitis occurring in a patient with known or suspected autoimmune disease; need to exclude these or treat infective causes

Cardiovascular system

When examining the cardiovascular system, look for the following:

- infective endocarditis, which can present with joint pains, swelling, heart murmur, and haematuria; note that heart murmur can also be a feature of vasculitis and lupus (Libman–Sacks endocarditis) or secondary aortic valve incompetence with aortitis from arteritis or ankylosing spondylitis; rheumatic fever is less common with antibiotic treatment of throat infections
- signs of right-sided cardiac failure in association with pulmonary hypertension or constrictive pericarditis, as these are possible complications of connective tissue disease
- absence of peripheral pulses (can occur in arteritis)
- peripheral oedema in cardiac failure, nephrotic syndrome, or liver disease

Respiratory system

When examining the respiratory system, look for the following:

- pneumonia; note that, particularly in the elderly and immunocompromised, this may present with systemic features without localizing symptoms
- pulmonary fibrosis in association with inflammatory arthritides, connective tissue disease, or vasculitis, or as complication of treatment (methotrexate, leflunomide)
- pulmonary embolism; usually associated with antiphospholipid syndrome, but also there is increased risk of this in connective tissue disease and from immobility due to musculoskeletal symptoms
- pleural effusion associated with serositis
- late-onset asthma in Churg–Strauss syndrome

Gastrointestinal system

When examining the gastrointestinal system, look for the following features:

- hepatosplenomegaly; mild enlargement can occur with autoimmune rheumatic disease, usually in association with reactive lymphadenopathy, although this finding should prompt exclusion of malignancy (lymphoma can occur at increased incidence in association with autoimmune disease, especially Sjögren's syndrome)
- liver disease, as a feature of autoimmune disease or drug therapy
- blood or mucous in the stool, or malabsorptive stool, in association with infective or inflammatory colitis, coeliac disease, or upper gastrointestinal dysmotility or bacterial overgrowth (e.g. in systemic sclerosis)

Urogenital system

When examining the urogenital system, look for the following features:

- peripheral oedema with nephrotic syndrome (suggests lupus, vasculitis, amyloidosis)
- the following urine dipstick results:
 - proteinuria and haematuria, suggesting glomerular inflammation
 - leucocytes and nitrites, suggesting infection
 - glucose suggesting diabetes mellitus
- genital ulcers (see 'Oral and genital ulceration')

Skin, nails, and mucosa

Typical diagnostic skin features

Typical diagnostic skin features include:

- butterfly malar rash (SLE)
- discoid rash (discoid lupus)
- rheumatoid nodules (seropositive rheumatoid arthritis)
- psoriasis and nail dystrophy (psoriatic arthritis)
- plantar palmar pustulosis (reactive arthritis)
- tophi (gout)
- heliotrope rash and Gottron's papules (dermatomyositis)

- sclerodactyly and scleroderma changes (systemic sclerosis; changes can be subtle)
- lupus pernio (sarcoidosis)

Features suggestive of autoimmune disease but not specific to one condition

Features suggestive of autoimmune disease but not specific to one condition include:

- pyoderma gangrenosum
- livedo reticularis
- photosensitivity
- purpura (including palpable); look for the more specific Henoch–Schönlein purpura distribution on lower limb, extensor aspects
- erythema nodosum

Other diagnostic clues

Other diagnostic clues include:

- erythema marginatum (streptococcal infection)
- erythema migrans (Lyme disease)

Oral and genital ulceration

If there is oral and/or genital ulceration, note the following:

- duration, frequency, severity, and size can help distinguish pathological ulcers
- it is important to exclude infectious causes, especially with genital-only ulcers (e.g. from herpes simplex, lymphogranuloma venereum)
- autoimmune causes include SLE, Behçet's syndrome, inflammatory bowel disease, reactive arthritis, and Stevens–Johnston syndrome (including reaction to drugs)
- lichen planus can be oral or genital; it is associated with Sjögren's syndrome

Eyes

When examining the eyes, look for the following:

- conjunctivitis or episcleritis (red eyes with itching, mild photophobia, and normal visual acuity)
- uveitis (red eyes with pain and loss of visual acuity); requires urgent ophthalmology review (NB: in children, uveitis is commonly asymptomatic, and all children with known or suspected inflammatory arthritis or connective tissue disease should be screened and monitored by an experienced ophthalmologist)
- dry, gritty eyes with or without dry mouth can occur with primary or secondary Sjögren's syndrome; Schirmer's test (the rate of tear chromatography down filter paper) and a wafer test (time to dissolve a thin wafer orally) can give a more quantitative assessment

ENT

When examining the ears, nose, and throat, be aware of the following:

- rhinosinusitis can occur with vasculitides but it is also a common allergic symptom, so it is non-specific
- nasal crusting, nosebleeds, nasal stuffiness, and conductive hearing loss can occur in Wegener's granulomatosis
- destructive cartilage changes can occur in the nasal septum or upper airways (in Wegener's granulomatosis and relapsing polychondritis) or pinna (in relapsing polychondritis); other causes such as trauma, surgery, cocaine abuse, or risk of leprosy need to be excluded
- parotid and salivary gland enlargement in Sjögren's syndrome, sarcoidosis, and DILS
- lymphadenopathy (with or without hepatosplenomegaly (see 'Gastrointestinal system')); exclude malignancy and infection

Prognosis

The prognosis of rheumatological disease is predominantly influenced by disease type and natural history, with the outcome modified by the extent of organ involvement and the degree of reversible versus permanent tissue damage. Extent of involvement forms part of the assessment of a patient with rheumatic disease and informs decisions on management. The extent of disability from symptoms is

influenced not only by the severity of organ involvement but also by a wider range of functional factors.

265 Investigation in rheumatological disease

Rachel Jeffery, Pradip Nandi, and Kenny Sunmboye

Introduction

In suspected rheumatological disease, the findings on careful clinical assessment, as detailed in Chapter 264, are crucial to the interpretation of test results. Investigation should not be used as a screening tool, but rather to clarify the differential diagnosis. In established disease, investigation should also be used to assess the extent and severity of organ involvement, establish prognosis, and guide treatment choices.

Full blood count

The full blood count is often affected by rheumatological diseases and their treatments. The haemoglobin concentration may be low because of anaemia of chronic disease, iron deficiency, or macrocytic anaemia. For example, in uncontrolled rheumatoid arthritis (RA), anaemia of chronic disease may be seen. If there is coexisting celiac disease, the patient may have an iron-deficiency anaemia. A macrocytic anaemia may be seen if there is folate deficiency related to methotrexate toxicity.

White blood cell count

The white blood cell count is useful in monitoring for neutrophilia from infection and neutropenia related to active disease or disease-modifying anti-rheumatic drugs (DMARDs). The platelet count may be raised in active RA. Felty's syndrome, a complication of untreated or poorly controlled RA, is associated with neutropenia, splenomegaly, and thrombocytopenia. SLE may result in leucopenia, lymphopenia, and thrombocytopenia.

Liver function tests

Liver function tests are used to monitor for liver injury due to DMARDs such as methotrexate and leflunomide.

Acute phase reactants

Acute phase reactants are described as 'positive' or 'negative' depending on whether they rise or fall in the presence of an inflammatory state. They are usually driven by cytokines such as interleukin-6, tumour necrosis factor alpha, interferon gamma, and transforming growth factor beta. Positive acute phase reactants include the erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and ferritin. Negative acute phase reactants include albumin and transferrin.

The two most widely used acute phase reactants are ESR and CRP. Both are elevated in most inflammatory diseases, and are helpful in assessing disease activity. In polymyalgia rheumatica, giant cell arteritis, and RA, ESR and CRP are indicators of severity, prognosis, and response to treatment. However, in early psoriatic arthritis and ankylosing spondylitis, these acute phase reactants can be normal. In SLE, a raised ESR with a normal CRP is typical; a raised CRP in SLE may reflect infection, lupus serositis, or vasculitis.

Procalcitonin is an emerging positive acute phase reactant which may have utility in differentiating bacterial infection from disease progression.

Uric acid

The plasma level of uric acid is useful in the diagnosis of gout. In a patient with risk factors for gout, and an acutely swollen joint or

joints, the presence of a raised uric acid confirms the diagnosis of gout. However, it is important to note that plasma uric acid may be normal during an acute attack of gout, and so this does not exclude the diagnosis. In this setting, an aspirate of the swollen joint is needed for crystal analysis.

Rheumatoid factor, and anti-cyclic citrullinated peptide antibodies

Rheumatoid factor (RF) is an antibody against the Fc portion of IgG in the patient's serum. The most commonly measured and clinically useful class of RF is IgM RF. Five per cent of a healthy population can be RF positive, and the prevalence increases with age. Testing for RF is useful in the diagnosis and management of RA, but RF positivity is not a necessary diagnostic criterion. RF positivity is associated with more severe joint disease, systemic disease (extra-articular features), and responsiveness to biological DMARDs such as rituximab. RF can also be seen in a number of other rheumatic diseases, as well as in non-rheumatic diseases.

Anti-cyclic citrullinated peptide (anti-CCP) antibodies are directed against citrulline residues formed in post-translational modification of arginine.

In patients with RA, anti-CCP antibodies have a sensitivity comparable to that of RF but with a much higher specificity of 95%–98%. The presence of anti-CCP antibodies can predate the onset of RA and may be positive in patients who are RF negative. Thus, these antibodies, if present, can help in making the diagnosis of RA, given their high specificity. Their presence is also associated with a more severe disease course and more extra-articular features. Unlike RF, anti-CCP antibodies are rarely found in patients with non-rheumatic disease.

Antinuclear antibodies

Antinuclear antibodies (ANAs) are autoantibodies that bind to components of the cell nucleus and (despite their name) cytoplasm. The most commonly used technique to detect ANAs is indirect immunofluorescence, in which HEp-2 cells (obtained from a human epithelial tumour line) are made permeable and incubated first with the patient's serum, and then with anti-human antibodies conjugated to a fluorescent molecule. The cells are then examined by microscopy, and the staining pattern noted. The results are reported as positive or negative and include a titre.

The presence or absence of ANAs is not sufficient to confirm or exclude any rheumatic disease. For example, nearly all patients with untreated SLE have a positive ANA test but not all people with a positive ANA have SLE. Given the low prevalence of SLE, the positive predictive value of a positive ANA for SLE is also low, at around 11%.

ANA titres of 1:160 or more are usually regarded as significant. However, amongst healthy people, 25%–30% have a positive ANA test with a titre of 1:40, 10%–15% have a titre of 1:80, and 5% have a titre of 1:160 or more. The positivity of the test also increases with age, particularly in women. An ANA titre of 1:40 is seen in 25%–30% of relatives of patients with rheumatic disease. In Raynaud's phenomenon, a positive ANA test increases the risk of developing an associated rheumatic disease from 19% to 30%, and a negative test decreases this risk to 7%. Table 265.1 summarizes the prevalence of ANAs in rheumatic diseases.

Table 265.1 Utility of autoantibodies in the diagnosis of rheumatological disease

Disease	Sensitivity (True positive rate)	Specificity (True negative rate)
SLE	93%	57%
Systemic sclerosis	85%	54%
Polymyositis/dermatomyositis	61%	63%
Rheumatoid arthritis	41%	56%
Sjögren's syndrome	48%	52%
Secondary Raynaud's phenomenon	64%	41%

Adapted with permission from Daniel H. Solomon, Arthur J. Kavanaugh, Peter H. Schur, Evidence-based guidelines for the use of immunologic tests: Antinuclear antibody testing, *Arthritis & Rheumatology*, Volume 47, Issue 4, pp. 434–444, Copyright © 2002 John Wiley and Sons.

Extractable nuclear antigens

In a patient with a positive ANA test, it is important to determine the target antigen of the ANA. These target antigens, also called extractable nuclear antigens, are soluble nuclear and cytoplasmic components that leach from the cell when extracted with saline. Table 265.2 summarizes the prevalence of extractable nuclear antigen antibodies in rheumatic diseases.

SLE-associated autoantibodies

SLE-associated autoantibodies include:

- anti-double-stranded DNA antibodies:
 - most strongly associated with SLE
 - important in the diagnosis and assessment of the disease, as their levels correlate with disease activity
 - also associated with the development of lupus nephritis
- the anti-Smith antibody:
- high specificity but low sensitivity for SLE
- associated with renal involvement and poor prognosis
- antiribonucleoprotein antibody:
 - high specificity for mixed connective tissue disorder and is an essential criterion in making this diagnosis
 - often present before the onset of disease

Table 265.2 Autoantibodies and their associated rheumatological disease

Antibody	Associated condition	Sensitivity (True positive rate)	Specificity (True negative rate)
Anti-dsDNA Ab	SLE	57%	97%
Anti-Smith Ab	SLE	25%–0%	High*
Anti-Ro/SS-A Ab	Sjögren, SCLE, neonatal lupus syndrome	8%–70%	87%
Anti-La/SS-B Ab	Sjögren, SCLE, neonatal lupus syndrome	16%–40%	94%
Anti-Scl-70 Ab	Systemic sclerosis	20%	100%
Anticentromere Ab	Limited cutaneous systemic sclerosis	65%	99.9%
Anti-U3-RNP Ab	Scleroderma	12%	96%

Abbreviations: Ab, antibody; anti-dsDNA, anti-double-stranded DNA antibody; RNP, ribonucleoprotein; SCLE, subacute cutaneous lupus erythematosus.

*Precise data not available.

Adapted from Sheldon J., Laboratory testing in autoimmune rheumatic diseases, *Best Practice & Research Clinical Rheumatology*, volume 18, issue 33, pp. 249–269, copyright © 2004 with permission from Elsevier.

- anti-SS-A/Ro and anti-SS-B/La antibodies:
 - female patients with SLE who become pregnant must have blood testing for these antibodies because of the associated risk of congenital heart block in the fetus or neonate, or neonatal lupus

Sjögren's syndrome antibodies

Antibodies associated with Sjögren's syndrome include the anti-SS-A/Ro and anti-SS-B/La antibodies. They are of importance in making a diagnosis of Sjögren's syndrome, as they are rarely seen in healthy people, although they may be present in other rheumatic diseases such as RA, SLE, and polymyositis.

Scleroderma-associated antibodies

Scleroderma-associated antibodies include anticentromere antibodies, the anti-Scl-70 antibody, and anti-U3-ribonucleoprotein antibodies.

Anticentromere antibodies

Anticentromere antibodies are associated with limited cutaneous systemic sclerosis, which was previously called CREST (calcinosis, Raynaud's phenomenon, oesophageal dysmotility, sclerodactyly, telangiectasia) syndrome, and have high specificity but limited sensitivity for the diagnosis. They are rarely found in patients with other connective tissue diseases or in healthy people. Their presence distinguishes patients with limited systemic sclerosis from those with diffuse systemic sclerosis or primary Raynaud's phenomenon.

Anti-Scl-70

The anti-Scl-70 antibody is also very useful in diagnosing diffuse systemic sclerosis. This antibody is highly specific for diffuse disease, although not very sensitive. Anti-Scl-70 and anticentromere antibodies rarely coexist in the same person. The presence of anti-Scl-70 antibodies is useful in predicting a greater likelihood for the development of diffuse cutaneous involvement and pulmonary fibrosis.

Anti-U3-ribonucleoprotein antibodies

Anti-U3-ribonucleoprotein antibodies are antinucleolar antibodies which have high specificity but low sensitivity for scleroderma.

Myositis-associated antibodies

Tests for myositis-associated antibodies are helpful in the diagnosis of polymyositis and dermatomyositis (Table 265.3). They have high specificity but low sensitivity for these diseases.

Antineutrophil cytoplasmic antibodies

Neutrophils contain enzymes including proteinase 3 (PR3), myeloperoxidase (MPO), and elastase, which are components of the immune response. Antibodies directed against these enzymes are associated with certain small vessel vasculitides. Antineutrophil cytoplasmic antibodies (ANCA) are detected by indirect immunofluorescence and have two main patterns of immunofluorescent staining in patients who are ANCA positive: cytoplasmic (cANCA) and perinuclear (pANCA).

Following the finding of cANCA or pANCA positivity, an enzyme immunoassay (i.e. ELISA) is done to determine the presence or absence of antibodies directed against either PR3 or MPO. A cANCA staining pattern in combination with a positive PR3 ANCA result from an ELISA is highly specific (99%) for small vessel vasculitis. A pANCA staining pattern in combination with a positive MPO ANCA is also highly specific for small vessel vasculitis. However, a pANCA staining pattern on indirect immunofluorescence can be seen in a number of non-rheumatic diseases. Table 265.4 summarizes the sensitivities of ANCA in selected rheumatic and non-rheumatic diseases:

Table 265.3 Myositis-associated antibodies

Antibodies	Significance
Anti-Jo1 antibody	Associated with rarer antisynthetase syndrome: interstitial lung disease, non-erosive symmetrical arthritis, Raynaud's phenomenon, and mechanic's hand
Anti-signal recognition particle antibody	Associated with acute onset severe illness with minimal evidence of inflammation on muscle biopsy, requiring aggressive immunosuppression
Anti-Mi2 antibody	Associated with classical dermatomyositis (erythroderma/shawl sign)

Human leukocyte antigen B27

Human leukocyte antigen B27 (HLA-B27) is a Class I surface antigen encoded by the B locus in the major histocompatibility complex on Chromosome 6. HLA-B27 is strongly associated with the seronegative spondyloarthritides, including psoriatic arthritis, ankylosing spondylitis, reactive arthritis, and inflammatory-bowel-disease-related arthritis.

HLA-B27's association with this group of diseases is strongest in ankylosing spondylitis. It is important to note, however, that the presence of HLA-B27 alone cannot be taken as indicating rheumatic disease: 8% of the healthy white population is HLA-B27 positive, while 4% of the healthy African-American population is HLA-B27 positive. HLA-B27 should only be tested in an individual with a strong clinical suspicion of seronegative spondyloarthritis.

Blood tests for monitoring DMARDs

Patients with rheumatic disease require monitoring via blood tests, to prevent medication-related complications. Table 265.5 highlights important DMARDs, with some comment on their adverse effects.

Urinalysis

Urinalysis is an effective method of detecting renal involvement in rheumatological disease (e.g. SLE, scleroderma) or a renal complication of therapy (e.g. gold and d-penicillamine in RA (see Table 265.6)).

Urinary Bence Jones protein (monoclonal free kappa or lambda light chains) should be measured if the differential diagnosis includes myeloma (because of bone pain, increased plasma alkaline phosphatase, renal impairment, or a monoclonal band on serum protein electrophoresis).

Table 265.4 Prevalence of antineutrophil cytoplasmic antibodies findings in vasculitic disease

Disease	cANCA/PR3	pANCA/MPO
Granulomatosis with polyangiitis (formerly Wegener's granulomatosis)	85%	10%
Microscopic polyangiitis	45%	45%
Allergic granulomatosis and angiitis (formerly Churg–Strauss syndrome)	10%	60%
Idiopathic crescentic glomerulonephritis	25%	65%
Polyarteritis nodosa	5%	15%
Anti-GBM disease (Goodpasture's disease)		20%–30%

Abbreviations: cANCA, cytoplasmic antineutrophil cytoplasmic antibody; GBM, glomerular basement membrane; MPO, myeloperoxidase; pANCA, perinuclear antineutrophil cytoplasmic antibody; PR3, proteinase-3.

Adapted from Sheldon J., Laboratory testing in autoimmune rheumatic diseases, Best Practice & Research Clinical Rheumatology, volume 18, issue 33, pp. 249–269, copyright © 2004 with permission from Elsevier.

Table 265.5 Adverse effects of disease-modifying agents in rheumatological disease

DMARD	Major adverse effects
Methotrexate	<ul style="list-style-type: none"> oral ulcers (patient may need to increase dose of folic acid) marrow suppression (patient may need folic-acid rescue therapy) hepatotoxicity (presents as deranged LFTs) pulmonary toxicity (ask patient about symptoms of dyspnoea) rashes alopecia
Sulphasalazine	<ul style="list-style-type: none"> GI discomfort (nausea and vomiting) rashes headaches, also mood alterations oligospermia (reversible once medication is stopped) marrow suppression (rare) major allergic reaction with Stevens–Johnson syndrome (rare) hepatotoxicity (rare)
Hydroxychloroquine	<ul style="list-style-type: none"> ophthalmology: abnormal colour vision, macular pigmentary changes, loss of visual acuity rash and photosensitivity (ask about sun-exposed areas) diarrhoea (not common) nausea
Azathioprine TPMT levels (pretreatment)	<ul style="list-style-type: none"> marrow suppression hypersensitivity hepatitis with cholestasis GI intolerance increased risk of infections
Ciclosporin Creatinine clearance (pretreatment)	<ul style="list-style-type: none"> hypertension (patient will need regular BP checks) hyperkalaemia and renal toxicity hypercholesterolemia (patient will need 3-monthly fasting lipids) increased hair growth (female patients may find this cosmetically unacceptable) gum hypertrophy
Leflunomide BP check (preferably <140/90 pretreatment)	<ul style="list-style-type: none"> marrow suppression (patient may need colestyramine rescue therapy) hepatotoxicity hypertension
Mycophenolate mofetil	<ul style="list-style-type: none"> marrow suppression increased infection risk
Biological therapies (anti-TNF α , rituximab (CD19 levels, Ig levels pretreatment for rituximab), tocilizumab}	<ul style="list-style-type: none"> marrow suppression hepatitis (usually with rituximab) increased infection risk

Abbreviations: BP, blood pressure; DMARD, disease-modifying anti-rheumatic drug; GI, gastrointestinal; LFTs, liver function tests; TPMT, thiopurine methyltransferase; TNF α , tumour necrosis factor alpha.

Data from BSR/BHPR DMARD guidelines.

Joint aspiration

Joint aspiration is done to diagnose the cause of acute mono- or oligoarthritis, in particular to confirm or exclude septic or crystal arthritis (see Table 265.7).

Imaging

Plain radiography

Plain radiography of peripheral joints is useful in well-established disease but may fail to detect abnormalities early in its course (see

Abnormality	Significance in rheumatological disease	Action	Comment
RBC	Important clue for glomerulonephritis, SLE, and vasculitis but other causes (e.g. renal, urological) need to be excluded	Address the cause	In glomerular disease (usually RBC casts, proteinuria, and dysmorphic RBCs) Microscopic haematuria in suspected vasculitis or glomerulonephritis with or without renal impairment (urea and electrolytes can be normal) Fresh urine sample for microscopy and cytology should be sent to see RBC casts in glomerulonephritis In females, think of period
WBC	Found in inflammation or infection	If infection is present, treat	
Nitrite positive	Organism : urinary infection	To treat	In patients on DMARDs or biologics, the infection must be treated aggressively May need to withhold biologics temporarily
Protein	Urine dipstick will primarily detect albumin and may not detect low concentrations of gamma globulins or Bence Jones proteins	Increase in urinary protein is an indication of kidney involvement Further evaluation of urinary proteinuria can done via either 24-hour urinary protein excretion or spot-urine protein:creatinine ratio, which allows quantification	Persistent proteinuria may be due to primary glomerular disease (glomerulonephritis), secondary glomerular disease (e.g. SLE, drugs (e.g. NSAIDs, penicillamine, gold, ACE-I)), or some other, general cause
Glucose	Urine dipstick is positive for DM	If diabetic, then treat	Can be positive in tubular renal acidosis in patient with Sjögren's syndrome

Abbreviations: ACE-I, angiotensin-converting enzyme inhibitor; DM, diabetes mellitus; DMARDs, disease-modifying anti-rheumatic drugs; NSAIDs, non-steroidal anti-inflammatory drugs; SLE, systemic lupus erythematosus, RBC, red blood cell; WBC, white blood cell.

Table 265.8). Findings on spinal radiography are summarized in Table 265.9, and those on chest radiography in Table 265.10. The diagnostic yield of high-resolution CT (HRCT) of the chest is substantially greater than that of chest radiography; HRCT should be considered if interstitial lung disease is suspected but the chest X-ray is normal.

Musculoskeletal ultrasonography

Ultrasonography can detect early inflammatory arthritis and can also detect erosions before they are evident on plain radiographs. Ultrasonography is also used to detect joint effusion and tendon rupture, and can guide joint aspiration or injection.

Synovial fluid	Colour	Cell	Comments
Normal	Transparent, straw colour	Contains <200 cells/mm ³	
Inflammatory	Slight turbid	Count can go up >2000 leucocytes/mm ³	Inflammatory arthritis, SLE, etc.
Septic	Turbid	>100 000 leucocytes/mm ³	In suspected septic joint, urgent aspiration and immediate Gram staining is essential Even few drops of fluid are adequate for WCC (count, differential), Gram staining, culture, and sensitivity and, if an adequate amount of fluid is available, then crystals Negative joint aspiration does not rule out septic arthritis; the entire clinical picture needs to be taken into consideration In suspected septic arthritis, consider routine FBC, renal function tests, liver function tests, CRP level, blood culture, synovial fluid culture, and urine culture Immunosuppression, steroid therapy, and diabetes are risk factors for septic arthritis
Crystal arthropathy	Can be slightly turbid	20 000–50 000 leucocytes/mm ³	Monosodium urate crystals cause gout (monosodium urate crystals are negatively birefringent, needle-shaped crystals seen in polarized microscopy) Calcium pyrophosphate dihydrate crystals are associated with pseudogout, and the deposition of these crystals may be superimposed on osteoarthritis X-ray may show chondrocalcinosis in pseudogout Other causes are calcium oxalate crystals (if the patient is on dialysis) and calcium phosphate crystals (Milwaukee shoulder/knee) Important reminder: crystals and infection can coexist
Haemorrhagic synovial fluid	Bloody, fluid Haematocrit >10% will appear grossly bloody	Predominantly RBC	Can be due to trauma, bleeding disorder, or pigmented villonodular synovitis

Abbreviations: FBC, full blood count, RBC, red blood cell; WCC, white-cell count.

Table 265.8 Findings on peripheral-joint radiography

Disease	Value of peripheral-joint radiography	Finding	Comment
Early inflammatory arthritis	May be uninformative in early disease	May show soft-tissue swelling and/or periarticular osteoporosis	High-frequency ultrasound or MRI may be more useful
Established rheumatoid arthritis or other inflammatory arthritis	Evidence of joint damage and structural deformity	In established rheumatoid arthritis, may show loss of cartilage, and bone erosion In a rheumatoid arthritis hand, MCP joints and PIP joints are more affected than DIP joints Erosion suggests late-stage disease, but erosion can be seen in other conditions (e.g. psoriatic arthritis, gout) In connective tissue disease, a peripheral-joint X-ray will show a non-erosive arthropathy	High-frequency ultrasound may be still of value for active disease
Osteoarthritis	Usually the first-line investigation	A plain X-ray may reveal loss of joint space, subchondral sclerosis, and cyst and osteophyte formation	In osteoarthritis of the hand, DIP joints are more affected than PIP joints; in the thumb, the carpometacarpal joint is commonly affected Other joints (e.g. hip, knee (medial compartment common), spine) may also be affected
Crystal arthropathy	Some value	In gout, soft-tissue swelling or punched-out erosion may be seen Nodular deposits of calcium urate can occur in the synovium In calcium pyrophosphate dihydrate crystal deposition (pseudogout), cartilage or meniscal calcification can be seen, especially in the knee	Joint aspiration for the presence of crystals is the gold-standard investigation
Osteoporosis	Limited value	A plain X-ray may show diffuse osteopenia with cortical thinning	FRAX score and DEXA scan
Osteomalacia	Value in advanced stages	A plain X-ray may show Looser zones (pseudofractures)	Looser zones most commonly seen in the medial femoral neck, the axillary border of scapula, the ribs, and the pubic rami Rare in the Western world
Paget's disease	Diagnostic value	A plain X-ray may show enlarged, sclerotic bones with a trabecular pattern	Stress fracture Bone softening Sarcomatous changes (1%) may occur

Abbreviations: DIP, distal interphalangeal; MCP, metacarpophalangeal; PIP, proximal interphalangeal.

CT

CT is superior to plain radiography in assessing disorders of the bone cortex (e.g. cortical fractures or metastases). It can detect fractures of the cervical spine, the hip, the wrist, and the foot when these are not evident on plain radiographs.

MRI

MRI shows non-calcified tissues that cannot be assessed by plain radiography or CT. Thus, it can demonstrate abnormalities present in synovium, tendons, and muscles and which may precede joint

involvement. For example, in early RA, pre-erosive changes like bone marrow oedema, synovitis, and tendinosis can be seen on MRI.

In suspected myopathy or myositis, MRI can be used to identify muscle inflammation and the best site for biopsy.

Dual X-ray absorptiometry

Dual X-ray absorptiometry (also called 'DEXA scan') measures bone mineral density (BMD) and is used to confirm or refute a diagnosis of osteoporosis and predict the fracture risk in patients with radiographic osteopenia or vertebral deformity.

Table 265.9 Findings on spinal radiography

Disease	Value of spinal X-ray	Findings	Comment
Spondyloarthropathy-like ankylosing spondylitis	Useful	An X-ray of sacroiliac joint may pick up early or advanced sacroiliitis In ankylosing spondylitis, an X-ray might show 'squaring of endplates', Romanus lesions, osteopenia, calcification, and, in late stages, bamboo spine	MRI may be useful early in diagnosis (other causes of sacroiliitis are inflammatory bowel disease, psoriatic spondyloarthropathy, and Reiter's syndrome)
Degenerative spinal disease	Limited value	Presence of osteophytes Lower cervical/lumbar findings	MRI is useful for radiculopathy
Osteoporosis	Limited value	X-ray of spine in an osteoporotic individual may show a wedge fracture Fracture to site previously may result in kyphosis of the spine	FRAX score and DEXA scan

Table 265.10 Findings on chest radiography		
Disease	Possible findings	Comment
Rheumatoid arthritis	Rheumatoid nodules (typically peripheral location in lower zones) Interstitial lung disease Pleural effusion (usually unilateral) Pneumonitis as complication of methotrexate therapy	Chest X-ray should be done as a baseline before methotrexate started
SLE	Pleural effusion (often bilateral) Acute pneumonitis Interstitial lung disease Pericardial effusion (enlarged cardiac silhouette)	SLE may present with pulmonary disease
Ankylosing spondylitis	Apical fibrosis	Apical fibrosis also seen in tuberculosis, in sarcoidosis, and after radiotherapy
Systemic sclerosis	Interstitial lung disease Oesophageal dilatation	Pulmonary involvement occurs in >80% of patients Echocardiography is needed to screen for pulmonary hypertension
GPA (formerly Wegener's granulomatosis)	Nodules that may be cavitory Lobar or segmental atelectasis Pleural opacities	Upper respiratory tract involvement (nasal, sinus, or ear) occurs in 90% of patients with GPA

Abbreviations: GPA, granulomatosis with polyangiitis; SLE, systemic lupus erythematosus.

The T-score compares individual results to those in a young population (aged 20–30) of the same gender and ethnic background, while the Z-score compares individual results to those in an age-matched population. BMD is classified by the WHO as being

normal (T-score within one standard deviation (SD) of the BMD of an average 25-year-old) or indicating the presence of osteopenia (T-score between –1 and –2.5 SD), osteoporosis (T-score below –2.5 SD), or established osteoporosis (T-score below –2.5 SD, with one or more fragility fractures). The risk of bone fracture is slightly increased in patients with osteopenia and considerably increased in those with osteoporosis.

Bone scan

A bone scan using technetium-99m-labelled methyl diphosphonate can be useful in the diagnosis of bone metastases, infection, occult fracture, and other bone disorders (e.g. fibrous dysplasia). In Paget's disease, a bone scan may show intense activity but, in sarcomatous change, there may be lower uptake.

PET-CT

PET-CT can be used to diagnose large vessel vasculitis (e.g. Takayasu arteritis). It can also be used to screen for cancer in patients with dermatomyositis and polymyositis.

Echocardiography

Echocardiography can be used to assess for cardiac and aortic involvement in diseases such as SLE, ankylosing spondylitis, and vascular Ehlers–Danlos syndrome. It is also used to screen for pulmonary hypertension complicating diseases such as systemic sclerosis.

266 Osteoarthritis

Michael Doherty

Definition of osteoarthritis

Osteoarthritis (OA) is a disorder of synovial joints and is characterized by the combination of (1) **focal hyaline cartilage loss**, and (2) accompanying subchondral **bone remodelling** and **marginal new bone formation** (osteophyte). It has genetic, constitutional, and environmental risk factors and presents a spectrum of clinical phenotypes and outcomes.

OA commonly affects just one region (e.g. knee OA, hip OA). However, multiple hand interphalangeal joint (IPJ) OA, usually accompanied by posterolateral firm swellings (nodes), is a marker for a tendency towards polyarticular **generalized nodal OA**.

Etiology of OA

OA is a dynamic, metabolically active condition involving all joint tissues. It is regarded as the inherent repair process of synovial joints. A variety of insults may trigger the need to repair, and often this slow but efficient process compensates for the insults, resulting in an anatomically remodelled but functioning asymptomatic joint. However, in some cases, due to overwhelming insult or inefficient repair, the OA process cannot compensate, resulting in pain, disability, and presentation as a patient with clinically relevant OA.

Risk factors vary according to joint site, and differ according to development and progression. For example, high bone mineral density (BMD) is a risk factor for development of hand, knee, and hip OA, but low BMD is a risk factor for more rapid progression of hip and knee OA. There are three main categories of risk factors:

- genetic factors: OA shows strong heritability (40%–60% for hand, knee, and hip OA), although the specific associations are currently poorly defined (specific associations, such as COL2A1 mutations, are identified for some rare monogenic disorders causing premature polyarticular OA (e.g. Stickler's syndrome))
- generalized, constitutional factors, such as age, obesity, female gender, bone density, and low muscle strength
- localized mechanical factors that cause abnormal joint loading, such as abnormalities of joint shape (dysplasia) or alignment; trauma; meniscectomy; instability; and occupational/recreational overloading

Some factors (e.g. obesity, muscle function, and occupation) may be modified and thus offer scope for primary, secondary, and tertiary prevention.

Typical and less common symptoms of OA

The two main symptoms of OA are pain and restricted activity and function. The pain is characteristically worse on usage/movement and is relieved by rest, typically being worst at the end of the day and best in the morning. The joint may feel stiff in the morning or after rest ('gelling') but, unlike inflammatory joint pain, it quickly 'loosens up' on moving. Pain is usually restricted to just one or a few joints. It is often variable, with 'good days' and 'bad days', and any progression is slow over many months or years.

Restricted activity and function often reflects pain severity but may be the presenting symptom, even in the absence of marked pain. The severity of pain and functional impairment are greatly influenced by psychosocial factors (anxiety, depression), daily activity requirements, and the presence of comorbidity.

Cartilage changes in OA facilitate crystal deposition, so superimposed symptoms of **acute crystal synovitis** are not uncommon (especially at the knee, for calcium pyrophosphate dihydrate

crystal deposition disease, and at peripheral lower and upper limb joints in gout).

Less common symptoms are **mechanical locking** and **rapid progression** of hip (less commonly, knee) symptoms.

Demographics of OA

OA has a higher prevalence than that of all other arthropathies considered together. Structural OA is frequently asymptomatic, so radiographic OA is always more prevalent than symptomatic OA. In general:

- OA increases markedly with age (especially after 40) and is more common in women than men at all sites other than the hip (equal prevalence)
- the prevalence is highest for hand OA, then knee OA, and then hip OA, with other joints (e.g. feet, shoulders, elbows) affected less commonly
- although hand OA is most prevalent, it only occasionally causes significant disability, and symptomatic knee and hip OA present the major burden
- knee OA alone is the single most common cause of disability in those aged over 65, and knee and hip OA together affect >20% of the older population

With the increasing proportion of older people, large-joint OA will become an even more important healthcare problem.

Natural history of OA, and complications

The natural history of OA, as well as its complications, varies according to joint site.

Natural history of hip OA

Symptomatic hip OA commonly progresses, eventually requiring surgery. **Superior pole** OA (i.e. maximal cartilage narrowing superiorly) is the usual pattern in men and usually progresses more rapidly, with superolateral femoral head migration, than other patterns. **Medial** and **axial** hip OA, mainly restricted to women, often associate with nodal OA and have a better prognosis.

Natural history of knee OA

Symptoms are often intermittent and sometimes improve and the correlation between clinical outcome and radiographic change is less strong than at the hip. In those that worsen, clinical progression is variable but is usually only slowly progressive and the transition from mild to severe typically takes many years.

Natural history of hand OA

The overall prognosis is good. Nodal hand OA typically improves symptomatically once nodes are fully developed, often after several years. The exception is thumb-base involvement (first carpometacarpal joint and trapezioscapoid joint), which sometimes progresses to require surgery.

Complications of OA

Complications of OA include poorly controlled pain, joint restriction, and deformity.

Approach to diagnosing OA

The diagnosis of OA is essentially clinical and depends on a full history and examination. Patients are usually over age 40 and have predominantly usage-related or 'mechanical' (non-inflammatory) symptoms

(see 'Etiology of OA') in one or a few joints. More widespread signs of asymptomatic OA are commonly present in older patients. The main findings are those of joint damage, which may include:

- restricted movement, with or without pain
- bony joint enlargement
- coarse, palpable crepitus, sometimes also audible, on movement (mainly large joints)
- weakness and wasting of muscles acting over the joint
- deformity (instability is uncommon, due to capsular thickening)
- varying degrees of inflammation (effusion, increased warmth)

There may be joint-line tenderness, but periarticular tenderness is also common with knee and hip OA.

Diagnosing hip OA

Pain from hip OA is typically felt maximally deep in the anterior groin but may be referred over a wide area including the lateral thigh and buttock, anterior thigh, knee, and as far down as the ankle. Pain is mainly a problem when walking but can occur at rest and disturb sleep. The gait is typically an antalgic limp, with less time spent weight bearing on the arthritic side. The usual first sign is painful restriction of internal rotation with the hip flexed, although, with advanced OA, there may be more widespread restriction, a fixed flexion and external rotation deformity, and leg length narrowing due to marked cartilage and bone attrition.

Diagnosing knee OA

Knee OA is usually bilateral and symmetrical, mainly targeting the medial tibiofemoral and patellofemoral compartments. Pain is usually well localized to the affected compartment, and quadriceps weakness, with frequent 'giving way', is common. Patellofemoral OA causes localized anterior knee pain which is worse on inclines or stairs, particularly when going down. Examination may reveal restricted flexion/extension, coarse crepitus, joint-line tenderness (with or without periarticular tenderness, especially over the upper medial tibia region), and small-to-moderate knee effusions. With advanced OA, there may be bony swelling (femoral condyles, tibial plateaux), flexion and varus (bow-legged deformity), or, less commonly, valgus (knock-knee deformity).

Diagnosing nodal hand OA

Nodal hand OA is a polyarticular arthropathy of hand IPJs and is characterized by multiple Heberden's nodes (see Figure 266.1) and Bouchard's nodes (proximal IPJs), mainly affecting women and often with a family history. It causes intermittent pain and stiffness and is well localized to the involved joints; it commonly starts around menopause but becomes less symptomatic once nodes are fully developed. Typical end-stage deformity is lateral (ulnar/radial) deviation without instability. Thumb-base OA may cause more persistent, aching pain which is maximal at the thumb base but often radiates distally up the thumb and proximally to the wrist. Advanced cases may show

Figure 266.1 Heberden's nodes: posterolateral hard swellings of distal interphalangeal joints.

thumb-base 'squaring' caused by subluxation, osteophyte, and bone remodelling.

Other diagnoses that should be considered

OA and **gout** co-associate, so gout should be considered in patients with OA if they develop typical acute attacks of crystal synovitis, if they have more pronounced symptoms and signs of joint inflammation, or if their established finger nodes become more swollen and symptomatic in older age. Other types of **inflammatory arthritis** (e.g. rheumatoid arthritis, seronegative spondyloarthritis) can be distinguished usually by pronounced early morning and inactivity stiffness, involvement of several or multiple joints, and frequent systemic upset. However, some cases of OA may have a lesser inflammatory component, and combined synchronous symptoms in hands and other sites. The presence of predominantly soft tissue rather than bony swelling and high inflammatory markers in the blood are more suggestive of inflammatory arthritis.

In patients with apparently **young-onset OA** (occurring at age <45) affecting just one or a few joints, the usual explanation is overt prior trauma (e.g. meniscectomy, subchondral fracture). However, in younger people with oligo- or polyarticular 'OA', especially with an atypical distribution, the following may need consideration:

- epiphyseal or spondylo-epiphyseal dysplasia
- haemochromatosis (predilection for hips, knees, carpus, metacarpophalangeal joints, sometimes with chondrocalcinosis)
- acromegaly (OA signs, often with normal or increased range of movement)
- osteonecrosis (hips, shoulders, knees, elbows)

Calcium crystals, notably calcium pyrophosphate and basic calcium phosphates such as apatite, commonly occur in cartilage and synovial fluid of OA joints. **OA with calcium pyrophosphate deposition** predominates in older people and may show an atypical distribution and more inflammatory features, as well as superimposed acute calcium pyrophosphate crystal arthritis.

Apatite-associated destructive arthritis

Apatite-associated destructive arthritis occurs in elderly women, is almost totally confined to the hips, shoulders (Milwaukee shoulder), and knees, and has a poor outcome. It typically presents as painful, rapidly progressive OA with large cool effusions, progressive instability, and atrophic radiographic changes with marked cartilage and bone attrition. Although modest amounts of apatite are present in most OA joints, large amounts occur in this condition.

'Gold-standard' diagnostic test

For OA, the gold-standard diagnostic test is a good clinical assessment. Asymptomatic radiographic OA is very common, and only careful enquiry and examination can determine the cause of pain. Generally, imaging and special investigations are not required, as they do not confirm the clinical diagnosis or alter decision-making.

Acceptable diagnostic alternatives to the gold standard

With good clinical assessment, the diagnosis of OA should be clear. If there is diagnostic uncertainty in a patient with significant or progressive symptoms in a large joint, then imaging (e.g. radiographs, MRI) and/or arthroscopy may be helpful in confirming focal cartilage fibrillation/loss and in excluding other causes of joint pain (e.g. internal derangement, inflammatory arthritis).

Other relevant investigations

Other relevant investigations for OA include:

- a full clinical assessment, including BMI and blood pressure, with screening for common comorbidities
- a plain radiograph; OA changes include focal loss of joint space; marginal osteophytes; subchondral sclerosis; subchondral 'cysts'; and small osteochondral 'loose' bodies (Figure 266.2)

Figure 266.2 Diagram of a normal (left) and an osteoarthritic (right) joint, showing focal joint-space narrowing, adjacent subchondral sclerosis, marginal osteophyte, cysts, and osteochondral bodies typical of osteoarthritis.

With permission from MD.

- synovial fluid analysis, for patients with more inflammatory-component or progressive OA; OA synovial fluid is usually clear, viscous, and low in volume; calcium pyrophosphate crystals may be identified by polarized light microscopy
- OA causes no abnormality in routine blood tests (e.g. full blood count, erythrocyte sedimentation rate, C-reactive protein, autoimmune profile) but blood tests may be helpful to screen for comorbidities, such as chronic renal impairment, prior to selection of treatment

Prognosis, and how to estimate it

Risk factors for OA progression vary according to joint site:

- for hip OA: superior pole involvement on radiographs, high BMI, low BMD, and chondrocalcinosis
- for knee OA: synovial fluid calcium pyrophosphate crystals, varus, instability, and high BMI
- for hand OA: radiographic subchondral erosions (so-called erosive OA), IPJ instability, thumb-base involvement

Not all OA patients worsen and many improve symptomatically (especially those with hand and knee OA). Rapidly progressive joint damage is uncommon in OA. However, if OA is not treated adequately, the quality of a patient's life can significantly deteriorate from pain and loss of mobility, with negative effects on activities and physical and mental health.

Treatment and its effectiveness

Objectives of management

The accepted objectives of management in OA are:

- to educate the patient and provide access to information about OA and its treatment
- to control pain
- to optimize function and reduce participation restriction
- to beneficially modify the OA process

Management principles

Guidelines for OA concur in recommending the following principles:

- non-pharmacological measures should be central to the management plan of any patient with OA
- pharmacological agents are mainly adjunctive, optional treatments
- management of a patient with OA needs to be **individualized and patient centred**; there is no algorithm that is applicable to all patients, and a **holistic approach is essential**
- although research evidence often examines monotherapy, a **package of combined therapies** is used successfully in clinical practice; although the individual effect of each component may

be small, the combined effects of the whole programme may be clinically significant

The National Institute for Health and Clinical Excellence (NICE) examined all three major forms of evidence relating to OA management (research evidence, expert opinion and experience, and patient opinion and acceptability) and, additionally, considered cost-effectiveness estimations. They found that the data reinforced the concept that key factors to be taken into account when treating individual patients include:

- the patient's perceptions and knowledge of OA and its treatment
- balancing the efficacy and side effects of appropriate evidence-based interventions
- the costs, availability, and logistics of treatment delivery
- the presence of comorbid disease, and its treatment
- the treatments and coping strategies already tried by the patient
- the patient's daily activity requirements and work and recreational aspirations

Core treatment for OA

NICE concluded that the following core non-pharmacological measures should be considered for all patients with OA (Figure 266.3):

- access to information about OA and its treatment: this can be provided to the patient in a variety of ways, is completely safe, and can reduce pain and disability in the long term
- weight loss, if the patient is overweight or obese: this reduces the risk of progression and further incident OA, improves functioning, and may reduce pain and low affect in the long term
- local muscle-strengthening exercise and aerobic fitness training: these act in different ways to reduce pain and disability in large-joint OA; initial instruction and subsequent reinforcement by a physiotherapist is beneficial

There is good research evidence to support these lifestyle changes, all of which are safe, increase self-efficacy, and may avoid, or reduce, the requirement for drug therapy. Unfortunately, undue emphasis on short-term symptomatic treatments such as NSAIDs and coxibs may deflect attention from these more important long-term measures.

Initial analgesics to consider

The following two agents are can provide simple and safe analgesia and are recommended to be considered first for pain relief of peripheral joint OA (e.g. OA in the hands and/or knees):

- paracetamol: in view of its efficacy, safety, and cost effectiveness, paracetamol is the preferred oral analgesic for symptomatic OA
- topical NSAIDs (usually applied three times daily over the area of pain); these are safe, very popular with patients, and, when directly compared to the equivalent oral NSAID, may give equal analgesic benefit, with many fewer adverse events; since topical NSAIDs vary considerably with respect to formulation, additives, and carrier/delivery systems, the evidence for each type needs to be assessed separately

Additional non-surgical treatments to consider

The addition of other systemic or local pharmacological agents and physical treatments for OA should be considered, depending on individual patient factors. The following are recommended for consideration, in no specific hierarchical order:

- topical capsaicin
- oral NSAIDs/coxibs
- mild- to moderate-strength opioids
- intra-articular long-acting corticosteroids
- reduction of adverse biomechanical measures

Topical capsaicin

Topical capsaicin (0.025%, three times daily) can provide very safe analgesia and is especially suited to hand and knee OA. Effectiveness should be judged after 2 weeks of daily application. Any initial burning sensations usually wear off after the first few days.

Oral NSAIDs/coxibs

The magnitude of benefit from oral NSAIDs in OA is usually modest and at a similar or slightly higher level to paracetamol or topical NSAIDs. However, they have potential for serious toxicity from gut bleeding/perforation, renal impairment, cardiovascular safety, and drug interactions. NICE guidance recommends these be considered only after topical NSAIDs and paracetamol have been unsuccessful and after careful consideration of potential risk factors for toxicity. If used, they should be co-prescribed with a proton-pump inhibitor. These drugs are contraindicated in many older patients with OA.

Mild- to moderate-strength opioids

Mild- to moderate-strength opioids may be used alone but may also achieve additive symptomatic benefit for OA patients when combined with paracetamol. Unfortunately, constipation and CNS side effects are common in the older OA population and often limit the use of these drugs.

Intra-articular long-acting corticosteroids

The use of intra-articular long-acting corticosteroids is an excellent and safe treatment for patients with OA of the knee, thumb base, and other joints (ultrasound guidance is recommended for hip OA). Controlled studies confirm an often marked and rapid reduction in pain (within 24–48 hours), although it is usually short-lived (less than 6 weeks). Steroid injection is therefore best reserved to obtain temporary control of moderate-to-severe pain, for example to enable a patient to participate in a special event such as a holiday or wedding.

Reduction of adverse biomechanical measures

Reduction of adverse biomechanical measures, such as via pacing of activities, use of appropriate footwear (e.g. footwear with a thick, soft sole, no raised heel, and a broad forefoot), can help prevent

excessive loading of the OA joint. Local assistive devices (e.g. a walking stick, other walking aids, hinged knee braces, wedged insoles) are also safe options to consider.

Joint surgery

At present, no drug has a licence for disease modification in OA. Suitable patients who fail to respond to conservative measures should be referred for a surgical opinion. For patients with severe, disabling hip or knee OA, total hip arthroplasty and total knee arthroplasty are acknowledged as appropriate and reliable interventions to control pain, restore function, and improve quality of life. Evidence for their efficacy is based on uncontrolled, observational studies and several large cohort studies, but also on a wealth of expert and patient experience. Over 95% of joint replacements continue to function well into the second decade after surgery, and most provide lifelong, pain-free function. However, around one in five patients are not satisfied with their replacement, and a minority obtains little or no pain relief following this procedure. Importantly, referral should be made before there is prolonged and established functional limitation and severe pain, since these often compromise a good outcome from surgery. Age and comorbidity (e.g. obesity, smoking status) are not reasons to defer referral for a surgical opinion. Surgery may also be useful for refractory thumb-base OA (simple trapeziectomy) and when OA in other joints is resistant to medical treatments.

267 Rheumatoid arthritis

Karim Raza, Caroline Cardy, and Elizabeth Justice

Definition of rheumatoid arthritis

Rheumatoid arthritis (RA) is a chronic systemic inflammatory disorder. It is characterized by inflammation of the synovium with consequent cartilage and bone destruction. Extra-articular manifestations are not uncommon.

Symptoms of RA

Joint inflammation is the characteristic feature. Patients typically present with symmetrical joint pain and swelling of the small joints of the hands (metacarpophalangeal (MCP), proximal interphalangeal (PIP), and wrist; see Figure 267.1) and feet (metatarsophalangeal). However, larger joints (e.g. ankle, knee, and elbow) are frequently involved and, in very early disease, asymmetric joint involvement is not unusual. Early morning stiffness of at least an hour is usual. Joint symptoms may improve with gentle activity. Constitutional systems such as fatigue are common. Extra-articular manifestations are summarized in Table 267.1. They are generally associated with longstanding disease, being relatively rare at presentation.

Demographics of RA

The worldwide prevalence of RA is 0.5%–1.0%. It is two to three times more common in females than males. It affects all ethnic groups, although an increased prevalence has been found in certain Native American populations. Patients can present at any age, with a peak incidence at 35–50 years.

Etiology of RA

In established RA, the inflamed synovium consists of a network of leukocytes (T-cells, B-cells, and macrophages) and stromal cells (fibroblasts). Cytokine and cell-contact-dependent interactions drive the persistence of inflammation, with fibroblasts playing a central role in leukocyte retention and survival. Synovial fibroblasts and macrophages drive joint destruction. Although mechanisms underlying

disease persistence are reasonably well defined, those causing the disease remain elusive.

Susceptibility to RA is strongly associated with certain HLA-DRB1 alleles, which encode DR beta 1 molecules with a conserved amino acid sequence (the shared epitope) in the third hypervariable region. An additional important and non-HLA linked risk factor is a single nucleotide polymorphism in the gene encoding the protein tyrosine phosphatase non-receptor 22 (PTPN22). These genetic risk factors define a subgroup of RA which is characterized by the presence of anti-citrullinated protein/peptide antibodies (ACPAs). Smoking, the best defined environmental risk factor for RA, also associates with ACPA-positive disease, supporting the concept that ACPA-positive and ACPA-negative RA are discrete subsets with etiological differences.

Natural history of RA, and complications

RA is a chronic progressive condition. It typically follows a relapsing and remitting course, with patients experiencing less symptomatic periods followed by disease flares. It is a heterogeneous condition and can range from mild to severe disease. Untreated, the presence of persistent joint synovial inflammation damages the underlying cartilage and bone resulting in joint deformity. Inflammation of the synovial lining of tendon sheaths can result in tendon damage and rupture. Classic deformities in the hands and feet may develop, such as ulnar deviation of the MCP joints, swan neck and Boutonniere deformities of the fingers, and hammer toes (see Figure 267.1). Muscle atrophy, often due to disuse, is common. Functional impairment with limitation of activities of daily living is frequent. Depression is a common sequel.

Abnormal joint structure predisposes RA patients to both secondary osteoarthritis and joint infection. Septic arthritis is a serious complication with a high mortality, and diagnosis requires a high degree of clinical suspicion. RA patients are also at increased risk of osteoporosis due to a combination of chronic systemic inflammation, immobility, and corticosteroid use.

Cervical spine involvement can be seen but is uncommon. Joint and ligament destruction of the upper cervical spine can result in

Figure 267.1 Hands of a patient with rheumatoid arthritis. Synovitis of the wrists and metacarpophalangeal joints is apparent. Rheumatoid nodules (present here over the right middle finger proximal interphalangeal joint) and fixed deformity (present here at the right little finger proximal interphalangeal joint) are unusual in early disease. Please see colour plate section.

Table 267.1 Extra-articular manifestations of rheumatoid arthritis

Site	Manifestation
Cutaneous	Subcutaneous nodules Vasculitis (palpable purpura, ulcers)
Ocular	Episcleritis Scleritis Keratoconjunctivitis sicca
Pulmonary	Interstitial lung disease Pleural effusion Pulmonary nodules Bronchiolitis obliterans
Cardiac	Ischaemic heart disease Pericarditis Myocarditis Coronary vasculitis
Neurological	Entrapment neuropathies (e.g. carpal tunnel syndrome) Peripheral neuropathy Mononeuritis multiplex Cervical myelopathy
Haematological	Felty's syndrome (rheumatoid arthritis, splenomegaly, leukopenia)

atlantoaxial instability and subluxation. This in turn may result in impingement of the spinal cord (cervical myelopathy), presenting a neurosurgical emergency.

Pulmonary involvement is one of the most frequent extra-articular manifestations of RA. Clinically significant interstitial lung disease occurs in around 5%–10% of patients, although radiographic evidence of disease is more common. Systemic vasculitis is probably the most serious extra-articular complication of RA. It appears to be on the decline, with the current incidence estimated at two to three patients per million per year. Typical features include fever, weight loss, cutaneous ulceration, and mononeuritis multiplex. Clinically significant involvement of the endocardium, myocardium, and pericardium are rare but there is a significantly increased risk of cardiovascular disease, explaining, in large part, the reduced life expectancy associated with RA.

Approach to diagnosing the disease

Classification criteria exist to identify cases of RA for inclusion in clinical studies. The 1987 American College of Rheumatology criteria (Table 267.2) were developed using hospital-based populations with long-standing disease (mean disease duration, 7.7 years) and they are of limited use in the early phase of RA. Reliance on these classification criteria to diagnose RA in clinical practice will lead to under-recognition of early disease as erosive change and subcutaneous nodules

Table 267.2 Summary of the 1987 American College of Rheumatology classification criteria for rheumatoid arthritis

1	Morning Stiffness (lasting at least one hour)
2	Swelling (soft tissue/fluid) in at least three joint areas
3	Swelling (soft tissue/fluid) in hand joints (wrist, MCP or PIP joints)
4	Symmetric joint swelling
5	Rheumatoid nodules
6	Positive rheumatoid factor
7	Typical changes of RA (erosions and/or periarticular osteopenia) on plain radiographs of the hand and wrists

Patients must have at least 4 of these 7 criteria. Criteria 1–4 must have been present for at least 6 weeks.

Reproduced with permission from Arnett FC, Edworthy SM, Bloch DA, McShane DJ, Fries JF, Cooper NS, et al., The American Rheumatism Association 1987 revised criteria for the classification of rheumatoid arthritis, *Arthritis & Rheumatology*, Volume 31, Issue 3, pp. 315–324, Copyright © 1988 John Wiley and Sons and American College of Rheumatology.

usually reflect advanced disease, and up to 40% of RA patients are rheumatoid factor (RF) negative at presentation.

Early diagnosis of RA is important, allowing rapid initiation of disease-modifying anti-rheumatic drugs (DMARDs), to reduce progression of radiological damage and loss of function. In 2010, new criteria were developed in a collaboration between the American College of Rheumatology and the European League Against Rheumatism, to facilitate the early identification of RA patients. These criteria consist of four domains (pattern and extent of joint involvement, serology (for both RF and ACPAs), duration of synovitis, and acute phase reactants). These criteria identify patients with RA at an earlier stage of disease than the 1987 criteria although a greater proportion of patients whose disease may resolve without therapy (e.g. patients with post viral arthritis) will fulfil the 2010 criteria as compared with the 1987 criteria. It is however important to appreciate that the 1987 criteria and the 2010 criteria are classification criteria, primarily for research purposes, and formal diagnostic criteria have not been developed for RA.

A major challenge is to predict which patients with early undifferentiated arthritis (UA) will develop RA and which will experience spontaneous remission (~50% of all cases of UA). Predictive models exist which utilize clinical variables related to joint assessment (mostly variants of criteria from the 1987 set) and other variables such as age, sex, C-reactive protein (CRP) levels, and presence of ACPAs to determine the probability of a patient with UA developing RA.

A pragmatic approach to diagnosing RA requires taking a careful history from the patient, eliciting symptoms of an inflammatory arthritis, looking at the pattern of joint involvement and examining the patient for articular and extra-articular features. The duration of the symptoms is important; their presence for at least 6 weeks is predictive of the development of persistent inflammation.

Other diagnoses that should be considered

Non-inflammatory conditions such as osteoarthritis can present with polyarthralgia (pain in five or more joints), but significant synovitis and protracted early morning stiffness are uncommon. There are, however, many conditions which can associate with an inflammatory arthritis and should be considered in the differential diagnosis of RA.

Reactive arthritis

An infective antecedent can point to a reactive etiology.

Reactive arthritis is usually oligoarticular and asymmetric and often affects the large joints of the lower limbs. Pain and stiffness of the lower back and sacroiliac regions is common. Other symptoms may include urethritis and conjunctivitis. Infections are often of the gastrointestinal (*Salmonella* spp., *Shigella* spp., and *Yersinia* spp.) or genitourinary (*Chlamydia trachomatis* and *Neisseria gonorrhoea*) tracts. The articular symptoms usually resolve within 6 months and may require NSAIDs and intra-articular steroids in the short term. Rarely (<10% of cases), symptoms persist and DMARDs may be warranted.

Several viral infections (e.g. parvovirus B19) can be associated with an inflammatory arthritis. In these cases, the pattern of synovitis is more consistent with RA (with a symmetric inflammatory polyarthritis), although the disease usually resolves within a few months.

Crystal arthritides

Gout results from the intra-articular deposition of monosodium urate crystals. Episodes of arthritis are usually monoarticular (the great toe is most commonly affected) and begin suddenly, often overnight. The joint is very painful, warm, and swollen with overlying erythema. Occasionally, gout can present in an oligo- or polyarticular manner and this can cause particular diagnostic confusion. Pseudogout is caused by the deposition of calcium pyrophosphate dihydrate crystals into joints. The presentation of pseudogout is similar to that of gout, although the knees and wrists are most commonly affected.

Psoriatic arthritis

Psoriatic arthritis (PsA) can present in five distinct ways: asymmetric oligoarthritis, distal interphalangeal arthritis, axial arthritis, arthritis mutilans, and 'rheumatoid-like' disease. No widely accepted diagnostic criteria exist for PsA. Classification criteria for psoriatic arthritis (CASPAR), developed in 2006, require patients to have inflammatory

disease of peripheral joints, the spine, or the entheses, together with at least three of the following:

- a personal or family history of psoriasis
- psoriatic nail dystrophy
- RF negativity
- dactylitis (sausage digits)
- juxta-articular new bone formation (excluding osteophytes)

The skin changes can be quite subtle (e.g. the appearance of minor plaques around the scalp and umbilicus).

Ankylosing spondylitis

Approximately 30% of patients with ankylosing spondylitis (AS) will have a peripheral arthritis. The most commonly affected joints are the hips and the shoulders, although more distal joints such as the knees and ankles can be involved. A history of inflammatory back pain, early morning stiffness of the back, and reduced spinal movement, when in a young patient, should alert the clinician to the diagnosis of AS, which is confirmed if sacroiliitis is evident on radiographs.

Connective tissues diseases

Connective tissues diseases (CTDs) such as SLE can present with arthritis alongside other systemic features. The arthritis found in association with SLE usually affects the small peripheral joints and is rarely erosive; in addition, when joint deformity does occur, it is usually due to ligament laxity (termed Jaccoud's arthropathy). CTDs are typically associated with elevated serum levels of antinuclear antibodies.

Polymyalgia rheumatica

In the elderly, RA can be preceded by a polymyalgia rheumatica (PMR)-like onset. The presence of synovitis of the wrist, MCP, and PIP joints and the presence of ACPAs (which should be checked in the presence of synovitis) is predictive of PMR-like onset RA.

'Gold-standard' diagnostic test

There is no gold-standard diagnostic test for RA. Clinically detectable synovitis affecting the small joints of the hands and wrists in a symmetrical pattern in the absence of any other features associated with an alternative diagnosis is the most reliable way to diagnose RA. Identification of serological markers for RA aids the diagnosis. RF (an immunoglobulin molecule that binds to the Fc portion of immunoglobulin G) is routinely measured by ELISA or latex agglutination techniques and has a sensitivity of ~75% and specificity of ~85%. Its specificity is limited because of its detection in other autoimmune conditions such as Sjögren's syndrome, following infections (e.g. hepatitis B and EBV), and in the healthy ageing population. The development of cyclic citrullinated peptides for use in ELISAs has allowed the development of commercially available assays (e.g. the anti-CCP2 test) for the identification of patients with circulating ACPAs. The presence of anti-CCP2 has an extremely high specificity for RA (~95%), with a sensitivity approaching that of RF. Anti-CCP2 antibody testing combined with RF has a particularly high specificity (~98%) for RA.

Other relevant investigations

Blood tests

Measurements of the full blood count, renal function, and liver function are essential. Anaemia may be the consequence of chronic disease, and renal impairment can be seen as a consequence of therapy (e.g. with NSAIDs). Furthermore, many DMARDs affect these parameters, and renal impairment is associated with an increased risk of toxicity associated with several DMARDs (e.g. methotrexate). Consequently, measurement before and during therapy is required. Inflammatory markers (e.g. erythrocyte sedimentation rate (ESR) and CRP levels) are helpful in assessing the extent of disease activity and form a component of the widely used Disease Activity Score (DAS; see 'Treatment and its effectiveness'). Antinuclear antibodies should be checked if a connective tissue disease is suspected.

Urinalysis

Urinalysis can be useful to detect proteinuria, casts, and red cells, all of which may point to a nephritis associated with a CTD.

Synovial fluid analysis

Synovial fluid analysis should be carried out if the diagnosis is uncertain and fluid is available, particularly if a septic arthritis is suspected. A cell count on the fluid can identify if the process is inflammatory (>1000 white blood cells/mm³), and polarized microscopy allows the identification of crystals.

Imaging

Plain radiographs

Plain radiographs of the hands and feet should usually be performed in patients with a symmetrical inflammatory arthritis. Radiographic features of RA include periarticular osteopenia, joint space narrowing, and erosive change. The latter usually occurs after several years of the disease; however erosions are occasionally evident within the first year of symptoms, and the initial radiographs serve as a baseline for comparison with future films.

Ultrasound

There is increasing interest in the ability of ultrasound to detect and quantify synovitis and to detect early erosive change not evident on plain radiographs. Ultrasound detection of synovitis in clinically uninvolved joints may be useful in identifying patients who present with joint pain and features suggestive of inflammation (e.g. prolonged early morning stiffness) but without clinically apparent synovitis.

MRI

As with ultrasound, MRI can be used to detect and quantify synovitis. Bone marrow oedema (which may precede erosive change) and early erosions can also be visualized. MRI is not used routinely in a clinical setting and is less practical than ultrasound for imaging large numbers of joints.

Prognosis and how to estimate it

RA causes joint destruction and functional impairment. About a third of patients stop working within 5 years of diagnosis. In addition, life expectancy is reduced (by ~10 years); accelerated cardiovascular disease is an important cause of this. Seropositivity (for RF and, in particular, ACPAs) and high disease activity at presentation are markers of worse articular outcomes. The early control of disease activity is associated with improved outcomes, and delays in diagnosis or the commencement of DMARDs are associated with worse prognosis.

Treatment and its effectiveness

DMARD therapy should be initiated as soon as a diagnosis of RA is made. Methotrexate is the DMARD of choice for initial management and should be used unless there are specific contraindications (e.g. pregnancy is planned in the near future, pulmonary fibrosis is present). Alternative DMARDs include sulfasalazine, hydroxychloroquine, and leflunomide. There is evidence that a combination of DMARDs may be more effective than DMARD monotherapy in the initial management of RA, and some national guidelines advocate this approach. The time from the initiation of DMARDs to an effect being apparent is typically 8 weeks. Approaches to control synovitis in the interim include steroids (which can be administered orally, intramuscularly or intra-articularly); NSAIDs can also be helpful. The aim of therapy is to induce disease remission, and DMARD treatment should be escalated to achieve this. Disease activity should be monitored using the DAS28 score (which incorporates measures of clinically apparent joint swelling and tenderness in 28 predefined joints; the patient's perspective on the extent and impact of their inflammatory arthritis; and the ESR or CRP).

If disease cannot be adequately controlled with oral conventional synthetic DMARDs, biologic drugs or targeted synthetic DMARDs (e.g. Janus kinase (JAK) inhibitors) should be used. Potential biologic agents include those that target tumour necrosis factor alpha (e.g. etanercept, adalimumab, infliximab, golimumab and certolizumab

pegol), interleukin 6 (tocilizumab), B-cells (e.g. rituximab), and T-cell co-stimulation (abatacept). The high cost of these drugs means that regulatory authorities typically restrict their availability to subgroups of patients with difficult-to-control, severe RA.

Attention must be paid to management of the comorbidities that accompany RA, particularly cardiovascular disease. There is evidence that the effective control of synovitis reduces the risk of accelerated cardiovascular disease. However, modifiable cardiovascular risk factors such as smoking, hypertension, and hypercholesterolaemia should be appropriately managed.

Input from clinical nurse specialists, physiotherapists, occupational therapists, and podiatrists is essential and should be sought at an early stage.

268 Seronegative spondyloarthropathy

Hill Gaston

Definition of the disease

Spondyloarthropathies consist of several rheumatic conditions, initially grouped together on the basis of shared clinical features, later reinforced by their strong association with HLA-B27. The distinctive features are axial involvement, including sacroiliac joints, and enthesitis—inflammation at ligament and tendon insertions—together with certain extra-articular manifestations.

The presentation of a patient with combinations of inflammatory spinal pain, peripheral synovitis and/or enthesitis, and typical extra-articular manifestations, often with a family history, is characteristic (Box 268.1).

The principal spondyloarthropathies are:

- ankylosing spondylitis
- reactive arthritis
- psoriatic arthritis
- arthropathy of inflammatory bowel disease (enteropathic arthritis)
- undifferentiated spondyloarthropathy
- juvenile spondyloarthropathy (enthesitis-related arthritis)

Classification criteria have been developed which cover the entire spectrum of spondyloarthropathy. The Amor criteria and the European Spondyloarthropathy Study Group criteria for spondyloarthropathies provide helpful algorithms which can be used to aid diagnosis (Sieper et al., 2009; see Table 268.1 and Box 268.2).

Etiology of the disease

The etiology of spondyloarthropathies is not yet fully understood. A complex interaction between genetic (e.g. HLA-B27) and environmental factors (e.g. infective triggers) is clearly implicated. The role of HLA-B27 has not been resolved. Initial theories postulated that HLA-B27 presented an 'arthritogenic' peptide to (CD8⁺) T-cells, possibly a bacterial peptide resembling a component of the joint or enthesis, thereby initiating autoimmunity through molecular mimicry. Evidence of involvement of CD8⁺ T-cells and for autoimmunity has been sparse, and more recent theories take note of atypical features of HLA-B27 such as the ability of HLA-B27 heavy chains to be expressed in unusual forms on the cell surface, and how their inefficient folding and assembly in the endoplasmic reticulum affects cytokine production in antigen-presenting cells.

Box 268.1 Common characteristics of spondyloarthropathies

- inflammatory spinal pain
- sacroiliitis
- peripheral arthritis (asymmetrical, predominately lower limb)
- enthesopathy
- dactylitis
- skin lesions (psoriasis, balanitis, keratoderma)
- inflammatory bowel disease
- family history
- HLA-B27 positivity
- eye inflammation: uveitis or conjunctivitis
- urethritis and/or cervicitis; acute diarrhoea and vomiting

Adapted from Watts R, Clunie G, Hall F, Marshall T (2009). Oxford Desk Reference Rheumatology, Oxford University Press, Oxford UK

Table 268.1 Amor criteria for spondyloarthropathy*

Criterion	Points
<i>Clinical symptoms or past history</i>	
Lumbar or dorsal pain during the night, or morning stiffness of lumbar or dorsal spine	1
Asymmetric oligoarthritis	2
Buttock pain	1
• if affecting buttocks alternately	2
Sausage-like digit	2
Heel pain, or any other well-defined enthesopathy	2
Iritis	2
Non-gonococcal urethritis or cervicitis accompanying, or within 1 month of, the onset of arthritis	1
Acute diarrhoea accompanying, or within 1 month of, the onset of arthritis	1
Presence or history of psoriasis, balanitis, or inflammatory bowel disease (ulcerative colitis or Crohn's disease)	2
<i>Radiological findings</i>	
Sacroiliitis (Grade >2 if bilateral; Grade >3 if unilateral)	3
<i>Genetic background</i>	
Presence of HLA-B27, or familial history of ankylosing spondylitis, reactive arthritis uveitis, psoriasis, or inflammatory bowel disease	2
<i>Response to treatment</i>	
Good response to NSAIDs within 48 hours, or relapse of pain within 48 hours if NSAIDs discontinued	2

*A patient is considered to have spondyloarthritis if the sum of the points is 6 or more. A total point score of 5 or more is classified as probable spondyloarthritis.

Box 268.2 European Spondyloarthropathy Study Group criteria

Inflammatory spinal pain **or** synovitis (asymmetrical or predominately lower limbs), **and** one or more of the following:

- positive family history
- psoriasis
- inflammatory bowel disease
- urethritis, cervicitis, or acute diarrhoea within 1 month of the onset of arthritis
- buttock pain alternating between right and left gluteal areas
- enthesopathy
- sacroiliitis

Adapted by permission from BMJ Publishing Group LTD [The assessment of Spondyloarthritis international Society (ASAS) handbook: a guide to assess spondyloarthritis, J Sieper, M Rudwaleit, X Baraliakos, J Brandt, J Braun, R Burgos-Vargas, M Dougados, K-G Hermann, R Landewe, W Maksymowych and D van der Heijde, Annals of the Rheumatic disease, 2009;68;ii1-ii44]

Typical symptoms of the disease

While spondyloarthropathies share common clinical features, each condition has a distinct set of symptoms. However, inflammatory back pain is a central feature, common to all the spondyloarthropathies and the most typical symptom. The term is applied to back or neck pain present most days for more than 3 months (except in reactive arthritis, where it may be acute). The pain, which is insidious in nature, improves with exercise, and worsens or does not improve with rest. Pain occurring at night is consistent, and the age of onset is typically before 40 years.

Ankylosing spondylitis presents with typical symptoms of inflammatory back pain in a young person (often male) and is typically insidious, often leading to diagnosis being delayed for many years. Associated symptoms, requiring careful questioning, include:

- alternating buttock pain
- enthesitis (e.g. heel pain), with plantar fasciitis or Achilles tendonitis
- decreased spinal movements
- fatigue or systemic features
- history of uveitis (painful red eye), inflammatory bowel disease, or psoriasis.

Reactive arthritis is characterized by inflammatory spinal pain and/or peripheral arthritis **within** 4–6 weeks of specific infections, principally bacterial gastroenteritis and genitourinary infection (usually chlamydia). Gastrointestinal symptoms vary in severity according to the triggering infection—severe with shigella, often mild with yersinia—while chlamydia infection is often asymptomatic, although symptoms of urethritis/cervicitis should be sought. Enthesitis is common, and dactylitis (diffuse swelling of a digit) may occur. Extra-articular features include mucocutaneous lesions, such as oral or penile ulcers, and keratoderma blennorrhagica (hyperkeratotic psoriatic lesions on hands and feet), as well as conjunctivitis or, occasionally, uveitis.

Psoriatic arthritis symptoms include peripheral inflammatory arthritis, which is often asymmetric and can occur with or without inflammatory back pain. Peripheral arthritis is subdivided into oligo- and polyarthritis, with the latter being commonest, and some patients have only distal interphalangeal joint disease. The presence of psoriasis at presentation or at any time in the past, or a family history of psoriasis, is key. Other spondyloarthropathy features, including dactylitis and enthesitis, occur frequently.

Arthropathy of inflammatory bowel disease (enteropathic arthritis) may present with typical axial and peripheral features of spondyloarthropathy, in addition to intestinal symptoms or a known diagnosis of inflammatory bowel disease. Other extra-intestinal manifestations include mouth ulcers, fatigue, systemic features, erythema nodosum, and pyoderma gangrenosum.

Undifferentiated spondyloarthropathy can include any of the symptoms of other forms of spondyloarthropathy, but the condition fails to satisfy classification criteria for any of them.

Juvenile spondyloarthropathy symptoms can include the spectrum of clinical characteristics of adult spondyloarthropathy. They tend to occur in children over 10 years of age, mostly boys, often with a family history of spondyloarthropathy.

Demographics of the disease

Spondyloarthropathy may present at any age but young adults are primarily affected. The prevalence of spondyloarthropathy as a whole is 1%–2% in the Caucasian population.

Natural history, and complications of the disease

Spondyloarthropathies are often progressive chronic conditions with long-term complications, both musculoskeletal and extra-articular. However, they may also be self-limiting, as in reactive arthritis, with 75% cases in remission at 2 years. Spondyloarthropathies often follow a relapsing–remitting course with short or extended symptom-free periods.

In ankylosing spondylitis, chronic spinal inflammation leads to bony ankylosis, resulting in progressive restriction of spinal movement.

Significant morbidity and mortality results from spinal disease, and complications arising include spinal fractures with or without neurological complications. The fractures occur due to spinal osteoporosis, which is often marked and related to chronic inflammation. Iritis may result in visual loss, while less common manifestations, including conduction defects, aortic valve incompetence, upper lobe lung fibrosis, renal complications, and amyloidosis, may result in poor outcomes.

Reactive arthritis is self-limiting in the majority of cases but may relapse or persist. Persistent arthropathy, axial involvement, and extra-articular manifestations may represent evolution into other forms of spondyloarthropathy in predisposed patients.

Psoriatic arthritis complications depend on the pattern of joint involvement and its severity, with a wide spectrum of outcomes ranging from mild, non-destructive polyarthritis to severe joint destruction with bone loss (arthritis mutilans; rarely seen now). Progressive joint destruction, or axial disease combined with significant skin disease, can produce significant disability and considerable psychosocial morbidity.

Approach to diagnosing the disease

The diagnosis of spondyloarthropathies can be difficult, due to the evolution of symptoms over time, as well as the overlap between different forms. In approaching the diagnosis of the disease you should:

- take a thorough history to identify **key or classical features** (e.g. a classical description of inflammatory back pain, with dactylitis or monoarticular joint swelling, and a preceding history of recent diarrhoea, is highly suggestive of reactive arthritis)
- consider the appropriate demographic group (e.g. ankylosing spondylitis primarily affects males under 40)
- perform relevant clinical examination looking for characteristic joint and enthesal inflammation, together with extra-articular manifestations (see Figure 268.1)
- obtain appropriate investigations, including radiology and blood tests, as well as others

Radiology includes plain X-rays and/or MRI of the following:

- sacroiliac joints: note that
 - plain X-rays demonstrate chronic changes and are not suitable for early diagnosis but are useful in established disease; sclerosis, erosions, bony bridges, and ankylosis are common findings
 - MRI is helpful in early diagnosis, with demonstration of bone marrow oedema, capsulitis, synovitis, and enthesitis, as well as of later progression to the more chronic changes
- spine: look for ankylosis, syndesmophytes, and spinal fractures in more advanced disease
- affected peripheral joints: look for evidence of periarticular osteopenia, erosions, and chronic joint deformity, as well as periosteal reaction or enthesitis (Sieper et al., 2009)

Blood tests can be used as follows:

- to find evidence of the acute phase response (e.g. elevated erythrocyte sedimentation rate (ESR) or C-reactive protein levels (CRP) and decreased haemoglobin levels)
- HLA-B27 typing
- to find serological evidence of infection by organisms associated with reactive arthritis (e.g. yersinia, campylobacter, and salmonella)

Other tests include:

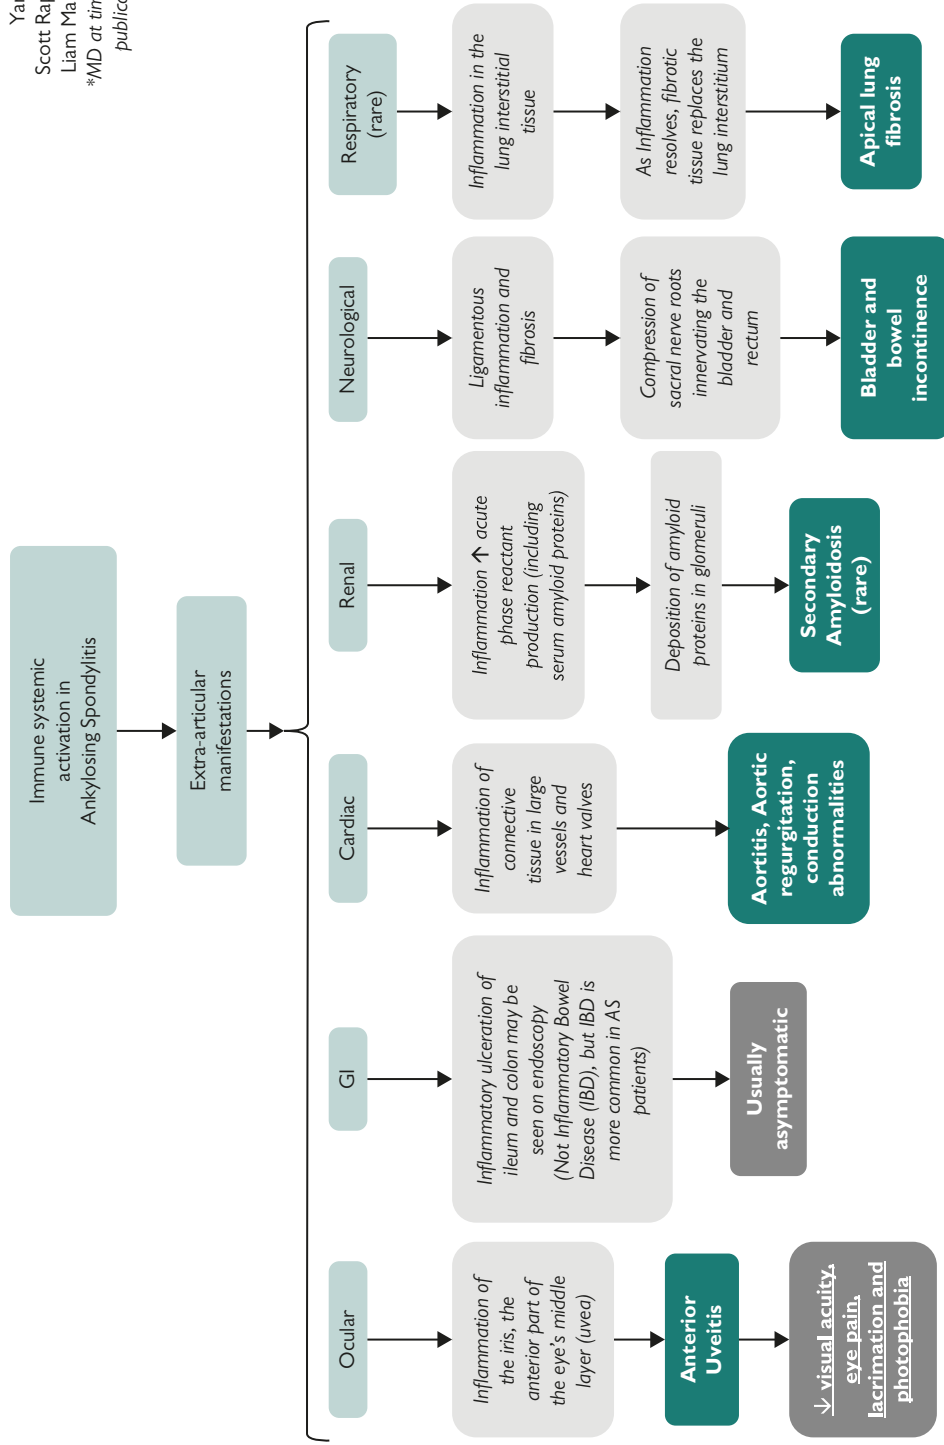

- culture of stool, and culture/PCR of urine or genital tract, with or without rectal swabs for organisms associated with reactive arthritis
- skin biopsy, where clinical diagnosis is uncertain
- colonoscopy, to investigate possible inflammatory bowel disease

Other diagnoses that should be considered

Given the wide and varied presentation of spondyloarthropathies, other inflammatory arthritides (e.g. rheumatoid arthritis) should be considered when inflammatory peripheral arthritis predominates. A monoarthritis should always raise the suspicion of septic arthritis

or a crystal arthropathy. Sarcoidosis can also present with dactylitis and/or enthesitis. In addition, mechanical back pain and diffuse idiopathic skeletal hyperostosis are diagnoses to be considered as alternatives to inflammatory spinal pain.

'Gold-standard' diagnostic test

There is no 'gold-standard' diagnostic test for seronegative spondyloarthritis; diagnosis is made using the framework detailed in 'Approach to diagnosing the disease'.

Acceptable diagnostic alternatives to the gold standard

As there is no 'gold-standard' diagnostic test for seronegative spondyloarthritis, there are also no acceptable diagnostic alternatives to the gold-standard test; instead, diagnosis is made using the framework detailed in 'Approach to diagnosing the disease'.

Other relevant investigations

For seronegative spondyloarthritis, only investigations used to clarify the diagnosis and exclude the differentials are relevant.

Prognosis and how to estimate it

The prognosis of seronegative spondyloarthritis depends principally on its form; for any given disease, severity varies considerably, and it is not currently possible to give an accurate prognosis.

In the early phase of ankylosing spondylitis, elevated acute phase reactants, hip involvement, and osteoporosis are markers of poor prognosis. As the disease progresses, extra-articular manifestations, spinal fracture, continued elevation of ESR/CRP, and anaemia are associated with a worse outcome.

Patients who have reactive arthritis and are HLA-B27 positive tend to have more severe and more persistent disease, with a higher likelihood of axial disease and extra-articular manifestations.

Indicators of poor outcome in psoriatic arthritis include polyarticular involvement, early decline in functional abilities, and HIV positivity (Watts et al., 2009).

Treatment and its effectiveness

Management of spondyloarthritis is according to disease subset, its activity, and the possibility of progression.

Initial conservative management includes NSAIDs and non-pharmacological measures such as education and physiotherapy. An escalation in treatment is often required and tailored according to the presence of peripheral or axial disease, as well as severity of symptoms and initial response to treatment.

Recently, international criteria for the management of ankylosing spondylitis have been established (Sieper et al., 2009). Both pharmacological and non-pharmacological management should run in parallel. In recent times, the use of anti-tumour necrosis factor (anti-TNF) agents has dramatically improved the quality of life of patients with ankylosing spondylitis, as these agents treat both peripheral and axial symptoms as well as extra-articular manifestations.

Psoriatic arthritis treatment aims for peripheral joint remission, symptom control, and prevention of disease progression. Initial management with NSAIDs, escalating to both oral and intra-articular steroids, is appropriate. Disease-modifying anti-rheumatic drugs (DMARDs), including methotrexate, sulfasalazine, and leflunomide, have been shown to be beneficial for peripheral disease but **not** for axial disease. For polyarthritis, very active oligoarthritis, or enthesopathy, DMARDs are introduced early in disease, as for the treatment of rheumatoid arthritis, although the rationale for doing this is less well established than in rheumatoid arthritis. Anti-TNF agents, used when DMARDs fail to control peripheral disease, treat both peripheral and axial symptoms. Additional biologic drugs, especially those targeting IL-17 and IL-23 are proving useful in psoriatic arthritis and ankylosing spondylitis.

The management of reactive arthritis involves treatment of the triggering infection, although there is no definitive evidence that this approach affects the outcome of the condition. Arthritis is controlled initially with full-dose NSAIDs, aspiration of affected joints, and intra-articular steroids. Short courses of oral steroids may be required. If synovitis fails to resolve by 4–6 months, particularly in HLA-B27-positive patients, or if there are flares, treatment with DMARDs (e.g. sulfasalazine, methotrexate, or leflunomide) may be used. In a proportion of these cases, the DMARD can be discontinued after ~2 years if the patient is asymptomatic, but 5%–10% of reactive arthritis patients have persistent disease which continues to require DMARD treatment; in severe cases, the use of anti-TNF agents can be effective without unmasking latent infection.

Spondyloarthritis associated with inflammatory bowel disease requires optimal management of the colitis/enteritis. NSAIDs may aggravate inflammatory bowel disease and worsen anaemia and so must be used with caution. Intra-articular steroids are useful for individual active joints. DMARDs such as sulfasalazine and methotrexate must be tailored to treat both joint and bowel symptoms (note that drugs that are used in inflammatory bowel disease but do not contain a sulfonamide component (e.g. mesalazine) are ineffective for arthritis). When DMARDs are inadequate, anti-TNF drugs can be used and are also effective for Crohn's disease.

Undifferentiated spondyloarthritis can also be managed via these strategies, according to whether peripheral or axial disease predominates.

Juvenile spondyloarthritis requires a multidisciplinary approach to treatment, which generally uses the same agents as for adult disease. As for all patients with juvenile arthritis, monitoring for eye disease is recommended, although anterior uveitis, which is the commonest complication, is usually symptomatic.

269 Systemic lupus erythematosus

Robert Stevens and Chee-Seng Yee

Definition and etiology of the disease

Systemic lupus erythematosus (SLE) is a chronic multisystem autoimmune inflammatory disorder of unknown etiology. Numerous abnormalities within the innate and adaptive immune system have been described. The hallmark of this disease is B-cell hyperactivity resulting in autoantibody production, abnormal T-cell function, impaired clearance of immune complexes (resulting in their deposition in tissues), complement activation, and defective cellular apoptosis. However, these abnormalities of the immune system are not uniform across patients and within the same patient at different stages of the disease, resulting in heterogeneity in its presentation and progress. The pathogenesis is complex, involving genetic, environmental, and hormonal factors.

Genetic factors

SLE is considered a complex genetic trait, with a lack of correlation between phenotype and genotype. The genetic basis is supported by the fact that there are ethnic differences in disease incidence/prevalence, the disease has a tendency for familial clustering, a higher concordance rate in monozygotic twins than in dizygotic twins, and several genetic associations. Genetic factors are a major determinant of susceptibility to the disease and possibly of disease severity as well.

Environmental factors

Environmental factors are thought to be involved in triggering the autoimmune process in a genetically susceptible individual. The three main environmental factors are UV light, infections (especially with Epstein–Barr virus), and drugs. Many drugs have been implicated in drug-induced lupus but the most recognized are procainamide and hydralazine.

Hormonal factors

The role of oestrogen is suggested by the strong female preponderance of this disease, the timing of disease onset (occurring mainly after puberty), and the increased risk of flare of disease during pregnancy.

Demographics and epidemiology

SLE has been reported worldwide, with differences in the incidence, prevalence, pattern of organ involvement, and severity of disease across different ethnic groups. Any age can be affected but it predominantly affects women of childbearing age, with a female to male ratio of 11:1. This is an uncommon disease, with a prevalence of about 1 in 2000 and an incidence of 7 per 100 000 per year amongst adult women in the UK. It is more common in those of Afro-Caribbean and South Asian descent than in those of Caucasian descent. There appears to be a trend towards increasing prevalence and incidence of the disease over time.

Clinical manifestations

SLE is a chronic disease that is characterized by periods of exacerbations with variable course. Recognized triggers of flare of disease activity are UV light, infection, oestrogen, and stress.

SLE is a multisystem disease that can affect any parts of the body, with protean manifestations. As any organ system can be involved, the disease may present in variable combinations of organ system manifestations that can vary both between patients and within the same patient over time.

Fatigue

Fatigue is the most common symptom of SLE and can be disabling. Another contributory factor is fibromyalgia, which is common in SLE patients and tends to be persistent, even when the disease is under controlled.

Non-specific mucocutaneous manifestations

Non-specific mucocutaneous manifestations of SLE include:

- mucosal ulcers (nasal or oral)
- photosensitivity
- cutaneous vasculitis (e.g. purpuric rash, urticaria, subcutaneous nodules, and ulcers)

Lupus-specific mucocutaneous lesions

Lupus-specific mucocutaneous lesions are characterized by deposition of IgG along the dermal–epidermal junction (known as positive lupus band test); this occurs both in obvious lesions and in normal-appearing skin. Lesions can be classified into three types:

- acute cutaneous lupus, which can be erythematous (including malar rash), exanthematous (resembling erythema multiforme), or bullous
- subacute cutaneous lupus, which can be psoriasiform or annular/polycyclic
- chronic cutaneous lupus, which can lead to scarring; this commonly manifests as discoid lesions with follicular plugging or, in the case of lupus profundus, as tender subcutaneous nodules

Musculoskeletal disorders

Musculoskeletal manifestations of SLE include:

- arthralgia/myalgia, which is very common but non-specific
- inflammatory arthritis, which is usually non-erosive
- Jaccoud's arthropathy, which is a deforming arthropathy that can be rheumatoid-like but is correctable

Serositis

Both pleurisy and pericarditis can occur in SLE.

Renal manifestations

Renal involvement in SLE is commonly asymptomatic or non-specific, especially in the early stages. It is most commonly picked up with urine dipstick testing (e.g. as proteinuria, haematuria, and/or pyuria). Hence, it is crucial that urine dipstick testing is performed as part of the routine assessment of SLE patients.

Haematological disorders

The following haematological disorders are common in SLE but are usually asymptomatic:

- anaemia (this is usually the anaemia of chronic disease)
- leucopenia with neutropenia and/or lymphopenia
- thrombocytopenia

Approach to diagnosis

There is no specific diagnostic test for SLE. Although classification criteria have been devised by the American College of Rheumatology, the criteria were developed for research studies and are not intended for diagnostic purposes.

The two key features of SLE are systemic involvement and the presence of autoantibodies.

Evidence of systemic involvement

As there is no diagnostic test, a good clinical assessment is essential to determine the pattern of systemic involvement. A high index of suspicion is required, particularly when there is multisystem involvement and the following common manifestations of SLE are present:

- mucocutaneous features (especially mouth ulcers, alopecia, rash, and photosensitivity)
- inflammatory arthritis
- renal involvement (as indicated by proteinuria and active urinary sediment)
- pleurisy or pericarditis
- haematological manifestations (especially haemolytic anaemia, leucopenia, neutropenia, lymphopenia, and thrombocytopenia)

As renal and haematological involvement may be asymptomatic, it is important to perform the following tests during the diagnostic workup:

- a urine test for proteinuria and active urinary sediment (a urine dipstick test on its own is not sufficient, as it is not accurate and is associated with a high level of false-positive results)
- a full blood count

Other investigations will be dictated by patient's presentation and are performed mainly to exclude other causes for the manifestation(s). These include:

- biopsy (e.g. renal biopsy, skin biopsy)
- imaging (e.g. MRI of the head/spine; high-resolution CT of the chest)
- electrophysiological tests (e.g. nerve conduction studies, electromyography)
- blood tests (e.g. Coomb's test, hepatitis serology, muscle enzymes)

Presence of autoantibodies

As B-cell hyperactivity is the hallmark of SLE, the absence of autoantibodies in an untreated patient makes the diagnosis unlikely (good negative predictive value). Autoantibodies that are specific to SLE are anti-double-stranded DNA antibodies (present in 60%–70% of cases) and anti-Sm antibodies (present in 10%–30% of cases).

Autoantibodies to be tested for include:

- antinuclear antibody (ANA), which is the most common type of autoantibody found in SLE (>95% of cases)
- extractable nuclear antigens, including anti-Ro, anti-La, and anti-Sm
- anti-double-stranded DNA antibodies
- antiphospholipid antibodies (anticardiolipin antibodies and lupus anticoagulant)

Two further important points to note regarding autoantibodies are that:

- ANA is not specific to SLE, as many different conditions can cause a positive result for the ANA test, and up to 5% of the normal population is positive for ANA; hence, a positive ANA test does not equate to a diagnosis of SLE
- a patient being treated for SLE can become negative for autoantibodies

Other diagnosis to be considered

As SLE is a multisystem disease with protean manifestations, of which most are not specific to the disease itself, the clinical presentation can mimic other conditions.

The main differential diagnoses are other multisystem conditions, in particular:

- sepsis (it is important to note that SLE patients have an increased risk of infection (in part due to immunosuppressive treatment) and that infection itself could trigger a flare of disease activity)
- primary systemic vasculitis (e.g. antineutrophil cytoplasmic antibody-associated vasculitis, and Behçet's syndrome)
- other connective tissue diseases (note that it is not uncommon for there to be overlapping features of other connective tissue

diseases (e.g. Sjögren's syndrome, dermatomyositis, polymyositis, and systemic sclerosis), termed overlap syndrome and mixed connective tissue disease)

- antiphospholipid syndrome (note that this can occur as part of SLE (secondary antiphospholipid syndrome))
- sarcoidosis
- other inflammatory arthritis (such as rheumatoid arthritis and seronegative spondyloarthritis)

Assessment of disease

In assessing SLE patients, there are three outcome domains to be considered: disease activity, damage, and the health status of patient. Disease activity is the immune-mediated process that is potentially reversible or 'inflammation', while damage is an irreversible process or 'scarring'. Damage can be a result of uncontrolled disease activity but, more commonly, it is multifactorial, due to a combination of disease activity, treatment, and comorbidities. Examples of damage are myocardial infarctions, joint erosions, and scarring alopecia. The health status of the patient is the person's sense of physical, emotional, and social well-being associated with the disease or its treatment; it is perhaps better known as the 'health-related quality of life'. These three outcome domains are managed differently; hence, it is crucial to differentiate these domains with regards to attribution of manifestations. In particular, immunomodulators are used to treat manifestations of disease activity but not manifestations of damage or health-related quality of life.

Assessing SLE can be challenging, particularly when trying to attribute clinical manifestations to disease activity. This is due to the lack of a good biomarker and the complexity of this multisystem disease, with its myriad of presentations that can vary between patients and within the same patient over time.

Complications

Organ damage

Organ damage caused by SLE includes skin scarring (including scarring alopecia), avascular necrosis of bone (especially hip), chronic kidney disease, and pulmonary fibrosis.

Premature atherosclerosis

SLE patients are at much higher risk of developing cardiovascular disease, compared to the general population. Furthermore, in women, the premenopausal protective effect for cardiovascular disease appears to be abrogated by the disease. It should be noted that the traditional Framingham risk calculator underestimates the risk of cardiovascular disease in SLE patients. It has been suggested that SLE patients should be considered to have the same level of risk for cardiovascular disease as those with diabetes mellitus.

Malignancy

SLE patients have an increased risk of cancer, compared to general population. This is even more so for:

- non-Hodgkin's lymphoma
- lung cancer
- cervical cancer

Pregnancy comorbidities

Comorbidities seen during pregnancy in SLE patients include:

- neonatal lupus syndrome
- pregnancy loss
- flare of disease activity

Prognosis

Before the advent of corticosteroids, the 5-year survival for SLE was less than 55%. Over the last few decades, survival has improved considerably; currently, the 10-year survival rate is ~90%. However, SLE patients still have much lower life expectancy, compared to the general population, and this is most pronounced in those under the

age of 45. The most common causes of deaths are cardiovascular disease, infection, and malignancy. The more damage a patient has accumulated, the higher is the risk of death.

Treatment

The treatment of SLE is aimed at controlling disease activity (through immunomodulation), prevention of development of damage, and management of complications.

The treatment options for disease activity are:

- symptomatic treatment (e.g. NSAIDs)
- antimalarials (e.g. hydroxychloroquine, chloroquine, and mepacrine)
- corticosteroids (e.g. topical, oral, intra-lesional, or parenteral)
- immunosuppressives (in particular, azathioprine, methotrexate, mycophenolate, and cyclophosphamide)
- biologicals (e.g. rituximab and belimumab)
- plasmapheresis
- IV immunoglobulins
- others (e.g. thalidomide, prasterone, dapsone, and retinoids)

The management of disease activity is tailored to the patient, and the major determinant of treatment option is the level of disease activity. Severe disease activity is defined as manifestations that are life-threatening or result in significant organ dysfunction, such as seizure, nephrotic syndrome, and inability of the patient to perform the activities of daily living. On the other end of the spectrum, mild disease activity refers to minor manifestations that cause some discomfort but leave the patient able to continue with their daily routines.

Severe disease activity requires treatment with high-dose corticosteroids and usually with immunosuppressives and/or biologicals. IV immunoglobulins and plasmapheresis are mainly reserved for life-threatening manifestations.

Moderate disease activity is commonly treated with lower doses of corticosteroids, and immunosuppressives may be added in. Antimalarials are also commonly used and have been shown to be

effective in controlling mucocutaneous manifestations and inflammatory arthritis. For certain manifestations, local treatment with corticosteroids (and occasionally immunosuppressives) could be used, such as intra-articular injection of methylprednisolone for inflammatory arthritis, and corticosteroid cream for discoid rash. Thalidomide, retinoids, and dapsone are used for the treatment of refractory skin lesions. Prasterone (an androgen) has been shown to have steroid-sparing properties and reduce the number of SLE flares.

Mild disease activity usually only requires symptomatic treatment. Due to their low toxicity, antimalarials are also used to treat recurrent or persistent milder mucocutaneous and musculoskeletal manifestations. There is also evidence supporting the ubiquitous use of hydroxychloroquine, as long-term usage is associated with lower cardiovascular events and improved survival.

Apart from managing disease activity, other measures that deserve special mention are:

- photoprotection (in the form of protective clothing and high-factor (at least SPF 30) sun cream); many SLE patients are photosensitive, and UV light is a well-recognized trigger of disease activity flare
- smoking cessation; this is important, as SLE patients have an increased risk of cardiovascular disease and lung cancer
- aggressive management of cardiovascular risk factors, given the increased risk of cardiovascular disease in SLE
- physiotherapy and occupational therapy; these non-pharmacological measures may help with inflammatory arthritis, fatigue, and fibromyalgia (commonly associated with SLE)

270 Crystal arthropathy

Michael Doherty

Definition of crystal arthropathy

Three main crystals associate with arthritis:

- monosodium urate (MSU)
- calcium pyrophosphate, the usual cause of cartilage calcification (**chondrocalcinosis (CC)**)
- basic calcium phosphates (BCP), including hydroxyapatite

Gout is a true crystal deposition disease caused by MSU. **Calcium pyrophosphate crystal deposition (CPPD)** is the umbrella term for calcium pyrophosphate deposition. Calcium pyrophosphate crystals cause inflammation in **acute calcium pyrophosphate crystal arthritis** and **chronic calcium pyrophosphate crystal inflammatory arthritis**. However, osteoarthritis (OA) commonly associates with calcium pyrophosphate (**OA with CPPD**) and BCP crystals and, in this context, it is unclear if the crystals are pathogenic.

Aetiology of crystal arthropathy

Crystals only form when the saturation point for crystallization is exceeded. A serum uric acid (SUA) of 360 $\mu\text{mol/L}$ (6.0 mg/dl) approximates to the saturation point for MSU. Extracellular pyrophosphate (ePPi) in cartilage is the key determinant of CPPD but cannot be measured clinically.

Uric acid (UA), produced from xanthine by xanthine oxidase (XO), is the end product of purine breakdown. About two-thirds of UA is produced endogenously, with the rest coming from dietary purines. UA is excreted mainly via the kidney. Risk factors for SUA elevation and gout are shown in Table 270.1. MSU preferentially deposits in and around joints, mainly feet, knees, hands, and elbows.

Risk factor	Mechanism
Hereditary, genetic risk	Inefficient renal excretion (>95%) due to polymorphisms related to URAT1 and other renal ion transporter systems Overproduction due to purine enzyme mutation (very rare)
Metabolic syndrome: <ul style="list-style-type: none"> • obesity • hypertension • hyperlipidaemia • insulin resistance 	Increased endogenous production Reduction in renal efficiency of urate clearance Reduction in renal efficiency of urate clearance Reduction in renal efficiency of urate clearance
Dietary risk factors: <ul style="list-style-type: none"> • excessive beer, spirits • diet high in red meat, shellfish, offal, etc. 	Increased exogenous uric acid production (from guanosine in beer) Increased exogenous uric acid production
Renal impairment: <ul style="list-style-type: none"> • chronic renal impairment • drugs (e.g. diuretics, ciclosporin) 	Reduction in renal efficiency of urate clearance Reduction in renal efficiency of urate clearance
Ageing, osteoarthritis	Altered balance between tissue inhibitors/promoters for crystal nucleation and growth (particularly in osteoarthritis) Age-related reduction in renal efficiency of urate clearance

Most ePPi comes from the breakdown of nucleoside triphosphates, although some comes from intracellular pyrophosphate transported outside by the progressive ankylosis protein homolog protein, which is encoded by the ANKH gene. ePPi is converted to orthophosphate by alkaline phosphatase (with magnesium as a cofactor). Moderate increases in ePPi stimulate, but high levels inhibit, BCP crystal formation, making ePPi a key regulator of normal mineralization (bones, teeth) and an inhibitor of unwanted BCP (cartilage, urine, saliva). High ePPi levels in hyaline and fibrocartilage predispose to CPPD, particularly in knees. Risk factors for CPPD are shown in Table 270.2.

Typical symptoms of crystal arthropathy, and less common symptoms

Acute gout and acute calcium pyrophosphate crystal arthritis

Acute gout and acute calcium pyrophosphate crystal arthritis present as acute mono-arthritis characterized by:

- rapid-onset severe pain ('worst ever'), reaching a maximum in 6–24 hours
- marked tenderness—even to clothing over the joint
- swelling, effusion, increased warmth (\pm erythema)

The 'attack' resolves within a few days or weeks. Occasionally, several joints are affected simultaneously. Milder, short-lived episodes

Table 270.2 Risk factors for calcium pyrophosphate dihydrate deposition disease

Risk factor	Mechanism
Ageing	Unclear; possible increase in pyrophosphate, alteration of tissue factors
Prior joint insult	Increased production of ePPi by hypertrophic chondrocytes
Osteoarthritis	Increased production of ePPi by hypertrophic chondrocytes Reduction in normal crystal inhibitors (e.g. proteoglycans) Increase in promoters of crystallization (e.g. osteopontin, collagen X)
Metabolic disease: <ul style="list-style-type: none"> • haemochromatosis • hyperparathyroidism • hypophosphatasia • hypomagnesaemia 	All of the following lead to increased ePPi levels: Iron inhibits alkaline phosphatase; iron is also a nucleating factor Ca^{++} inhibits alkaline phosphatase and increases the ionic product Reduced breakdown of ePPi to orthophosphate Reduced breakdown of ePPi by alkaline phosphatase
Diuretics	Possibly due to diuretic-induced hypomagnesaemia
Familial CPPD	Rare; families with polyarticular CC and variable arthropathy Some cases due to a mutation in the ANKH (CCAL2) gene

Abbreviations: CPPD, calcium pyrophosphate dihydrate deposition; ePPi, extracellular pyrophosphate.

Figure 270.1 Tophi on a finger (A) and toes (B) of a patient with chronic tophaceous gout; in some cases, the white colour of monosodium urate crystals can be seen, allowing distinction from rheumatoid nodules.

('petite attacks') are common. Gout also causes acute self-limiting bursitis, tenosynovitis, or cellulitis.

Acute gout targets the first metatarsophalangeal joint (1MTPJ), the mid-foot, the ankle, the knee, the wrist, the metacarpophalangeal (MCP) joints, the finger joints, and the elbows. First attacks often affect feet (1MTPJ especially). Acute calcium pyrophosphate crystal arthritis targets knees and, less commonly, wrists, MCP joints, elbows, and shoulders (rarely, it occurs in other joints).

Both conditions can be triggered by intercurrent illness, surgery, or joint trauma. Initiation of urate-lowering drugs can trigger gout.

Recurrent and chronic tophaceous gout

Acute attacks usually recur, become more frequent, and involve new sites. With continuing deposition, enlarging crystal concretions (tophi) damage cartilage and bone, causing chronic pain, stiffness, and disability. Tophi may be clinically evident (Figure 270.1) mainly over extensor surfaces of feet, knees, hands, and elbows, sometimes discharging pus-like fluid containing white MSU. Occasionally, tophi occur without preceding attacks.

OA with CPPD and chronic calcium pyrophosphate crystal inflammatory arthritis

OA with CPPD is identical to OA (see Chapter 266). It may be asymptomatic or associate with usage-related pain and functional limitation, with or without superimposed attacks. Chronic calcium pyrophosphate crystal inflammatory arthritis resembles OA but with more inflammation (stiffness, effusion) and involvement of joints (e.g. wrists, MCP joints) typically affected by OA.

Demographics

Gout is the most common inflammatory arthritis in men, and in women aged >65. Overall prevalence is 1.4% but it is more common

in men (~5:1) and increases with age, rising to 7% prevalence in older men. Usually, it presents after age 30 and is rare before the menopause (oestrogen is uricosuric).

Knee CC is rare under the age of 50, but increases from 4% in those aged 50–60 to 20% in those over the age of 80, affecting both sexes equally.

Natural history, and complications of crystal arthropathy

Untreated gout typically progresses through an asymptomatic phase to presentation with acute gout, to recurrent attacks separated by asymptomatic inter-critical periods and, finally, to chronic tophaceous gout. Evolution is slow, usually taking several decades to reach tophaceous gout.

Renal complications include nephrolithiasis (UA, but also common calcium stones) and chronic interstitial nephritis (due to MSU deposition). There is growing evidence that high SUA is an independent risk factor for cardiovascular disease and renal impairment, unrelated to MSU deposition.

The natural history of CPPD is variable. Acute attacks usually occur only a few times in a patient's lifetime.

Approach to diagnosing crystal arthropathy

For typical attacks, clinical features alone permit a diagnosis. Factors such as age, the joint involved, comorbidity, drug history and presence of joint damage/OA usually allow distinction between MSU and calcium pyrophosphate. However, for atypical presentations and chronic disease, crystal identification becomes increasingly important.

Other diagnoses that should be considered

For typical attacks, the following require consideration:

- septic arthritis (see Chapter 271): this is subacute and progressive; crystals and sepsis can coexist so, if sepsis is suspected, microbiological investigation should still be undertaken, despite identification of synovial fluid (SF) crystals
- psoriatic and reactive arthritis (see Chapter 264)
- palindromic rheumatism: this produces progressive synovitis with adjacent inflammation and erythema over 1–3 days and which resolves in a similar amount of time
- acute haemarthrosis: this presents a tense effusion with no periarticular inflammation or erythema

Both chronic gout and chronic calcium pyrophosphate crystal inflammatory arthritis may superficially resemble rheumatoid arthritis. A routine search for SF crystals should be undertaken in any undiagnosed inflammatory arthritis.

'Gold-standard' diagnostic test

The gold-standard test for crystal arthropathy is crystal identification in SF or a tophus aspirate, using compensated polarized microscopy. MSU crystals are needle shaped and brightly birefringent (negative sign). Calcium pyrophosphate crystals are smaller rhomboid crystals with weak (positive) or no birefringence.

Acceptable diagnostic alternatives to the gold standard

In the absence of crystal confirmation, diagnosis may be supported by imaging, via radiographs or ultrasound.

Radiographs

Radiographs may show CC (Figure 270.2) and, occasionally, synovial/capsular calcification, with or without OA. Radiographic changes in gout occur late and are mainly those of OA. More specific are para-articular 'punched-out' cortical erosions and well-defined cysts (intra-osseous tophi; see Figure 270.3).

Figure 270.2 Radiographic knee chondrocalcinosis, with predominant involvement of the fibrocartilaginous menisci.

Ultrasound

Crystals can produce hyperechogenicity in cartilage of peripheral joints (e.g. 1MTPJs, knees). MSU occurs at the cartilage surface, whereas CPPD targets the midzone, allowing differentiation. Elevated SUA is a strong risk factor for gout but is unhelpful in diagnosis.

Other relevant investigations

Renal function and SUA are relevant to gout, and X-rays of clinically abnormal joints help assess damage. Metabolic screening (of e.g. calcium, ferritin, alkaline phosphatase, magnesium) is recommended for polyarticular CC and for patients presenting with CC but are under the age of 60.

Prognosis, and how to estimate it

A therapeutic aim for troublesome gout is elimination of the crystals. Therefore, the main prognostic factor, as for CPPD, is the degree of irreversible damage (OA), which is assessed clinically and by radiographs.

Treatment and its effectiveness

Acute gout and acute calcium pyrophosphate crystal arthritis

The following treatments are recommended for acute gout and acute calcium pyrophosphate crystal arthritis:

- **rest the joint** and apply **ice packs**
- if possible, **aspirate** the affected joint and **inject a long-acting steroid** (e.g. methylprednisolone) into it; this gives rapid relief and

Figure 270.3 Foot radiograph of a patient with chronic tophaceous gout, showing cyst-like bone lesions, cortical erosion, cartilage loss, and the soft-tissue swelling of the clinically evident tophi.

is the preferred treatment in hospital; also, the SF can be examined to confirm the diagnosis and, if required, exclude sepsis

- **an oral NSAID** (naproxen, diclofenac, etoricoxib) plus a proton-pump inhibitor; although widely used, NSAIDs often are contraindicated in older patients due to comorbidity (e.g. renal impairment) or concomitant drugs (e.g. warfarin, diuretics)
- **oral colchicine**: this alkaloid effectively reduces the neutrophil-driven inflammation of crystal synovitis; its main side effect of severe diarrhoea is dose dependent, so use only low doses (0.5 mg twice daily for elderly or those with renal impairment; up to three to four times daily for more robust patients)
- **systemic steroids**: A short course of prednisolone (e.g. 15 mg daily for 5 days) or single intramuscular injection of methylprednisolone (80–120 mg) may be considered for oligo-articular attacks and for patients with contraindications or intolerance to NSAIDs and colchicine, if aspiration/injection is impractical

Long-term management of gout

The following are recommended for long-term management of gout:

- provide **information** concerning gout and its management
- **modify risk factors** (e.g. advise the patient to lose weight, if the patient is obese, and to reduce excessive intake of high purine foods, beer, and spirits; stop diuretics, if possible)
- initiate **urate-lowering therapy** (ULT): this is indicated for frequent attacks, tophi, joint damage, or urolithiasis, with the aim being to reduce SUA well below the saturation point (360 $\mu\text{mol/l}$), to prevent further crystal formation and dissolve existing crystals; with the increasing realization that microtophi (seen on ultrasound or MRI) are widespread at first presentation, the trend is towards earlier definitive treatment (see 'Drugs used for ULT')
- **treat comorbidity**: treatment of hypertension, hyperlipidaemia, and insulin resistance helps lower SUA; the antihypertensive losartan and the lipid-lowering agent fenofibrate have an additional beneficial, mild, uricosuric effect

Drugs used for ULT

Allopurinol, the first-line ULT, is a purine, non-specific, XO inhibitor that reduces UA production. Its active metabolite oxypurinol is excreted via the kidney. The recommended starting dose is 100 mg daily (50 mg in older patients or those with impaired renal function). SUA is measured every 3–4 weeks, and the dose increased in 100 mg increments (50 mg if elderly or with renal impairment) until this is achieved (maximum 900 mg; algorithms allow calculation of the lower maximum in renal impairment). The reduction in UA following the initiation of ULT can partially dissolve MSU crystals, encouraging crystal shedding and triggering of attacks. The patient should be warned of this and told to continue ULT if an attack occurs. This triggering is minimized by slow upward titration, or by prophylaxis for several months using daily colchicine (0.5 mg 12 hourly) or NSAIDs (plus a proton-pump inhibitor). Allopurinol is usually well tolerated but 10% of patients experience gastrointestinal upset, a headache, or mild rashes. Vasculitic rashes and allopurinol hypersensitivity syndrome are serious but rare (mainly in renal impaired patients). Annual SUA monitoring is advised to ensure continuing effective treatment. ULT usually is required indefinitely.

Febuxostat is a new, non-purine, specific XO inhibitor that undergoes hepatic metabolism, requiring no dose adjustment in renal impairment. It is recommended for patients intolerant of allopurinol or in whom allopurinol is contraindicated (e.g. those with severe renal disease). It usually provokes attacks at the starting dose (80 mg), so prophylaxis with colchicine/NSAID is advised. It has just two dose options (120 mg daily being the maximum).

Uricosuric drugs such as **sulfinpyrazone** or **prebenedicid** have restricted availability, are less efficient than allopurinol, require high fluid intake to avoid UA crystallization in renal tubules, and are contraindicated in patients with renal impairment or urolithiasis. Benzbromarone (50–200 mg daily) is a very efficient uricosuric that is effective and safe in mild-to-moderate renal impairment. Because

of rare hepatotoxicity, it has limited availability and is used on a named-patient basis.

Long-term management of CPPD

No drugs are available to modify CPPD. Principles of management of OA with CPPD are identical to those for OA (see Chapter 266). For frequent flares or chronic calcium pyrophosphate crystal inflammatory arthritis, oral colchicine (0.5 mg twice daily) or NSAIDs (plus a proton-pump inhibitor) may be helpful, and hydroxychloroquine or low-dose methotrexate is sometimes used empirically.

271 Infection of joints and bones

Benjamin Bloch

Definition and classification of infection

Infection can arise at any time within the bone or soft tissues, and sepsis should always be a consideration in the assessment of an acutely swollen, painful joint. A variety of organisms can be responsible (Table 271.1). An acute infection is an orthopaedic emergency, and prompt assessment should always be sought.

Infection can affect either joints (septic arthritis) or bones (osteomyelitis).

Septic arthritis can affect either a native joint or a prosthetic one, and the presentation can be acute or chronic. Similarly, osteomyelitis can present acutely or chronically, and can be due to haematogenous spread (particularly affecting the long-bone metaphyses in children, and the vertebral bodies in adults), direct inoculation via trauma or surgery, or communication from a contiguous infection site.

Presentation

Acute septic arthritis is usually as a result of haematogenous infection, and presents typically with pain, swelling, restriction of movement,

and fever. Care should be taken when assessing patients who are immunocompromised or taking immunosuppressive drugs, as their inflammatory response may be depressed and they may not show the same pyrexia, leucocytosis, or elevation of serum C-reactive protein (CRP) levels as healthy patients would.

Chronic septic arthritis is rare, but generally presents with a more prolonged course, and may not have as dramatic a rise in blood parameters as acute septic arthritis. In these cases, other organisms such as mycobacteria or atypical bacteria should be considered.

Septic arthritis following a prosthetic joint replacement may present acutely or some time after the joint is replaced. Acute presentations tend to be due to local contamination and will present with a hot, red, swollen joint that is usually discharging, as the wound will not have healed fully. A joint replacement that becomes infected many years down the line will have done so either due to an indolent infection that has been present long term or, more commonly, due to haematogenous spread from another source.

Acute osteomyelitis is more commonly seen in children, and is typically rapid in onset and severe in presentation. In adults, acute osteomyelitis is usually associated with the presence of lowered resistance to infection due to conditions such as diabetes or immunosuppression secondary to chemotherapy, HIV/AIDS, or post-transplant suppression. Finally, those patients with sickle cell disease are at risk of developing salmonella osteomyelitis.

The cardinal signs of osteomyelitis are pain, fever, acute tenderness, and inflammation. Radiographs will look normal in the acute stage, and MRI is more useful for diagnosing osteomyelitis.

Chronic osteomyelitis is a more indolent process, often as a result of open fractures, surgery, or (in the foot) the sequelae of diabetes. Patients often have sinuses or scars of previous surgery, and will present with recurrent flares of pyrexia, redness, and swelling. The sinus may recommence drainage. The overlying tissues are usually of poor quality and are tethered and adherent to the underlying bone. Plain radiographs may show the typical features of sequestrum (sclerotic, avascular bone) and involucrum (new bone formation as a result of lifting of the periosteum). Further imaging can include the use of radioisotope bone scans, which will show increased uptake in osteomyelitis, and CT and MRI scans are both useful for preoperative planning, particularly in showing the surgeon how much of the bone is involved.

Diagnosis and treatment

In all cases, a history and examination is the starting point. The duration of symptoms is important, as it may guide further treatment.

Haematological investigations include a full blood count, particularly looking at the white-cell count, the erythrocyte sedimentation rate, and the CRP level.

Radiological investigations generally start with plain X-rays of the affected bone or joint. However, acute infections rarely show any changes on plain radiographs and, if there is any doubt about the diagnosis, an MRI scan can be beneficial. For those joints that are deep, such as the hip, an ultrasound scan can help to detect an effusion and these can also be aspirated under ultrasound guidance.

Septic native joints should be aspirated, and the fluid sent for microscopy, culture, and sensitivities. It is possible to aspirate the shoulder, elbow, wrist, knee, and ankle without radiological guidance. The aspirate should also be examined for the presence of crystals, but infection can, of course, coexist with crystal arthropathy. Whenever possible, aspiration should be done before the administration of antibiotics, to maximize the possibility of identifying the responsible organism.

Infection	Acute	Chronic
Native septic arthritis	<ul style="list-style-type: none"> <i>Staphylococcus aureus</i> <i>Streptococcus pyogenes</i> <i>Neisseria gonorrhoeae</i> Gram-negative organisms such as <i>Escherichia coli</i> and <i>Pseudomonas</i> sp. (in elderly and immunocompromised patients) Anaerobes (rare; associated with penetrating trauma) 	<p>In addition to those causing acute infection:</p> <ul style="list-style-type: none"> <i>Mycobacterium tuberculosis</i> low-virulence organisms (e.g. coagulase-negative staphylococci)
Prosthetic septic arthritis	<ul style="list-style-type: none"> <i>Staphylococcus aureus</i> (including MRSA) <i>Streptococcus pyogenes</i> <i>Enterococcus</i> sp. Gram-negative organisms (<i>Escherichia coli</i>, <i>Pseudomonas</i> sp.) 	<ul style="list-style-type: none"> Coagulase-negative staphylococci <i>Staphylococcus aureus</i> (including methicillin-sensitive <i>Staphylococcus aureus</i> and MRSA) <i>Streptococcus pyogenes</i> <i>Enterococcus</i> sp. Corynebacteria Gram-negative bacilli Anaerobes Mycobacteria (rare) Fungi (even rarer) <p>Up to 50% of infections are polymicrobial</p>
Osteomyelitis	<ul style="list-style-type: none"> <i>Staphylococcus aureus</i> <i>Streptococcus pyogenes</i> <i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i> type b (more common in children) Salmonella (sickle cell) <i>Pseudomonas aeruginosa</i> 	<ul style="list-style-type: none"> <i>Staphylococcus aureus</i> <i>Streptococcus pyogenes</i> <i>Escherichia coli</i> <i>Pseudomonas aeruginosa</i> <i>Enterobacter</i> sp. <p>>30% of infections are polymicrobial</p>

A prosthetic joint should never be aspirated without prior orthopaedic discussion, and it should be done in the operating theatre in a clean environment.

The treatment of an acutely septic joint is urgent washout and debridement. In the case of an acutely infected prosthetic joint, it may be possible to salvage the joint by aggressive debridement and exchange of easily accessible parts such as polyethylene bearings. A chronically infected prosthetic joint is likely to need a planned revision, and this may be done either as a single-stage revision or as a two-stage revision in which the first stage is removal of the infected replacement and implantation of a temporary spacer, usually with antibiotics given both locally and systemically.

In the case of osteomyelitis, a biopsy of the infection may be required for diagnostic purposes, and this drainage can also be therapeutic. Acute osteomyelitis, if appropriately treated, can be arrested before it becomes chronic and the bone becomes necrotic. Chronic osteomyelitis exhibits the radiographic changes of sequestrum (dead bone) and involucrum (an encasing sheath of live bone walling off the sequestrum). Both acute and chronic osteomyelitis require prolonged antibiotic treatment, usually of 6 weeks' duration, and microbiological advice should be sought for the most appropriate regime.

The treatment of chronic osteomyelitis is more complex and requires aggressive surgical debridement of dead bone, removal of

infected metalware, and reconstruction of any bony defects. This may involve the use of bone grafts or Ilizarov frames and bone transport techniques, and amputation may be required.

Chronic osteomyelitis is commonly seen in diabetic patients with ulcers, particularly affecting the metatarsal heads and the calcaneus. In these patients, following initial debridement, the most appropriate treatment may be amputation. Depending on the level of involvement, it may be possible to preserve part of the foot through the use of ray or partial foot amputations but, if not, then a below-knee amputation would be required. Management of these patients is best done in a multidisciplinary setting, with input from diabetologists, vascular surgeons, orthopaedic surgeons, prosthetists, and podiatrists.

272 Vasculitis

Raashid Luqmani, Joanna Robson, and Ravi Suppiah

Definition of the disease

The vasculitides are a heterogeneous group of disorders that can range from mild inflammation of blood vessels in the skin, to organ- and life-threatening diseases. The term 'vasculitis' is a pathological description of blood vessel wall inflammation which leads to ischaemia and infarction of the target organs. Definitions and classifications of the primary vasculitides are mainly based on the predominant calibre of the blood vessels involved but incorporate clinical, pathological, and laboratory features. The secondary vasculitides usually occur in the context of other connective tissue diseases and are not discussed further in this section. Anti-glomerular basement membrane disease (previously known as Goodpasture's disease) is not usually included in the primary vasculitides, but has compatible clinical features of pulmonary capillaritis and glomerulonephritis. The definitions of the most common types of primary vasculitis proposed at the Chapel Hill Consensus Conference are given in Table 272.1. The 2013 conference advised changing the name of 'Wegener's granulomatosis' to 'granulomatosis with polyangiitis' and 'Churg–Strauss syndrome' to 'eosinophilic granulomatosis with polyangiitis'.

Aetiology

Hepatitis B virus infection and resulting immune complex deposition cause hepatitis B-related polyarteritis nodosa. Hepatitis C virus is the cause of over 90% of mixed cryoglobulinaemia. For all other forms of primary vasculitis, the aetiology is unknown. Antineutrophil cytoplasm antibodies (ANCA) may play a role in the pathogenesis of granulomatosis with polyangiitis and microscopic polyangiitis; furthermore, *Staphylococcus aureus* infection is implicated in granulomatosis with polyangiitis.

Symptoms

The specific symptoms listed in Table 272.2, some alone but especially in combination, may occur in patients with systemic vasculitis. Non-specific symptoms such as fever, weight loss, myalgia, and arthralgia are common but not very discriminatory between vasculitis and other conditions.

Demographics of the disease

The demographics depend on the type of systemic vasculitis and are shown in Table 272.3. We have not discussed isolated cutaneous vasculitis any further.

Natural history and complications of the disease

The natural history of untreated multisystem vasculitis is likely to be death within the first year. Giant cell arteritis can result in blindness from ischaemic optic neuropathy (in up to 60% of untreated patients) and, rarely, strokes (especially brainstem infarcts). Takayasu arteritis can result in limb ischaemia, gangrene, aortic aneurysms, aortic dissections, aortic ruptures, and potentially death. The ANCA-associated vasculitides, especially granulomatosis with polyangiitis and microscopic polyangiitis, are associated with acute renal failure from rapidly progressive glomerulonephritis and/or fulminant pulmonary haemorrhage due to pulmonary capillaritis, both of which can cause long-term morbidity such as end-stage renal failure or death.

Anti-glomerular basement membrane disease has a poor untreated outcome (most cases will die from pulmonary haemorrhage and renal failure). Henoch–Schönlein purpura in childhood is usually a self-limiting disease but in adulthood only has 75% survival at 5 years (mainly due to renal disease). Kawasaki disease is associated with coronary aneurysms in 15%–25% of untreated cases; in the short term, these can be fatal in approximately 1% of children and, in the remainder, can cause complications such as premature atherosclerotic disease and myocardial infarction later in life.

Approach to diagnosing the disease

A high index of suspicion and a detailed history and examination are the key to making an accurate diagnosis. In some cases, the clinical history will be highly suggestive. For example, in a patient over the age of 50, the presence of a new-onset headache with temporal tenderness, jaw claudication, and raised inflammatory markers implies giant cell arteritis. The temporal artery biopsy is the gold standard but may be negative in around 40% of cases. Other patients can present in a more subtle way, and a systematic approach is required to evaluate these patients. It is very important to consider the differential diagnoses and avoid either missing the diagnosis of vasculitis or, conversely, over-diagnosing it. Ideally, patients should be identified before potentially organ- and life-threatening features develop, but this can be difficult in the early, non-specific stages. A systematic approach to the patient with multisystem disease is shown in Table 272.4. Where there is a high clinical suspicion, a biopsy from an affected organ is then obtained to try and confirm the diagnosis and exclude other conditions.

Other diagnoses that should be considered

The differential diagnosis of primary systemic vasculitis is wide and can be broadly divided into the following categories: infection (e.g. HIV, subacute bacterial endocarditis), malignancy (e.g. lymphoma, atrial myxoma), drugs (e.g. cocaine, ciprofloxacin, allopurinol), secondary forms of vasculitis (e.g. connective tissue diseases), and other miscellaneous causes (e.g. thromboembolic disease, calciphylaxis, amyloid).

'Gold-standard' diagnostic test

Although there is no gold standard for the diagnosis of systemic vasculitis, a confirmatory biopsy from an involved organ such as a kidney, a lung, or a nerve demonstrating active vasculitis should always be sought. In practice, histological findings can be inconclusive, possibly because of early disease, patchy involvement in a particular organ, or the effect of previous treatment with corticosteroids or other immunosuppressants (which may have to be started promptly in severe life- or organ-threatening disease). Histology and microbiology are important to exclude as far as is possible the presence of infection or malignancy but clinical judgement is still essential, especially when the pathological findings are non-diagnostic. ANCA testing can be very helpful in patients with clinical features suggestive of systemic small vessel vasculitis, but its indiscriminate use is not encouraged. Furthermore, not all cases of granulomatosis with polyangiitis, eosinophilic granulomatosis with polyangiitis, or microscopic polyangiitis are ANCA positive. There is a strong association between the presence of anti-glomerular-basement-membrane antibodies and Goodpasture's disease.

Table 272.1 Definitions for vasculitides adopted by the 2012 International Chapel Hill Consensus Conference on the Nomenclature of Vasculitides

CHCC2012 name	CHCC2012 definition
Large vessel vasculitis (LVV)	Vasculitis affecting large arteries more often than other vasculitides. Large arteries are the aorta and its major branches. Any size artery may be affected.
Takayasu arteritis (TAK)	Arteritis, often granulomatous, predominantly affecting the aorta and/or its major branches. Onset usually in patients younger than 50 years.
Giant cell arteritis (GCA)	Arteritis, often granulomatous, usually affecting the aorta and/or its major branches, with a predilection for the branches of the carotid and vertebral arteries. Often involves the temporal artery. Onset usually in patients older than 50 years and often associated with polymyalgia rheumatica.
Medium vessel vasculitis (MVV)	Vasculitis predominantly affecting medium arteries defined as the main visceral arteries and their branches. Any size artery may be affected. Inflammatory aneurysms and stenoses are common.
Polyarteritis nodosa (PAN)	Necrotizing arteritis of medium or small arteries without glomerulonephritis or vasculitis in arterioles, capillaries, or venules, and not associated with antineutrophil cytoplasmic antibodies (ANCA).
Kawasaki disease (KD)	Arteritis associated with the mucocutaneous lymph node syndrome and predominantly affecting medium and small arteries. Coronary arteries are often involved. Aorta and large arteries may be involved. Usually occurs in infants and young children.
Small vessel vasculitis (SVV)	Vasculitis predominantly affecting small vessels, defined as small intraparenchymal arteries, arterioles, capillaries, and venules. Medium arteries and veins may be affected.
ANCA-associated vasculitis (AAV)	Necrotizing vasculitis, with few or no immune deposits, predominantly affecting small vessels (i.e., capillaries, venules, arterioles, and small arteries), associated with myeloperoxidase (MPO) ANCA or proteinase 3 (PR3) ANCA. Not all patients have ANCA. Add a prefix indicating ANCA reactivity, e.g., MPO-ANCA, PR3-ANCA, ANCA-negative.
Microscopic polyangiitis (MPA)	Necrotizing vasculitis, with few or no immune deposits, predominantly affecting small vessels (i.e., capillaries, venules, or arterioles). Necrotizing arteritis involving small and medium arteries may be present. Necrotizing glomerulonephritis is very common. Pulmonary capillaritis often occurs. Granulomatous inflammation is absent.
Granulomatosis with polyangiitis (Wegener's) (GPA)	Necrotizing granulomatous inflammation usually involving the upper and lower respiratory tract, and necrotizing vasculitis affecting predominantly small to medium vessels (e.g., capillaries, venules, arterioles, arteries, and veins). Necrotizing glomerulonephritis is common.
Single-organ vasculitis (SOV)	Vasculitis in arteries or veins of any size in a single organ that has no features that indicate that it is a limited expression of a systemic vasculitis. The involved organ and vessel type should be included in the name (e.g., cutaneous small vessel vasculitis, testicular arteritis, central nervous system vasculitis). Vasculitis distribution may be unifocal or multifocal (diffuse) within an organ. Some patients originally diagnosed as having SOV will develop additional disease manifestations that warrant redefining the case as one of the systemic vasculitides (e.g., cutaneous arteritis later becoming systemic polyarteritis nodosa, etc.).
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss) (EGPA)	Eosinophil-rich and necrotizing granulomatous inflammation often involving the respiratory tract, and necrotizing vasculitis predominantly affecting small to medium vessels, and associated with asthma and eosinophilia. ANCA is more frequent when glomerulonephritis is present.
Immune complex vasculitis	Vasculitis with moderate to marked vessel wall deposits of immunoglobulin and/or complement components predominantly affecting small vessels (i.e., capillaries, venules, arterioles, and small arteries). Glomerulonephritis is frequent.
Anti-glomerular basement membrane (anti-GBM) disease	Vasculitis affecting glomerular capillaries, pulmonary capillaries, or both, with GBM deposition of anti-GBM autoantibodies. Lung involvement causes pulmonary hemorrhage, and renal involvement causes glomerulonephritis with necrosis and crescents.
Cryoglobulinemic vasculitis (CV)	Vasculitis with cryoglobulin immune deposits affecting small vessels (predominantly capillaries, venules, or arterioles) and associated with serum cryoglobulins. Skin, glomeruli, and peripheral nerves are often involved.
IgA vasculitis (Henoch-Schönlein) (IgAV)	Vasculitis, with IgA1-dominant immune deposits, affecting small vessels (predominantly capillaries, venules, or arterioles). Often involves skin and gastrointestinal tract, and frequently causes arthritis. Glomerulonephritis indistinguishable from IgA nephropathy may occur.
Hypocomplementemic urticarial vasculitis (HUV) (anti-C1q vasculitis)	Vasculitis accompanied by urticaria and hypocomplementemia affecting small vessels (i.e., capillaries, venules, or arterioles), and associated with anti-C1q antibodies. Glomerulonephritis, arthritis, obstructive pulmonary disease, and ocular inflammation are common.
Variable vessel vasculitis (VVV)	Vasculitis with no predominant type of vessel involved that can affect vessels of any size (small, medium, and large) and type (arteries, veins, and capillaries).
Behçet's disease (BD)	Vasculitis occurring in patients with Behçet's disease that can affect arteries or veins. Behçet's disease is characterized by recurrent oral and/or genital aphthous ulcers accompanied by cutaneous, ocular, articular, gastrointestinal, and/or central nervous system inflammatory lesions. Small vessel vasculitis, thromboangiitis, thrombosis, arteritis, and arterial aneurysms may occur.
Cogan's syndrome (CS)	Vasculitis occurring in patients with Cogan's syndrome. Cogan's syndrome characterized by ocular inflammatory lesions, including interstitial keratitis, uveitis, and episcleritis, and inner ear disease, including sensorineural hearing loss and vestibular dysfunction. Vasculitic manifestations may include arteritis (affecting small, medium, or large arteries), aortitis, aortic aneurysms, and aortic and mitral valvulitis.
Vasculitis associated with systemic disease	Vasculitis that is associated with and may be secondary to (caused by) a systemic disease. The name (diagnosis) should have a prefix term specifying the systemic disease (e.g., rheumatoid vasculitis, lupus vasculitis, etc.).
Vasculitis associated with probable aetiology	Vasculitis that is associated with a probable specific aetiology. The name (diagnosis) should have a prefix term specifying the association (e.g., hydralazine-associated microscopic polyangiitis, hepatitis B virus-associated vasculitis, hepatitis C virus-associated cryoglobulinemic vasculitis, etc.).

Vessel size	Symptoms	Comments
Large vessel	New-onset/unaccustomed headache Jaw claudication Tongue pain Limb claudication Sudden onset of blindness	Any of these symptoms alone should raise the suspicion of vasculitis
Medium vessel	New-onset hypertension Abdominal ischaemic symptoms Ischaemic chest pain Polyneuropathy	Hypertension in itself is not very discriminatory, but in combination with abdominal ischaemia and polyneuropathy is very suggestive
Small vessel	Pulmonary haemorrhage or haemoptysis New-onset asthma or treatment-resistant asthma Chronic upper respiratory symptoms (e.g. nasal crusting, discharge) Sensory or motor peripheral neuropathy (mononeuritis multiplex) Haematuria, proteinuria, and/or oliguria Inflammatory arthritis Purpura	A combination of these symptoms is suggestive of vasculitis but other causes such as infection should be excluded first

Disease	Incidence per million population	Age distribution	Notes
Giant cell arteritis	37–350 (for patients older than 50 years of age)	Almost always over the age of 50	Incidence is in the higher range in northern Europe, and in the lower range in central and southern Europe Female-to-male ratio is 3:1
Takayasu arteritis	0.4–2.6	Usually below the age of 40, but cases reported as old as 60	Prevalence is thought to be higher in Turkey and Asia but there is no epidemiological data to support this
Kawasaki disease	55–146 (for children less than 5 years of age and living in the UK)	Usually children under 5	Incidence is lowest in children of Caucasian ancestry and highest in children of Asian origin A significantly higher incidence is reported in China and Japan
Polyarteritis nodosa	0.0–0.9	Any age, but peak in 40–60-year-old age group	Incidence has been dramatically reduced in the past two decades due to widespread vaccination and better screening of blood products for hepatitis B virus
Granulomatosis with polyangiitis	4.9–10.5	Any age	Prevalence is higher in northern Europe
Microscopic polyangiitis	2.7–11.6	Any age	Prevalence is higher in southern Europe
Eosinophilic granulomatosis with polyangiitis	0.5–4.2	Any age	
Henoch–Schönlein purpura	62–240 (for children under the age of 17 and living in the UK)	Usually children under 15, but can occur in adults	Lowest incidence observed in children of black Caribbean descent, and highest in children with Asian ancestry

General: Myalgia, arthralgia/arthritis, fever >38°C, weight loss			
Skin	Infarcts, purpura, ulcers, gangrene	Respiratory	Wheeze, nodules or cavities, effusions, infiltrates, haemoptysis, haemorrhage, respiratory failure
Mucous membranes/eyes	Mouth or genital ulcers, uveitis, scleritis, episcleritis, retinal changes	Cardiovascular	Valvular disease, loss of pulses, pericarditis, IHD, cardiomyopathy, CCF
Ear nose and throat	Bloody nasal discharge, crusts, granulomata, deafness, subglottic stenosis, sinusitis	Gastrointestinal	Peritonitis, bloody diarrhoea, ischaemic abdominal pain
Neurological	Headache, meningitis, confusion, seizures, cranial nerve and peripheral nerves, spinal cord lesions, CVA	Renal	Hypertension, proteinuria, haematuria, rise in creatinine

Abbreviations: CCF, congestive cardiac failure; CVA, cerebral vascular accident; IHD, ischaemic heart disease.

Table 272.5 Mortality in systemic vasculitis: Five-year survival compared with age-matched population

Diagnosis	5-year survival (%)
Granulomatosis with polyangiitis	75
Microscopic polyangiitis	45–75
Eosinophilic granulomatosis with polyangiitis	68–100
Adult-onset Henoch–Schönlein purpura	75
Polyarteritis nodosa	75–80
Kawasaki disease	>99
Giant cell arteritis	100
Takayasu arteritis	70–93

Data from Phillip R and Luqmani R. Mortality in systemic vasculitis: a systematic review. *Clin Exp Rheumatol*, 2008. 26(5 Suppl 51): p. S94–104.

Acceptable diagnostic alternatives to the gold standard

Temporal artery ultrasound is more sensitive but less specific than temporal artery biopsy for the diagnosis of giant cell arteritis. In Takayasu arteritis and in polyarteritis, the use of MRI and magnetic resonance angiography for diagnosis and monitoring of the disease is now replacing invasive conventional angiography. PET scans may prove valuable in suspected large vessel disease but have a considerable radiation load, especially when used in conjunction with CT.

Table 272.6 Recommendations for the treatment of vasculitis

Vasculitis type	Recommendations for treatment
Large vessel vasculitis (giant cell arteritis and Takayasu arteritis)	<p>For suspected giant cell arteritis, treatment should be initiated even before the biopsy or scan has been obtained and may be continued despite a negative biopsy or scan if the clinical suspicion is high</p> <p>Early use of high-dose corticosteroids (approximately 1 mg/kg of prednisolone (maximum 60 mg) per day or equivalent) to achieve remission; continue with this high dose for 1 month</p> <p>Taper steroids to achieve a target daily dose of 10–15 mg per day by 3 months</p> <p>Do not use alternative-day steroids, as this is more likely to lead to relapse of disease</p> <p>Immunosuppressive therapy (e.g. methotrexate or azathioprine) can be considered as an adjunct to treatment with corticosteroids</p> <p>There is growing evidence of benefit from anti-cytokine therapy, targeting interleukin-6, and in some cases from targeting interleukin -12</p> <p>Adequate bone protection (e.g. bisphosphonates) should be considered because patients are likely to require several years of glucocorticoid therapy</p>
Small or medium vessel vasculitis (including granulomatosis with polyangiitis; microscopic polyangiitis; eosinophilic granulomatosis with polyangiitis; polyarteritis nodosa (not hepatitis B related); and non-infectious essential mixed-cryoglobulinaemia vasculitis)	<p>Induction therapy in generalized disease (to induce remission):</p> <ul style="list-style-type: none"> ● cyclophosphamide and rituximab are equivalent in efficacy for treatment of GPA and MPA ● IV pulse cyclophosphamide 15mg/kg (maximum 1.2g) fortnightly for first three doses, then 3 weekly for the next 3–7 doses; less commonly, continuous oral cyclophosphamide 2mg/kg/day (maximum 200mg/day) for 3–6 months may be given ● daily prednisolone 1 mg/kg per day (maximum 60 mg/day) for the first months, and then taper to a target of 15 mg/day by the end of the third month ● consider an initial pulse of IV methylprednisolone (0.5–1.0 g) as a single dose at the start of therapy, in addition to oral steroids ● plasma exchange should be used as an adjunct to cyclophosphamide and steroid therapy in patients with severe renal disease (creatinine >500 µmol/l) ● trimethoprim/sulfamethoxazole (800/160 mg on alternate days) should be used to prevent <i>Pneumocystis jiroveci</i> infection, which can result from severe immunosuppression ● oral or IV mesna should be given to patients receiving pulse cyclophosphamide, to reduce the risk of bladder toxicity ● consider rituximab, mycophenolate mofetil, 15-deoxyspergualin, anti-thymocyte globulin, infliximab, or IV immunoglobulin in patients who are refractory to induction therapy with cyclophosphamide <p>Induction therapy in limited disease (to induce remission):</p> <ul style="list-style-type: none"> ● methotrexate (20–25 mg/day) can be used as an alternative to cyclophosphamide to induce remission in patients with mild disease and normal renal function <p>Maintenance therapy (to maintain remission once this is achieved with induction therapy) in limited and generalized disease:</p> <ul style="list-style-type: none"> ● azathioprine (2 mg/kg per day), methotrexate (20–25 mg/week), mycophenolate mofetil (2–3g per day), or leflunomide (20–30 mg/day) should be used to maintain remission; continue for a minimum of 18 months ● taper glucocorticoids to 10 mg/day by 6 months and then slowly taper further by 18 months ● the addition of trimethoprim/sulfamethoxazole (800/160 mg twice daily) may reduce the risk of relapse in granulomatosis with polyangiitis
Hepatitis B-associated polyarteritis nodosa	<p>Combination therapy utilizing high-dose glucocorticoids, antiviral therapy, and plasma exchange</p> <p>Hepatitis B can usually be cured with antiviral therapy</p>
Hepatitis C-associated mixed-cryoglobulinaemia vasculitis	<p>Antiviral therapy; usually, long-term dual therapy with ribavirin and interferon alfa, due to chronic persistence of infection despite antiviral therapy</p>
Henoch–Schönlein purpura	<p>In children, supportive therapy only</p> <p>Adults may be managed using immunosuppressive therapy +/- plasma exchange as for small vessel vasculitis, although there is no evidence base for effectiveness</p>
Kawasaki disease	<p>IV immunoglobulin 2 g/kg as a single infusion as soon as diagnosis is made</p> <p>High-dose aspirin 80–100 mg/kg per day in four divided doses for a minimum of 14 days and patient afebrile for >72 hours, then reduce dose to 3–5 mg/kg per day for 6–8 weeks; if there is evidence of coronary aneurysm, continue low-dose aspirin indefinitely</p>

Other relevant investigations

Baseline investigations in all patients with suspected vasculitis should include a full blood count, tests for urea and electrolytes, liver function tests, inflammatory markers, urinalysis, a chest radiograph, and an ECG. Further investigations, such as CT scans, can then be arranged as indicated from the pattern of organ involvement.

Prognosis and how to estimate it

Historically, patients with untreated systemic vasculitis had an 80% mortality rate. Improved recognition of these diseases and immunosuppressive therapy has reversed this to a 5-year survival of approximately 80%. Table 272.5 summarizes the outcome from a variety of studies of vasculitis over the last 50 years. Early deaths are usually secondary to uncontrolled vasculitis and highlight the need for aggressive early therapy in life- or organ-threatening disease. The other major cause of early death is infection. Due to more patients surviving the initial presentation, the effects of immunosuppressive therapy and comorbidities such as cardiovascular disease become important causes of death in the long term. A five-factor score (FFS) which comprises renal impairment, proteinuria, cardiomyopathy, CNS involvement, and gastrointestinal involvement predicts prognosis in polyarteritis nodosa and eosinophilic granulomatosis with polyangiitis. Patients with a FFS of 0 have a 5-year mortality of 12%, whereas, in patients with three or more factors, the mortality is 46%.

Treatment and its effectiveness

The treatment recommendations differ between the types of vasculitis but, in general, large vessel vasculitis is treated with moderate-to-high doses of corticosteroids alone, whereas most small and medium-sized vessel vasculitides require stronger immunosuppression in

conjunction with steroids. The choice and intensity of immunosuppressive treatment for small vessel vasculitis is dependent on the severity of disease and the distribution of the organs involved. The exceptions are childhood-onset Henoch–Schönlein purpura, which is normally self-limiting, and Kawasaki disease (which requires aspirin and IV Ig). Antiviral strategies are necessary for the vasculitides associated with an infectious cause such as hepatitis B-associated polyarteritis and hepatitis C-related mixed-cryoglobulinaemia vasculitis.

Modern treatment strategies are usually very effective at treating acute disease, but patients are still prone to recurrent flares and long-term sequelae from low-grade, grumbling disease, from relapse, or from the therapy itself. Table 272.6 is based on the current recommendations from the European League Against Rheumatism and the American Heart Association.

273 Osteomalacia

Kassim Javaid

Definition of the disease

Osteomalacia is a disorder of bone mineralization and is due to a lack of vitamin D.

Aetiology of the disease

Vitamin D is a prohormone formed by the action of UV radiation on the vitamin's precursor (7-dehydrocholesterol) in the skin. It then undergoes two hydroxylation steps to become an active hormone: the step to become 25-hydroxyvitamin D (25-OH vitamin D) occurs in the liver, and the second conversion takes place in the kidney to produce 1,25-dihydroxyvitamin D (1,25-OH vitamin D; also known as calcitriol), which is the active form. Conversion to calcitriol also occurs in most tissues for auto-/paracrine functions.

The commonest cause of osteomalacia is vitamin D deficiency due to a lack of UVB skin exposure. This is likely in those with darker skin, a reduced cutaneous exposure to the sun due to cultural clothing or lifestyle restrictions, or an ageing-associated reduced cutaneous capacity to metabolize vitamin D. Other causes include malabsorption (due to coeliac disease or pancreatic insufficiency), obesity, and chronic kidney disease. Rarer causes include Fanconi syndrome, distal renal tubular acidosis, drugs (e.g. phenytoin, carbamazepine, aluminium), cancer, and monogenic diseases that present in early life (e.g. X-linked hypophosphataemic rickets, autosomal dominant hypophosphataemic rickets).

Typical symptoms of the disease, and less common symptoms

The typical symptoms of osteomalacia are non-specific bone pain, proximal myopathy (which can be severe), fatigue, and polyarthralgia. The presence of unexplained groin pain may reflect an underlying insufficiency fracture of the proximal femur. Hypocalcaemia is uncommon but may lead to fits if severe. In patients with vitamin D deficiency, serum calcium is usually maintained by a secondary rise in parathyroid hormone (PTH), which resorbs bone to release calcium. If however, there is then a sudden substantial pharmacological block to resorption with drugs, such as with IV bisphosphonates or RANKL inhibitors, sub-clinical vitamin D deficiency can lead to clinically severe hypocalcaemia.

Oncogenic osteomalacia is due to ectopic production of fibroblast growth factor (FGF23) by benign, small, mesenchymal tumours. Patients present with profound proximal weakness with skeletal complications of vitamin D deficiency. Treatment is aimed to remove the tumour(s) with supportive with use of phosphate supplements and calcitriol. However, tumour localization can be challenging and may involve whole-body MRI, 18F-labelled FDG-PET, and octreotide scintigraphy.

Demographics of the disease

Clinical osteomalacia is uncommon and usually seen in specific ethnic groups. In contrast, biochemical vitamin D deficiency (<50 nmol/l 25-OH vitamin D) has a much higher prevalence of 10%–65% in the UK population throughout the life course.

Natural history, and complications of the disease

The natural history of the osteomalacia, if untreated, is progressive bone pain and weakness leading to falls or pathological fracture. If

severe, the secondary hyperparathyroidism can transform to tertiary hyperparathyroidism.

Approach to diagnosing the disease

The key is to establish abnormalities blood bone chemistry such as hypocalcaemia, hypophosphataemia, raised alkaline phosphatase levels, and raised PTH in conjunction with a low level of 25-OH vitamin D. Levels of 1,25-OH vitamin D are only helpful in cases of oncogenic osteomalacia, in which case FGF23 should also be measured. The 1,25-OH vitamin D level in patients with osteomalacia is elevated in early cases and then declines to within and then below the normal range with time and therefore is of no use, except in oncogenic osteomalacia. Radiology is indicated if there is a suspicion of insufficiency fracture, such as a Looser zone on the medial femoral neck.

Other diagnoses that should be considered

As the symptoms of osteomalacia are non-specific, the differential is wide and includes osteoporotic fracture, fibromyalgia, and polymyalgia rheumatica.

'Gold-standard' diagnostic test

The gold-standard diagnostic test for osteomalacia is a transiliac trephine bone biopsy to demonstrate excess osteoid.

Other relevant investigations

In osteomalacia, the creatine kinase level is normal. If there is concomitant iron deficiency or a history of malabsorption, then a coeliac screen should be requested.

Prognosis and how to estimate it

With effective treatment of osteomalacia, symptoms usually remit.

Treatment and its effectiveness

There is little agreement on the optimal strategy for treating vitamin D deficiency. Current evidence favours an oral rather than an intramuscular route, cholecalciferol rather than ergocalciferol, and only using concomitant calcium if required. Proposed dosing strategies include 50 000 IU weekly for 8 weeks, or 4000 IU daily for 12 weeks. Response to treatment is variable and can take 6–9 months. Following loading, maintenance therapy with 800–2000 IU per day is needed. If the vitamin D level is to be rechecked, this should be done at the end of the winter or in early spring, when it is at its nadir.

274 Paget's disease of bone

Kassim Javaid

Definition of the disease

Paget's disease of bone is an uncommon bone disorder with increased bone resorption and disorganized bone formation of woven bone.

Aetiology of the disease

The aetiology of Paget's disease of bone is unclear. There is a clear genetic component, with an eightfold increase in risk with an affected sibling. Additional environmental factors are important, given the reduction in severity and prevalence in the UK. Half of familial adult cases and 10% of non-familial cases are due to mutations in sequestosome 1, which is part of the intracellular RANK signalling pathway. The genetic causes are better characterized for the less common subtypes of Paget's. Mutations in RANK are important for the early onset type of Paget's, which is characterized by severe polyostotic disease and osteoarthritis of the hands. Juvenile Paget's is due to abnormalities in osteoprotegerin, the antagonist of the RANK ligand, and is characterized by childhood onset with accelerated cardiovascular disease. Paget's associated with inclusion body myopathy and frontotemporal dementia is due to mutations in valosin-containing protein.

Typical symptoms of the disease, and less common symptoms

Paget's disease is usually asymptomatic and detected by an unexplained raised level of alkaline phosphatase (ALP) on routine biochemistry. Symptoms include focal bone pain, including headache, which can be severe, nocturnal, and associated with bony tenderness. The most commonly affected bones are the pelvis, then the lumbar spine, the femur, the thoracic spine, the sacrum, the skull, the tibia, and then, finally, the humerus.

Other symptoms include bone deformity and complications such as fracture and nerve conduction. Paget's disease can rarely present with immobilization-associated hypercalcaemia or high-output cardiac failure. Rarely, Paget's disease can transform into an osteosarcoma in the sixth and seventh decades, most commonly at the humerus.

Demographics of the disease

Paget's disease of bone affects up to 5% of the population aged over 55 years, with an equal gender risk. It is commonest in the UK and rare in Japan.

Natural history and complications of the disease

The natural history of the disease, if the disease is left untreated, is progressive bone pain and local deformity with resulting local symptoms and complications. Common local complications include:

- nerve compression (auditory nerve, optic nerve, spinal cord)
- secondary osteoarthritis (due to loss of joint congruity)
- pathological fracture

Approach to diagnosing the disease

Paget's has characteristic radiographic features of cortical expansion with disorganized trabeculation. The main stay of diagnosis is radiographic imaging of the affected area and a technetium-99 isotope

bone scan. In the early lytic phase, Paget's may be difficult to distinguish from other lytic bone disease. For those identified by a raised ALP level, the key issue is to first ascertain whether the increase in ALP is due to bone isoenzymes and not hepatobiliary in origin. The next stage is to ascertain the sites affected, which do not change with the natural history of disease, using plain radiography and an isotope bone scan. Skull involvement highlights the potential for auditory or, less commonly, optic nerve compression and the potential for headaches which can become severe; the involvement of bones forming an articular surface raises the risk of secondary osteoarthritis, and the involvement of load-bearing bones raises the possibility of insufficiency fractures. For this reason, it is important to X-ray affected loading-bearing bones.

Other diagnoses that should be considered

When diagnosing Paget's disease of bone, important diagnoses to exclude include primary and secondary bone malignancy as well as local osteomyelitis. However, the radiological findings and lack of systemic features usually make the diagnosis.

'Gold-standard' diagnostic test

While bone biopsy is the gold-standard test for Paget's disease of bone, the presence of both radiographic and/or nuclear medicine findings is usually definitive. In cases of possible transformation to osteosarcoma, the biopsy may not be definitive and may require serial imaging with correlation with clinical features (increasing bone pain, local heat, and markedly raised ALP).

Other relevant investigations

Other investigations relevant for Paget's disease include the measurement of serum calcium (usually normal), ALP (raised; if possible, test for the bone isoenzyme), and 25-hydroxyvitamin D (to exclude concomitant osteomalacia raising ALP), and a renal profile (to guide treatment).

Prognosis and how to estimate it

The prognosis of Paget's disease has been revolutionized by the advent of bisphosphonates. However, late presentation or diagnosis may lead to bone complications.

Treatment and its effectiveness

The first line of treatment is patient education, as this is an uncommon disease, and, in the UK, linking the patient to the Paget's Association. Current first-line treatment is with a single infusion of 5 mg zoledronic acid. This requires an estimated glomerular filtration rate of >35 ml/min per 1.73 m², normocalcaemia, and a 25-hydroxyvitamin D level of more than 50 nmol/l. Zoledronic acid is highly effective in this disorder, and a single infusion appears to result in a sustained improvement in symptoms for many years. It is unusual for the markers of bone turnover (ALP or other bone turnover markers) to not suppress after treatment; if this is the case, one would want to exclude vitamin D deficiency and then repeat the infusion. For those with ongoing joint symptoms, where it is unclear if symptoms are due to Paget's disease or secondary osteoarthritis, if pain persists following zoledronic acid infusion, it is likely that secondary osteoarthritis is established. The patient's treatment pathway should then focus on analgesics, physiotherapy, and referral for

consideration of arthroplasty. For those unable to take zoledronic acid, 30 mg daily of oral risedronate for 2 months is recommended. Other treatments such as calcitonin are no longer used except in exceptional circumstances. Treatment of asymptomatic Paget's disease of bone is controversial, and some wait for symptoms to occur before initiating treatment.

275 Osteoporosis and fragility fracture

Kassim Javaid

Definition of the disease

Osteoporosis is defined as a systemic bone disease with reduction in both bone density and microarchitectural integrity, resulting in an increase in fragility fracture risk.

Aetiology of the disease

Osteoporosis is a multifactorial disease, through effects on bone formation and resorption on both the peak bone mass achieved during early adulthood and on rates of bone loss in later adulthood. Regulation of bone mass is currently thought to involve mechanosensing by osteocytes, which regulate osteoblast activity through sclerostin and DKK1 inhibition of the WNT pathway. Osteoblasts then regulate osteoclast proliferation and activity through a balance of pro-osteoclastic RANKL and anti-osteoclastic osteoprotegerin. There is a significant genetic component for osteoporosis, with studies identifying pathways including WNT, RANKL, osteoprotegerin, and the oestrogen receptor. Environmental factors are thought to influence fracture risk across the life course, including vitamin D deficiency during in utero life, inadequate physical exercise, and vitamin D and calcium deficiency during childhood. In later adulthood, the commonest cause is sex hormone deficiency, including deficiency due to menopause, premature menopause (menopause occurring before the age of 45), testosterone deficiency, drug-induced gonadal deficiency (via the use of progesterone-only contraception, aromatase inhibitors, or androgen deprivation therapy), glucocorticoid excess (iatrogenic or due to Cushing's disease), current smoking, excess alcohol intake (greater than 3 units per day), and secondary diseases (malabsorption (e.g. coeliac disease), inflammatory diseases (e.g. inflammatory arthritides, inflammatory bowel disease, asthma), endocrine disorders (e.g. hyperparathyroidism, hyperthyroidism, diabetes)). Falls are an important risk factor for fracture and it is important to differentiate contributors such as syncope, poor balance, poor gait, postural hypotension, medication, and neurological diseases. Finally, there are rare genetic causes of osteoporosis, such as osteogenesis imperfecta and Turner's syndrome.

Typical symptoms of the disease, and less common symptoms

Osteoporosis is clinically silent until a fragility fracture occurs, as defined as due to a fall from standing height or less. The commonest sites are the distal forearm, the proximal femur, the thoracic/lumbar vertebra, the ribs, and the proximal humerus. However, recent evidence such a fracture in an older person from any level of trauma should raise the suspicion of osteoporosis. Fractures of the digits, the face, the skull, the scaphoid, and the ankle, by some, are not usually considered osteoporotic. While fractures in the young typically heal with limited ongoing morbidity and excess mortality, osteoporotic fractures are associated with poorer healing and excess mortality (hip, spine, and pelvis). The morbidity after fracture depends on the site and includes chronic back pain for vertebral fracture, and wrist pain and weakness after distal forearm fracture. Progressive kyphosis from vertebral fracture reduces respiratory reserve.

Demographics of the disease

There are 3 million patients with osteoporosis in the UK, with over 200 000 fractures per year and 80 000 hip fractures. Fractures are commoner in those over 65 years and in women. A 50-year woman

has a 1:2 lifetime risk of future fracture, with the risk being 1:5 for men. While, with an ageing population, the absolute number of fractures is set to rise, for reasons not completely understood, the age-specific rate of fracture is reducing in the USA and Northern Europe while still increasing in other parts of the world.

Natural history, and complications of the disease

Initially, patients present with peripheral fractures and then vertebral fractures before proximal femoral fractures. Half of patients with a proximal femoral fracture have a history of previous first fracture. Without therapy, bone mineral density (BMD) progressively declines with age. The outcomes after hip fracture are 50% fail to return home, with a significant reduction capacity to independently mobilize, and a 30% 1-year mortality. Further, only half of patients with a distal forearm fracture report a satisfactory recovery. Vertebral fractures lead to chronic back pain but only rarely lead to neurological compromise.

Approach to diagnosing the disease

The key issue is the ascertainment of primary versus secondary fracture prevention. The next stage is to determine BMD at the hip and spine using DEXA and then to exclude secondary causes and establish the most appropriate therapy according to patient-specific factors. The identification of a fragility fracture after the age of 40 years substantially increases the risk of future fracture and guides therapy. However, identification of occult vertebral fragility fractures can be challenging and requires radiological confirmation. The presence of one of the risk factors listed in 'Aetiology of the disease' warrants DEXA measurement. Those over 75 years with a fracture or with two or more risk factors can start treatment without a BMD test if DEXA imaging is clinically not appropriate. It is also important to rule out secondary causes of osteoporosis as well as ensure that patients are calcium and vitamin D replete.

Other diagnoses that should be considered

Osteoporosis is effectively a disease of exclusion. Important diagnoses to exclude include those diseases listed in 'Aetiology of the disease' as well as myeloma, malabsorption, osteomalacia, hyperthyroidism, chronic-kidney-disease-associated metabolic bone disease, and Cushing's syndrome.

'Gold-standard' diagnostic test

The gold-standard diagnostic test for osteoporosis is a BMD T-score for the lumbar spine, total hip, or femoral neck area of -2.5 or lower, as measured by DEXA. Some DEXA scanners can also measure the lateral and anterior posterior thoracolumbar X-ray as part of instant vertebral assessment, which often detects occult vertebral fractures. Care must be taken to exclude fractured vertebra(e) from the BMD assessment and to ensure optimal positioning.

Acceptable diagnostic alternatives to the gold standard

Patients over 75 years old with a fragility fracture or two or more risk factors for osteoporosis can start treatment. Peripheral DEXA and ultrasound may also be used as screening tools in experienced departments or as part of research.

Other relevant investigations

Other investigations that are relevant to osteoporosis include measurements of:

- serum calcium
- serum phosphate
- serum alkaline phosphatase
- serum 25-hydroxyvitamin D
- serum parathyroid hormone
- thyroid-stimulating hormone

Other tests include:

- a renal profile
- a liver profile
- full blood count
- erythrocyte sedimentation rate

Optional investigations include:

- a coeliac screen
- a myeloma screen
- the urinary calcium/creatinine ratio

- 24-hour urinary calcium excretion
- 24-hour urinary cortisol

Prognosis and how to estimate it

The prognosis of osteoporosis can now be assessed using the online FRAX tool. This uses readily ascertained risk factors with or without BMD measurement to provide an estimate of the 10-year risk of major fracture and hip fracture. Caveats for its use are that it does not include measurements of the lumbar spine BMD, dose of glucocorticoids, or measures of fracture number or site. There is some evidence that FRAX predicts fracture risk both off and on therapy.

Treatment and its effectiveness

Treatment for osteoporosis is aimed at reducing future fracture risk. As there is no symptomatic benefit from therapy, and oral treatment requires complex administration regimens, it is important to ensure adequate patient information using the National Osteoporosis Society literature. The first line of treatment is to ensure patients are calcium (>800 mg/day) and vitamin D (25-hydroxyvitamin

Table 275.1 NICE guidance for primary and secondary prevention of osteoporotic fragility fractures in postmenopausal women

Age	50/54	55/65	65/69	70/74	75+
Primary prevention					
Alendronic acid	T-score ≤ -2.5 , 1 CRF*, and 1 BRF†	T-score ≤ -2.5 , 1 CRF, and 1 BRF	T-score ≤ -2.5 , and 1 CRF	T-score ≤ -2.5 , and 1 CRF/BRF	2 CRFs/BRFs

NICE: Denosumab for the prevention of osteoporotic fractures in postmenopausal women (2010).

<http://www.nice.org.uk/guidance/ta204>.

D >50 nmol/l) replete. Diet is a good source of calcium, with 600 mg in a pint of milk, and 200 mg in a small pot of yoghurt or a small matchbox of cheese. The ideal intake is 800–1200 mg/day. Vitamin D is difficult to find in the diet and often requires use of supplements.

Next requires selection of the optimal bone therapy and the National Institute for Health and Clinical Excellence (NICE) have produced intervention thresholds based on primary versus secondary prevention, BMD, clinical risk factors, and patient tolerability (see Table 275.1). Most of the agents show fracture reductions in the range of 30% for non-vertebral fracture, and 50%–70% for vertebral fracture.

The first-line agent is 70 mg oral alendronate weekly. This is an amino bisphosphonate that inhibits farnesyl transferase and osteoclast function. As it has a very poor bioavailability (0.7%), there are four key aspects for administration: (1) to take it first thing in the morning after an overnight fast with a large glass of tap water; (2) not to take any other drink, food, or medication for the next 30 minutes; (3) to remain upright (standing, sitting, and/or walking) for the next 30 minutes; and (4) to take any calcium supplements in the afternoon on the day that the oral bisphosphonate is taken. Alendronic acid is contraindicated in those with significant upper gastrointestinal pathology, hypocalcaemia, an estimated glomerular filtration rate (eGFR) of less than 30 ml/min, and pregnancy. Dyspepsia is common and should be managed by switching to another agent rather than adding a proton-pump inhibitor (PPI), as there is evidence that PPI use blunts the fracture reduction benefit.

Alternative oral therapies include risedronate (35 mg weekly with similar administration and contraindications) and strontium ranelate. Strontium ranelate 2 g is taken in the middle of a 4-hour calcium- and magnesium-free dietary fast. Typically, it is given at bedtime after a 2-hour fast. It is an insoluble powder that patients suspend in water and then take. Common unwanted effects are loose stool to diarrhoea. Rarely, a DRESS syndrome (drug rash with eosinophilia and systemic symptoms) can occur, and patients should be advised to stop and consult their doctor if they develop a rash on treatment.

Given the poor adherence to oral therapies, three groups of parenteral therapy are available. Denosumab is a monoclonal antibody that binds RANKL and inhibits osteoclast proliferation and function. It is given every 6 months as a subcutaneous injection and has efficacy with an eGFR of greater than 15 ml/min. Unwanted effects are uncommon and we await Phase 4 analyses for more information. Zoledronic acid is an IV bisphosphonate given as a short infusion every year for 3–6 years. It is slightly renally toxic and so is contraindicated in patients with an eGFR of less than 35 ml/min. It commonly causes flu-like symptoms for up to 7 days but, in some cases, it leads to an acute inflammatory response in specific organs, causing iritis or colitis. Both denosumab and zoledronic acid as well as oral bisphosphonates have been associated with osteonecrosis of the jaw (ONJ). This is an exposure of the mandible for more than

6 weeks, despite antibiotic therapy, usually after an invasive dental procedure. However, cases are usually cancer patients receiving 3–12-times-higher doses of bone agents than are used in osteoporosis therapy. Currently, the risk of ONJ is considered rare in osteoporosis therapy.

Teriparatide is a humanized 1-34 parathyroid hormone analogue. It is the only pure anabolic agent available and is given as a daily subcutaneous injection, for 18 months. It is usually reserved for those with severe osteoporosis, as evidenced by a T-score less than –3.5, the presence of more than two fractures, and intolerance/fracture on treatment with oral agents. The higher cost of teriparatide is offset by its observed greater fracture reduction, especially at the spine. The duration of therapy with bone-specific therapies is only clear for teriparatide, for which 24 months is the licensed duration. In the absence of evidence, currently, the recommendation is 5 years' treatment and then a drug holiday for 2 years before considering another cycle of therapy. In those with a vertebral fracture, 10-year cycles are appropriate. For those who refracture while on treatment, a switch in therapy, usually to a parenteral therapy, should be considered.

Atypical subtrochanteric fractures are a growing concern in the field of osteoporosis. They are typically preceded by atypical thigh pain and lead to a spontaneous or minimal-trauma horizontal femoral fracture with a characteristic breaking on one side and relatively thickened femoral shaft cortices. They appear to be associated with prolonged use of bisphosphonates. Key principles in their management are effective orthopaedic intervention, given that the bone is likely to be brittle; early imaging of the contralateral side with radiographs; MRI of the whole femur, to exclude a contralateral fracture; and cessation of bisphosphonate therapy. If the patient remains at risk of fracture at other sites, strontium ranelate or teriparatide therapy should be considered. The role of denosumab in this patient group is not known. The estimated rate of subtrochanteric fracture is 5 per 10 000 patient years of treatment, and the risk rapidly diminishes with cessation of bisphosphonate therapy.

Vertebroplasty and kyphoplasty are used to manage painful vertebral fractures but currently undergoing NICE reappraisal, as two sham-controlled trials have not replicated the benefits of usual care-controlled trials.

276 Genetic bone and joint disease

Susan Price

Introduction

Genetic conditions affecting the skeleton and supporting structures are individually rare and heterogeneous. This chapter suggests approaches to assessing patients for suspected skeletal dysplasia, osteogenesis imperfecta, Marfan syndrome, and Ehlers–Danlos syndrome.

Skeletal dysplasia

Aetiology of skeletal dysplasia

Skeletal dysplasias are caused by abnormalities of bone growth and modelling. Many are linked to mutations in genes for particular collagens or for growth factors and their receptors.

Typical symptoms of skeletal dysplasia, and less common symptoms

Skeletal dysplasias predominantly cause short stature and deformity. However, the affected sites are linked to different complications.

Conditions affecting the epiphyses (the area of secondary ossification at the ends of long bones) affect articulation and predispose to early arthritis, requiring joint replacement.

The metaphysis is adjacent to the epiphysis and is the main growth region. **Conditions affecting metaphyses** (including achondroplasia) shorten long bones, compromising eventual height.

The diaphysis is the central shaft and is affected by conditions, like osteogenesis imperfecta, that alter the early collagen bone model.

The term 'spondylo' is used where the spine is affected. The spine may be short, with kyphosis or scoliosis.

The skeletal dysplasias can be classified clinically, radiologically, or by the causative genetic mutation. One such classification, which is regularly revised, is from the International Skeletal Dysplasia Society and is referred to as the International Nomenclature and Classification of the Osteochondrodysplasias.

Demographics of skeletal dysplasia

Each specific type of skeletal dysplasia is individually rare. The commonest non-lethal type is achondroplasia, with an incidence of 1/10 000 to 1/30 000.

Natural history of skeletal dysplasia, and complications of the disease

In achondroplasia, disordered endochondral bone formation can result in compression of the cervical cord and medulla at the foramen magnum, spinal stenosis, atlantoaxial subluxation, and macrocrania, with or without hydrocephalus.

Approach to diagnosing skeletal dysplasia

When diagnosing skeletal dysplasia, take a three-generation history with details of adult height, joint replacement, and specific questions about consanguinity. Document whether growth was normal in pregnancy and try to obtain early growth records. Ask about fractures and developmental delay.

Assess whether the growth problem is proportionate or disproportionate. Measure span, height, and lower segment length. If the growth problem is disproportionate, is the shortening proximal (rhizomelic) or distal (mesomelic)? Is there any bowing of the bones or contractures? There are many other features that can be linked to specific dysplasias, particularly polydactyly or abnormal thumbs; cleft

palate; abnormal teeth and hair; cataract or myopia; and congenital heart disease. Many patients with skeletal dysplasia will have lax joints.

Other diagnoses that should be considered aside from skeletal dysplasia

When considering a diagnosis of skeletal dysplasia, exclude other causes of short stature (e.g. chromosomal or syndromic causes). These will often have proportionate short stature. Storage disorders and a wide range of other metabolic and hormonal conditions can affect growth.

'Gold-standard' diagnostic test for skeletal dysplasia

A definitive diagnosis of skeletal dysplasia is generally made after specialist review of a skeletal survey; this is often most helpful in childhood. Mutation analysis may then be possible. A skeletal survey should include the following X-rays:

- skull AP and lateral
- chest PA
- spine AP and lateral
- pelvis with hips
- unilateral humerus, radius, ulna, femur, tibia, and fibula
- hand carpal bones and phalanges

Acceptable diagnostic alternatives to the gold-standard test for skeletal dysplasia

When skeletal dysplasia is suspected, an acceptable diagnostic alternative to a skeletal survey is a descriptive diagnosis based on family history and examination findings, with patients classified according to the following clinical diagnostic groups:

- those with short limbs but in whom the trunk less affected: hypochondroplasia, achondroplasia, and pseudoachondroplasia
- those with short limbs and trunk: diastrophic dysplasia
- those with epiphyseal dysplasias: multiple epiphyseal dysplasia
- those with a short trunk but in whom the limbs are less affected: spondyloepiphyseal and spondyloepiphyseal disorders
- metaphyseal disorders: metabolic disease
- abnormal bone density: osteogenesis imperfecta

Other relevant investigations for skeletal dysplasia

Other relevant investigations for skeletal dysplasia include:

- a metabolic screen, if a metaphyseal disorder is suspected
- MRI of the brain with the cervical and lower spine, if there are neurological signs or there is evolving hydrocephalus
- molecular analysis (e.g. FGFR3 in achondroplasia and hypochondroplasia)
- cytogenetic screen for X-chromosome deletions

Prognosis of skeletal dysplasia, and how to estimate it

In skeletal dysplasia, severe conditions can present in utero, and many are lethal because of reduced lung capacity or evolving hydrops. Prognosis in terms of eventual height and complications is condition specific.

Treatment of skeletal dysplasia, and its effectiveness

As treatment for skeletal dysplasia, surgical management of deformities to improve function and, occasionally, operations to lengthen

limbs may be suggested. Growth hormone treatment is of no benefit to the majority of children. Exercise can be helpful, to maintain range of movement and build strength. A referral for mobility aid assessment can be considered.

Osteogenesis imperfecta

Aetiology of osteogenesis imperfecta

Most patients with osteogenesis imperfecta have mutations in COL1A1 or COL1A2. Abnormal collagen production gives a more open meshwork to the early bone model, and this eventually leads to reduced mineralization. There are four main types of osteogenesis imperfecta (see 'Natural history of osteogenesis imperfecta, and complications of the disease'); osteogenesis imperfecta types I and IV are dominantly inherited, type II is generally caused by a de novo dominant mutation, and type III is mostly dominant, although some recessive families have been described.

Typical symptoms of osteogenesis imperfecta, and less common symptoms

The typical presentation of osteogenesis imperfecta is with multiple fractures, sometimes prenatally. There may be associated short stature, bone deformity, dentogenesis imperfecta, blue sclera, and hearing loss. This is a collagen disease, and patients can have the soft skin, lax joints, scoliosis, and mitral valve prolapse seen in other conditions affecting collagen. Spinal deformity can cause neurological and respiratory compromise.

Demographics of osteogenesis imperfecta

The most common form of osteogenesis imperfecta, osteogenesis imperfecta type 1, has a frequency of 2–5/100 000.

Natural history of osteogenesis imperfecta, and complications of the disease

The natural history of osteogenesis imperfecta is linked to the severity of the condition, but also the degree of osteoporosis in later life. The clinical classification of osteogenesis imperfecta (called the Sillence classification) is useful in predicting severity and outcome. The main types are:

- type I:
 - mild
 - non-deforming
 - mild short stature
 - blue sclera
 - normal teeth
- type II:
 - perinatally lethal due to respiratory compromise
 - multiple rib and long-bone fractures present at birth, with deformity and dark sclera
 - low bone density
 - separated into types IIA, IIB, and IIC, depending on the radiographic appearance
- type III:
 - severe
 - deforming
 - very short stature
 - scoliosis
 - multiple fractures
 - patient must often use a wheelchair
 - grey sclera
 - dentogenesis imperfecta
 - triangular facies
- type IV:
 - moderately deforming
 - moderate short stature
 - patient may have scoliosis
 - grey/white sclera
 - dentogenesis imperfecta

Hearing loss is common, being found in ~50% of cases by 30 years of age, and 95% of cases in later life, but is not usually seen in those

under 10 years old. About 10% of cases will have asymptomatic mitral valve prolapse, and 24% of affected males (but only 4% of affected females) have non-progressive aortic dilatation.

Approach to diagnosing osteogenesis imperfecta

When diagnosing osteogenesis imperfecta, take a three-generation family history of fracturing, deformity, and the associated features. It is generally possible to diagnose the type on history and examination findings alone.

Other diagnoses that should be considered aside from osteogenesis imperfecta

Recurrent childhood fractures require sensitive questioning, given the possible confusion with non-accidental injury. Juvenile and pre-mature osteoporosis can lead to fractures, as can hypophosphatasia. Bruck syndrome is a recessive condition linking blue sclera, Wormian bones, and congenital contractures of large joints.

'Gold-standard' diagnostic test for osteogenesis imperfecta

The following are gold-standard diagnostic tests for osteogenesis imperfecta:

- skin biopsy for examination of fibroblast collagens via electron microscopy
- COL1A1, COL1A2 and rarer gene mutation testing

Acceptable diagnostic alternatives to the gold-standard for osteogenesis imperfecta

Wormian bones on a skull X-ray are often seen in osteogenesis imperfecta type I but bone density generally can be variable and often normal. For more severe forms of osteogenesis imperfecta, a full skeletal survey will be helpful. Offer hearing tests throughout life, and an initial biochemistry screen to exclude metabolic bone disease.

Other relevant investigations for osteogenesis imperfecta

Another investigation that is relevant in osteogenesis imperfecta is echocardiography, to assess for valve involvement.

Prognosis of osteogenesis imperfecta, and how to estimate it

The prognosis of osteogenesis imperfecta will be related to the severity of the bone disease, but also the site of fractures (e.g. if they affect the joints). Often, children with osteogenesis imperfecta fracture recurrently until puberty, when the condition improves. Multiple fractures in childhood may predict later osteoporosis, and bone density scanning in adult life is indicated.

Treatment of osteogenesis imperfecta, and its effectiveness

Treatment of osteogenesis imperfecta requires prompt, specialist, orthopaedic management of fractures, with full physiotherapy and rehabilitation support. The use of bisphosphonates is under assessment; these drugs can reduce osteoclast bone reabsorption. However, they are used in specialist centres only, and for severer types of the disease.

Marfan syndrome

Aetiology of Marfan syndrome

Between 66% and 91% of individuals with Marfan syndrome have a mutation in fibrillin 1 (FBN1; locus: 15q21). Some families have mutations in TGFBR1 or TGFBR2. Marfan syndrome is a dominantly inherited condition, but up to a third of cases are caused by a spontaneous mutation.

Typical symptoms of Marfan syndrome, and less common symptoms

Marfan syndrome is a connective tissue disease with a pattern of symptoms related to the presence of fibrillin in tissues. Typically

affected individuals are of tall, thin stature, with long fingers and toes (arachnodactyly), a pectus deformity, and scoliosis. They may have a high palate with dental crowding; lax joints; excessive striae; and a history of recurrent herniae or pneumothoraces.

Demographics of Marfan syndrome

The estimated prevalence of Marfan syndrome is 1/3000 to 1/5000.

Natural history of Marfan syndrome, and complications of the disease

In Marfan syndrome, joint hypermobility can give chronic pain and early arthritis. There may be bilateral ectopia lentis (in ~50% of cases), myopia (in 30% of cases), and, rarely, retinal detachment. However, the most serious complication is aortic dilatation, and an annual echocardiogram is requested for affected individuals. Particular care is needed in pregnancy.

Approach to diagnosing Marfan syndrome

When diagnosing Marfan syndrome, take a three-generation family history detailing symptoms of Marfan syndrome. Measure height, weight, arm span, and lower segment length. A standard examination scoring system for assessing individuals with suspected Marfan syndrome is used. This is referred to as the Ghent criteria and has been shown to detect about 86% of individuals carrying a fibrillin 1 mutation (see Table 276.1); however, this system is less reliable in children. The system scores common features in the skeleton, eyes, heart, lungs, and skin, and notes the presence or absence of dural ectasia or a family history. There are major and minor criteria; in the absence of a family history, two of the major criteria and one of the minor criteria must be present to confirm a clinical diagnosis. An echocardiogram (to measure the aortic root diameter at the level of the sinuses of Valsalva and screen for mitral prolapse) and eye examination (to look for refractive error and lens instability) will be requested. Mutation detection can be undertaken where resources allow, and can be useful for defining screening in large families.

Other diagnoses that should be considered aside from Marfan syndrome

Other diagnoses that should be considered aside from Marfan syndrome are summarized in Table 276.1. If there is learning difficulty, homocystinuria should be excluded. Mild Ehlers–Danlos syndrome can give similar joint hypermobility.

‘Gold-standard’ diagnostic test for Marfan syndrome

The gold-standard diagnostic test for Marfan syndrome is fibrillin 1 mutation testing.

Acceptable diagnostic alternatives to the gold-standard test for Marfan syndrome

An acceptable diagnostic alternative to fibrillin 1 mutation testing is an assessment of family history and the application of Ghent criteria.

Other relevant investigations for Marfan syndrome

Relevant investigations for Marfan syndrome include monitoring the ratio of the aortic diameter to the body surface area, as this can be used to assess the progression of aortic dilatation over time. In addition, an X-ray of the hip or spinal MRI may be relevant if these features would alter assessment using the Ghent criteria.

Prognosis of Marfan syndrome, and how to estimate it

Untreated, unscreened people with Marfan syndrome have a 40% reduced life expectancy from aortic complications, predominantly dissection. Plotting the aortic root diameter over time helps to plan if aortic replacement is indicated.

Treatment of Marfan syndrome, and its effectiveness

The major complication of Marfan syndrome is aortic root dilatation, which predisposes to aortic dissection. Regular surveillance of the aortic root by echocardiography, the use of beta blockers and angiotensin-receptor blockers to retard dilatation, and aortic root repair when the diameter reaches 5.0 cm improve the prognosis. Contact sports and sports causing high cardiovascular stress should be avoided. Regular ophthalmic review is suggested until adolescence.

Ehlers–Danlos syndrome

Aetiology of the disease

Classical Ehlers–Danlos syndrome (types I and II) is caused by dominant mutations in COL5A1 and COL5A2. Hypermobility (Ehlers–Danlos syndrome type III) is dominantly inherited and molecularly undefined. Vascular Ehlers–Danlos syndrome (type IV) can be dominantly or recessively inherited with mutations in COL3A1. Kyphoscoliosis (Ehlers–Danlos syndrome type VI) is a recessive condition caused by mutations in PLOD1. Arthrochalasia (Ehlers–Danlos syndrome types VIIA and B) is linked to dominant exonic deletions in COL1A1 and COL1A2. Dermatosporaxis (Ehlers–Danlos syndrome type VIIC) is caused by recessive mutations in a collagen N-peptidase (ADAMTS2).

Table 276.1 Differential diagnosis of Marfan syndrome

Differential diagnosis	Gene	Discriminating features
Loeys–Dietz syndrome (LDS)	TGFBR1/2	Bifid uvula/cleft palate, arterial tortuosity, hypertelorism, diffuse aortic and arterial aneurysms, craniosynostosis, clubfoot, cervical spine instability, thin and velvety skin, easy bruising
Shprintzen–Goldberg syndrome (SGS)	FBN1 and other	Craniosynostosis, mental retardation
Congenital contractural arachnodactyly (CCA)	FBN2	Crumpled ears, contractures
Weill–Marchesani syndrome (WMS)	FBN1 and ADAMTS10	Microspherophakia, brachydactyly, joint stiffness
Ectopia lentis syndrome (ELS)	FBN1 LTBP2 ADAMTSL4	Lack of aortic root dilatation
Homocystinuria	CBS	Thrombosis, mental retardation
Familial thoracic aortic aneurysm syndrome (FTAA)	TGFBR1/2, ACTA2	Lack of Marfanoid skeletal features, levido reticularis, iris flocculi
FTAA with bicuspid aortic valve (BAV)		
FTAA with patent ductus arteriosus (PDA)	MYH11	
Arterial tortuosity syndrome (ATS)	SLC2A10	Generalised arterial tortuosity, arterial stenosis, facial dysmorphism
Ehlers–Danlos syndromes (vascular, valvular, kyphoscoliotic type)	COL3A1, COL1A2, PLOD1	Middle sized artery aneurysm, severe valvular insufficiency, translucent skin, dystrophic scars, facial characteristics

Reproduced from *Journal of Medical Genetics*, Loeys et al., The revised Ghent nosology for the Marfan syndrome, volume 47, issue 7, pp. 476–485, copyright © 2010 with permission from BMJ Publishing Group Ltd.

Typical symptoms of Ehlers–Danlos syndrome, and less common symptoms

All forms of Ehlers–Danlos syndrome present with variable thinning and fragility of skin, leading to easy bruising and poor scar formation. There is skin and joint laxity. In severe forms, blood vessels and internal organs are affected.

Demographics of Ehlers–Danlos syndrome

The incidence of Ehlers–Danlos syndrome (as a group) is about 1 in 5000.

Natural history of Ehlers–Danlos syndrome, and complications of the disease

In Ehlers–Danlos syndrome, the degree of hypermobility can decrease with age and move to more stiffness related to arthritis. Vascular Ehlers–Danlos syndrome causes increasing complications with age.

Approach to diagnosing Ehlers–Danlos syndrome

When diagnosing Ehlers–Danlos syndrome, take a three-generation family history of joint dislocation/early arthritis and abnormal scarring. Examine all joints for range of mobility to give a Beighton score, which is calculated as follows:

- passive extension of little finger beyond 90°: score 1 for each hand
- passive opposition of thumb to the flexor surface of forearm: score 1 for each hand
- hyperextension of elbow beyond 10°: score 1 for each elbow
- hyperextension of knee beyond 10°: score 1 for each knee
- flex the spine; if the patient's hands are flat on the floor, score 1

Therefore, the total Beighton score could be at most 9.

Assess the skin for softness, elasticity, and atrophy. The Villefranche classification is used to describe the various patterns of Ehlers–Danlos syndrome. A shortened summary of main types is as follows:

- classical Ehlers–Danlos syndrome (types I and II):
 - soft hyperextensible skin
 - lax joints
 - easy bruising
 - thin scars
 - varicose veins
 - risk of prematurity in affected fetuses
- hypermobility (Ehlers–Danlos syndrome type III):
 - merges into the general population
 - use if Beighton score >5/9
- vascular (Ehlers–Danlos syndrome type IV):
 - more serious condition
 - patients tend to look aged, with deep-set eyes and thin skin
 - little joint laxity, but high risk for rupture of blood vessels, bladder, bowel, or uterus
- kyphoscoliosis (Ehlers–Danlos syndrome type VI):
 - soft skin
 - joint hypermobility
 - muscle hypotonia
 - scoliosis
 - rupture of the optic globe
- arthrochalasia (Ehlers–Danlos syndrome types VIIA and B):
 - normal scars
 - severe joint problems, including hip dislocation
- dermatosporaxis (Ehlers–Danlos syndrome type VIIC):
 - affects the skin which is sagging, redundant, and fragile

Other diagnoses that should be considered aside from Ehlers–Danlos syndrome

Other diagnoses that should be considered aside from Ehlers–Danlos syndrome include cutis laxa and Marfan syndrome, which share some features, and benign hypermobility, which is common.

'Gold-standard' diagnostic test for Ehlers–Danlos syndrome

The gold-standard diagnostic tests for Ehlers–Danlos syndrome are a skin biopsy, to provide a fibroblast culture for electron microscope analysis of collagen fibres, and targeted collagen mutation testing, particularly when Ehlers–Danlos syndrome vascular type is being considered.

Acceptable diagnostic alternatives to the gold-standard tests for Ehlers–Danlos syndrome

An acceptable diagnostic alternative to the gold-standard tests for Ehlers–Danlos syndrome is clinical classification.

Other relevant investigations for Ehlers–Danlos syndrome

Other relevant investigations for Ehlers–Danlos syndrome are an echocardiogram, to look for aortic diameter and mitral valve prolapse in classical, hypermobile, and kyphoscoliotic Ehlers–Danlos syndrome, and MRI of major vessels in vascular Ehlers–Danlos syndrome, although it is still unclear if aneurysm repair is indicated, given the extreme tissue fragility.

Prognosis of Ehlers–Danlos syndrome, and how to estimate it

The majority of individuals with Ehlers–Danlos syndrome are primarily affected by morbidity from skin and joint problems. Only the vascular type is associated with high mortality. About 25% of affected individuals will have serious complications by 20 years of age, and 50% by 40 years of age. The median life expectancy is around 48 years, with most dying of arterial rupture. Pregnancies are very high risk.

Treatment of Ehlers–Danlos syndrome, and its effectiveness

The management of Ehlers–Danlos syndrome is largely supportive, with surgical treatment of dislocation and careful management of wounds. Celiprolol has been shown (in one randomized controlled trial) to reduce the risk of complications in vascular Ehlers–Danlos syndrome.

PART 13

Haematological disorders

277 Normal blood function

Chris Bunch

Introduction

Haematology concerns blood, its formation, function, and disorders. It holds a special position in clinical medicine, as many diseases affect the blood at some stage of their course, and disorders of the blood itself often have effects on one or more of the other organ systems. The accessibility of blood and its cells has allowed the pathophysiology of many haematological disorders to be unravelled in detail, before that of many other diseases, at both the cellular and the molecular level. Indeed, many of the analytical techniques now widely used in molecular biology and genetics were developed for, and first applied to, the study of the blood.

The composition and function of blood

Blood consists of cells of three main types, suspended in a nutrient fluid called plasma. The cellular component comprises about 40%–50% of the total volume, and consists of red cells (erythrocytes), white cells (leucocytes), and platelets (see Table 277.1).

Red cells and haemoglobin

The red cell is a biconcave disc about 7 μm in diameter. It lacks a nucleus and contains a concentrated solution of **haemoglobin**—an iron-containing protein responsible for oxygen transport from the lungs to the tissues—together with a few enzymes necessary to maintain the function and integrity of the haemoglobin and the cell membrane. The biconcave shape maximizes the cell's surface area in relation to volume—important for gas exchange—and contributes to the cell's flexibility and deformability, allowing it to pass easily through narrow capillaries.

In a normal stained blood film, the red cells appear reasonably similar in size, shape, and colour. Abnormal appearances are seen in a variety of conditions (see Table 277.2).

Table 277.1 Indicative reference ranges for haematological values in normal adults

Parameter (unit)	
Haemoglobin (g/dl)	Men: 14–18 Women: 12–16
Haematocrit (packed cell volume)	Men: 0.40–0.52 Women: 0.35–0.47
Red-cell count ($\times 10^{12}/\text{l}$)	Men: 4.5–6.0 Women: 3.8–5.2
Mean red-cell volume (fl)	80–100
Mean red-cell haemoglobin (pg)	27–33
Mean cell haemoglobin concentration (g/dl)	31.5–36.5
White cells (leucocytes) ($\times 10^9/\text{l}$)	4.00–10.00
• neutrophils	2.00–7.00 (40%–80%)
• lymphocytes	1.00–3.00 (20%–40%)
• monocytes	0.20–1.00 (2%–10%)
• eosinophils	0.04–0.40 (1%–6%)
• basophils	0.00–0.10 (0%–2%)
Platelets ($\times 10^9/\text{l}$)	150–450

Note: These values are typical, but may vary between laboratories; results marginally outside these ranges are not necessarily abnormal, and should be evaluated in the clinical context.

Table 277.2 Common abnormalities of red-cell morphology

Abnormality	Meaning	Associations
Anisocytosis	Variation in cell size (usually red cells)	Iron deficiency Thalassaemia
Poikilocytosis	Variation in cell shape (usually red cells)	Often associated with Anisocytosis Myeloclerosis
Hypochromia	Pale red cells	Reduced haemoglobin content Iron deficiency Thalassaemia
Microcytosis	Small red cells	Reduced haemoglobin content Iron deficiency Thalassaemia
Macrocytosis	Large red cells	Various
Spherocytes	Spherical rather than biconcave red cells	Membrane defect leading to loss of surface area
Schistocytes	Fragmented red cells	Microangiopathy Disseminated intravascular coagulation

Reticulocytes are young red cells (less than 2–3 or less days old) recently released from the marrow. They contain residual traces of globin mRNA, which gives the cells a bluish tinge (**polychromasia**) that contrasts with the normal red colour in a stained blood film. The reticular RNA strands can be demonstrated directly with suitable stains, facilitating estimation of the reticulocyte percentage.

Structure of haemoglobin

The haemoglobins are a family of molecules with a basically similar structure consisting of two pairs of globin chains, each associated with a haem moiety. Normal adult haemoglobin (Hb A) is formed from two alpha (α) and two beta (β) globin chains ($\alpha_2\beta_2$). Interaction between the amino acid side chains leads to complex folding of the globin molecule to give a quaternary structure, with the haem molecules tucked inside the folds of the chains (see Figure 277.1).

Figure 277.1 A haemoglobin molecule, showing the position of one of the haem molecules in a cleft formed by the globin chain.

<http://www.mhhe.com/biosci/genbio/maderinquiry/234329.html>

Figure 277.2 Oxygen dissociation curves for a normal patient (black line) and an anaemic patient (blue line), showing enhancement of oxygen loading by decreased red-cell oxygen affinity in the latter: the anaemic patient, with a 50% reduction in haemoglobin concentration, has only a 27% reduction in oxygen unloading, compared to a normal patient; P_{50} , partial pressure of oxygen in the blood at which the haemoglobin is 50% saturated; PO_2 , partial pressure of oxygen in the blood.

Haem consists of a porphyrin ring, with an iron atom at its centre. It has a certain affinity for oxygen, which is sensitive to the surrounding pH and CO_2 concentration: as blood passes through the lungs, the pH is relatively high and the CO_2 concentration is relatively low, so oxygen readily binds to haem. In the tissues, the reverse is true: oxygen dissociates from haem and becomes available to the surrounding milieu. This can be illustrated by an oxygen-dissociation curve, which has a characteristic sigmoid shape (see Figure 277.2). The affinity of haem for oxygen, and the position of the dissociation curve, are also profoundly affected by intracellular levels of 2,3-bisphosphoglycerate (2,3-BPG, previously known as 2,3-diphosphoglycerate or 2,3-DPG).

Adaptation to anaemia

The amount of oxygen extracted from the blood by the tissues depends primarily on:

- the circulating haemoglobin level
- blood flow
- the difference in oxygen tension between the red cell and the tissues
- the affinity of the haemoglobin for oxygen

Under resting conditions, the tissues require about 250 ml of oxygen per minute. Normal blood carries 20 ml of oxygen per 100 ml (1.34 ml of oxygen per gram of haemoglobin). Thus, at a resting cardiac output of 5 l per minute, about 1 l of oxygen per minute would be available to the tissues. As blood flows through the capillaries, the lower oxygen tension in the tissues promotes the release of oxygen from haemoglobin. Extraction of 250 ml of oxygen is associated with a reduction in the red-cell oxygen tension from 100 mm Hg (13.5 kPa) at the arterial end of the capillary to 40 mm Hg (5.5 kPa) at the venous end.

In anaemia, the extraction of the same amount of oxygen from a reduced amount of haemoglobin would involve a greater degree of oxygen desaturation and would eventually lead to tissue hypoxia if a number of compensatory mechanisms did not come into play. These include:

- increased cardiac output: this becomes evident once the haemoglobin level has fallen to around 7–8 g/dl. The output then rises

progressively as the level falls further, and may reach four to five times the normal output

- increased blood flow: this is partly due to a rise in cardiac output, but is facilitated by the reduced blood viscosity and a decrease in peripheral vascular resistance; there is a redistribution of blood flow in favour of tissues such as the brain and the myocardium, for which oxygen delivery is especially critical
- reduced red-cell oxygen affinity: this is reflected in a right shift in the haemoglobin oxygen dissociation curve and is mainly due to an increase in the levels of red-cell 2,3-BPG, which interacts with the haemoglobin molecule to reduce its affinity for oxygen, allowing greater oxygen release at similar oxygen tensions

Developmental changes in haemoglobin production

Other normal human haemoglobins consist of α or the α -like ζ chain, combined with one of the β -like chains, ϵ or γ . The first haemoglobins to appear in the embryo are haemoglobin Gower 1 ($\zeta_2\epsilon_2$), haemoglobin Portland ($\zeta_2\gamma_2$), and haemoglobin Gower 2 ($\alpha_2\epsilon_2$). These are replaced in the fetus by fetal haemoglobin (Hb F; $\alpha_2\gamma_2$). Shortly before birth, production switches to HbA, which largely replaces Hb F by the end of the first year of life. In postnatal life, a minor adult haemoglobin, HbA₂ ($\alpha_2\delta_2$), accounts for less than 2.5% of total haemoglobin. The switch from fetal to adult haemoglobin is affected by some of the molecular lesions responsible for the thalassaemias, and may lead to continued or increased production of HbF, with some amelioration of the expression of the disease.

Genetic control of haemoglobin synthesis

The genes for the α chains are found on chromosome 16, together with the embryonic ζ chain gene. The α gene is duplicated on each haploid chromosome, making four in all. The non- α genes are clustered on Chromosome 11, closely linked and in order of developmental expression: 3'- ϵ - γ^G - γ^A - δ - β -5'. These genes are sequentially activated and then repressed during fetal development to ensure the appropriate developmental changes in haemoglobin production. In addition, α -chain synthesis and non- α -chain synthesis are synchronized, with haem being incorporated into each chain by a separate pathway before they are combined to form the complete haemoglobin molecule.

The genetic control of haemoglobin production has several important consequences. First, abnormalities affecting individual globin genes may be inherited from one or both parents (heterozygosity and homozygosity, respectively). Second, different abnormalities can be inherited from each parent (double heterozygosity). Third, abnormalities affecting the β chain will not become apparent until after the first 3–6 months of life, when β -chain synthesis supersedes γ -chain production. On the other hand, disorders affecting α -chain production may become apparent during fetal life, although duplication of the α -chain gene affords protection from limited abnormalities.

White cells (leucocytes)

The white cells are a group of cells whose principal collective function is defence against infection. This role is principally played out in the tissues, and the white cells' presence in the blood is largely transitory. There are three main groups of white cells:

- **polymorphonuclear cells (polymorphs) or granulocytes**, which have multilobed, condensed nuclei and contain prominent cytoplasmic granules; they are classified according to the staining characteristics of the main granule type as **neutrophils**, **eosinophils**, or **basophils**
- **lymphocytes**, which are the cells of the immune system
- **monocytes**, which are the precursors of tissue macrophages.

Neutrophils are the predominant granulocytes and are phagocytic cells primarily concerned with defence against bacterial invasion. They spend just a few hours in the bloodstream before migrating into the tissues, where they become attracted to sites of infection and inflammation, by a process of **chemotaxis** along a gradient of soluble mediators released by other inflammatory cells at the affected site. A reduction in the concentration of neutrophils in the blood is termed **neutropenia**; an increase is a **neutrophil leucocytosis**,

Box 277.1 Quantitative alterations in circulating neutrophil and eosinophils**Increased neutrophils: Neutrophilia**

- infection
- inflammation
- stress/exercise
- corticosteroids
- malignancy
- tissue damage/infarction

Decreased neutrophils: Neutropenia

- marrow failure
- severe infection
- endotoxin
- hypersplenism
- immune destruction

Increased eosinophils: Eosinophilia

- parasitic infestations
- allergies: asthma, drugs, hay fever, polyarteritis nodosa
- skin disorders: eczema, urticaria, pemphigus, dermatitis herpetiformis
- sarcoidosis
- malignancy: carcinoma, lymphoma
- hypereosinophilic syndrome

Reduced eosinophils: Eosinopenia

- hypercortisolaemia: Cushing's disease, steroids, stress
- adrenaline
- congenital (very rare)

or **neutrophilia**. Causes of neutropenia and neutrophilia are shown in Box 277.1.

Eosinophils have granules that stain deep red with eosin and represent 2% or less of total leucocytes. They are phagocytic but less so than neutrophils. They are important in the defence against certain parasitic infestations, and in modulating hypersensitivity reactions. Common causes of an increase in circulating eosinophils (eosinophilia) are given in Box 277.1.

Basophils are the least numerous of the leucocytes. They have deeply basophilic granules containing a variety of substances including histamine, heparin, a factor chemotactic for eosinophils, and one that promotes platelet aggregation and degranulation. They are probably related to tissue mast cells. They have membrane receptors for the Fc portion of IgE, and participate in immediate hypersensitivity reactions.

Platelets

The platelets are small discoid bodies that are primarily concerned with haemostasis. Their morphology, function, and disorders are described in Chapter 281.

Plasma

Plasma is the liquid phase of blood and normally makes up around 55% of blood volume. It consists of a variety of proteins and salts suspended in water. The predominant proteins are albumin (35–45 g/dl), immunoglobulins (IgG, IgA, IgM), coagulation factors, and a number of transport proteins such as caeruloplasmin and transferrin. Serum is that part of plasma that remains after blood (or plasma) has clotted: the principal difference is the absence of fibrinogen in serum.

The formation of blood cells: Haemopoiesis

Blood cells are formed from progenitor cells in the bone marrow by haemopoiesis, which is a process of proliferation and differentiation. This process is carefully regulated throughout life to ensure both the steady replacement of ageing blood cells, and to provide a brisk increase in production when required. Given the central role

that erythrocytes, leucocytes, and platelets have in sustaining life and maintaining the body's integrity, it is not surprising that failure of marrow function can have serious consequences.

Normal haemopoiesis

All peripheral blood cells arise from progenitor cells known as stem cells (see Figure 277.3). Stem cells have the responsibility for providing all the blood cells required in a lifetime: to do this, they must maintain their own numbers by proliferation, as well as regularly 'committing' some to differentiate down the pathways that lead to mature cells. The number of stem cells is very small: differentiation and proliferation go hand in hand at first, so that each stem cell eventually gives rise to a large number of mature, non-dividing cells.

Regulation of haemopoiesis

Growth and differentiation of haemopoietic progenitors is to a large extent governed by a series of glycoprotein hormones, or **growth factors**. These react with specific cell-surface receptors to stimulate proliferation and differentiation, and some also enhance granulocyte function. Growth factors are produced by cells that are in a good position to 'sense' the need for increased haemopoietic activity. For example, specialized cells in the juxtaglomerular region of the kidney (an organ with very high oxygen demand) sense reduced oxygen delivery and release erythropoietin, a hormone which stimulates erythropoiesis. Analogous granulocytic growth factors are produced by a wide range of connective tissue cells, macrophages, and activated T-cells, which are all cells that are affected by tissue injury or infection.

Most of the haemopoietic growth factors have been isolated and their genes molecularly cloned. This has enabled several factors to be synthesized and made available for clinical use, via recombinant DNA techniques.

Erythropoietin

Erythropoietin is secreted by the kidney in response to reduced oxygen delivery. It acts both to expand the committed erythroid progenitor pool and to stimulate differentiation, increasing the output of red cells. Reduced erythropoietin production leads to reduced red-cell production. This is largely responsible for the anaemia of renal failure and contributes to the anaemia of infection and chronic inflammatory disorders. On the other hand, increased erythropoietin production leads to erythrocytosis or polycythaemia.

Recombinant human erythropoietin is now widely used to treat the anaemia of chronic renal failure, and clinical studies are currently under way in the anaemia of chronic disorders and in myelodysplasia.

Granulocyte colony-stimulating factor

Granulocyte colony-stimulating factor (G-CSF) is produced by macrophages and stimulates granulocyte production and release from the marrow. Recombinant human G-CSF accelerates granulocyte recovery after chemotherapy for malignant disease and bone marrow transplantation, and reduces the risks of infection after these treatments.

Granulocyte-macrophage colony-stimulating factor

Granulocyte-macrophage colony-stimulating factor (GM-CSF) is also produced by macrophages, but has a wider spectrum of action than G-CSF does, stimulating the production of monocytes as well as granulocytes. Recombinant GM-CSF has also been used to stimulate granulocyte recovery after chemotherapy for malignancy, but has more pronounced side effects of fever, fluid retention, bone pain, pruritus, and possibly thrombosis.

Interleukin-3

Interleukin-3 has an even broader spectrum of action than G-CSF and GM-CSF do. It acts on a more primitive cell, and is able to stimulate erythroid and megakaryocytic as well as granulocytic activity. It is currently undergoing clinical trials in a range of marrow failure states.

Other factors affecting haemopoiesis

Proliferating cells require both vitamin B₁₂ and folate for DNA synthesis. Lack of either results in megaloblastic haemopoiesis (see Chapter 279).

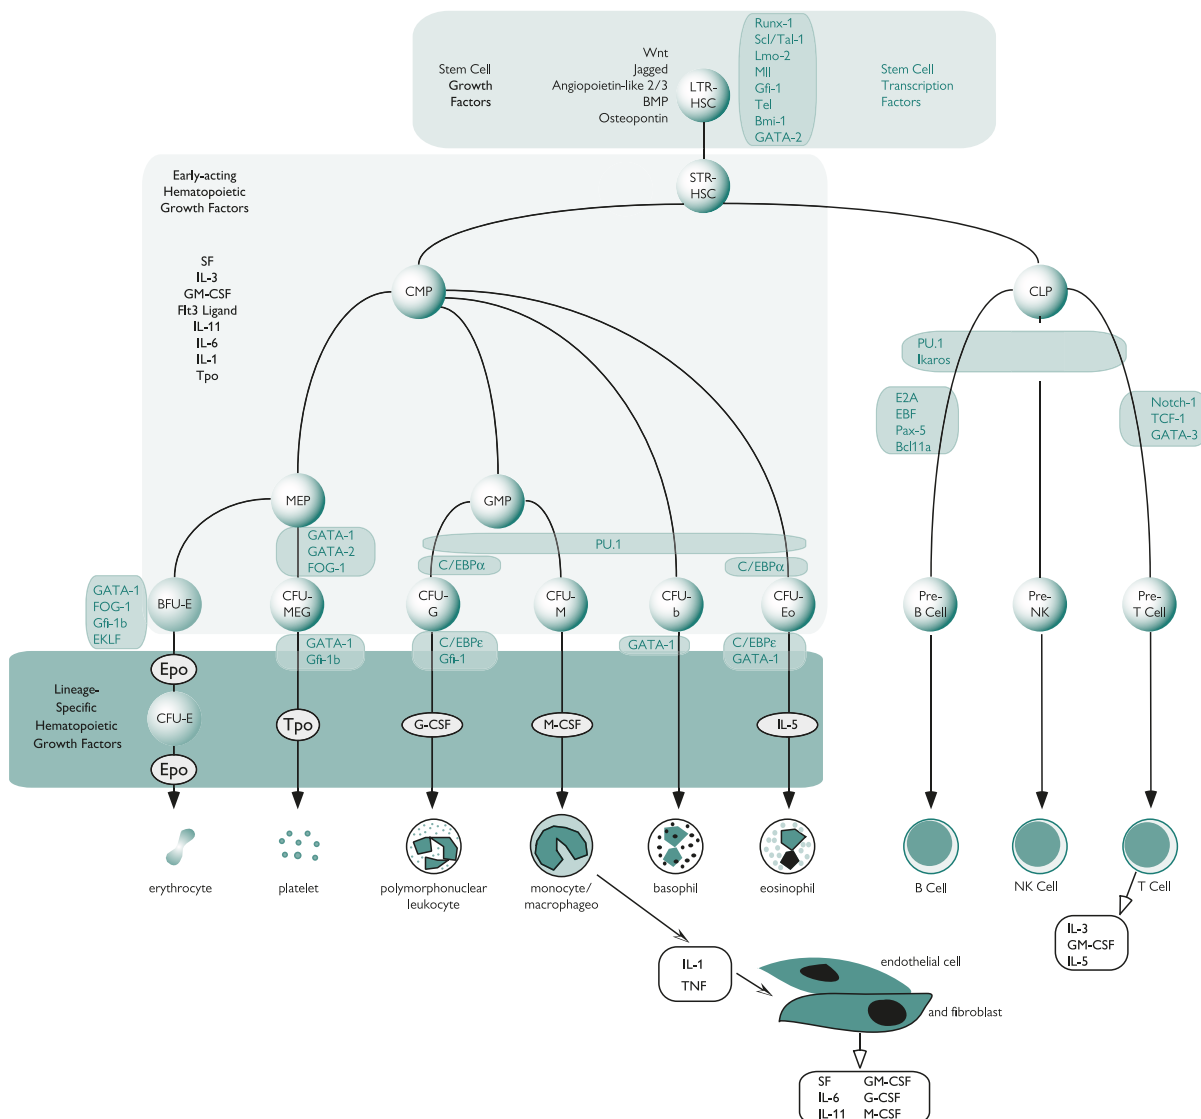

Figure 277.3 Major cytokine sources and actions and transcription factor requirements for haematopoietic cells. Cells of the bone-marrow micro-environment, such as macrophages, endothelial cells, and reticular fibroblastoid cells, produce macrophage-colony-stimulating factor (M-CSF), granulocyte-macrophage-colony-stimulating factor (GM-CSF), granulocyte-colony-stimulating factor (G-CSF), interleukin 6 (IL-6), and probably stem cell factor after induction with endotoxins (macrophages) or interleukin 1 (IL-1)/tumour necrosis factor (TNF; endothelial cells and fibroblasts). T-cells produce interleukin 3 (IL-3), GM-CSF, and interleukin 5 (IL-5) in response to antigenic and IL-1 stimulation. These cytokines have overlapping actions during haematopoietic differentiation, as indicated and, for all lineages, optimal development requires a combination of early acting and late-acting factors. Transcription factors important for survival or self-renewal of stem cells are shown at the top, and stages of haemopoiesis blocked after the depletion of indicated transcription factors are shown for multipotent and committed progenitors; CLP, common lymphoid progenitor; CMP, common myeloid progenitor; EPO, erythropoietin; GMP, granulocyte-macrophage progenitor; LTR-HSC, long-term repopulating haematopoietic stem cell; MEP, megakaryocyte-erythrocyte progenitor; NK, natural killer; SF, scatter factor; STR-HSC, short-term repopulating haematopoietic stem cells; TNF, tumour necrosis factor; Tpo, thrombopoietin.

Reproduced with permission from Sieff, *Stem cells and haemopoiesis*, in *Oxford Textbook of Medicine*, Fifth Edition Oxford University Press, Oxford, UK, Copyright © 2010.

A further important regulatory factor for erythropoiesis is the **iron supply**. Developing erythroblasts acquire iron for haemoglobin synthesis directly from adjacent marrow macrophages. Iron availability is reduced not only in iron deficiency (see Chapter 279), but also in inflammation and infection, when macrophages retain iron and the serum iron falls. Why this happens is a matter of some controversy, but sequestration of body iron may disadvantage bacteria, which depend on iron for their growth.

Disorders of haemopoiesis

Disorders of haemopoiesis may involve over- or underproduction of one or more cell types by the marrow (see Box 277.2). Intrinsic or

primary disorders affecting haematopoietic progenitors themselves are discussed here. Megaloblastic haemopoiesis and anaemia is covered in Chapter 279, and disorders of red-cell production due to abnormal haemoglobin synthesis in Chapter 280.

The majority of primary haematopoietic disorders are acquired and arise from a single defective progenitor. Congenital disorders are rare and often associated with other congenital abnormalities (see Box 277.2).

The concept of clonality

One of the central concepts in cell biology is that every individual differentiated cell originates from a single progenitor, or stem cell and,

Box 277.2 Disorders of haemopoiesis*Clonal disorders originating in pluripotent stem cells and so affecting all three cell lines*

- myeloproliferative disorders: chronic granulocytic leukaemia, polycythaemia rubra vera, thrombocythaemia, myelofibrosis
- paroxysmal nocturnal haemoglobinuria
- acute myeloid leukaemia (some)
- myelodysplastic syndromes
- congenital cyclical neutropenia (rare)

Clonal disorders affecting committed progenitors

- acute myeloid leukaemia (some)
- myelodysplasia (some)
- acute lymphoblastic leukaemia
- chronic lymphocytic leukaemia
- myeloma
- lymphomas

Non-clonal disorders affecting all cell lines

- aplastic anaemia (some cases may have underlying clonal abnormality)
- megaloblastic haemopoiesis

Non-clonal disorders affecting primarily a single cell line

- selective cytopenias (autoimmune or drug induced)
- thalassaemias
- iron-deficiency anaemia
- congenital dyserythropoietic anaemia
- pure red-cell aplasia
- parvovirus infection (erythroid progenitors)

conversely, that each stem cell gives rise to a family (or 'clone') of differentiated daughter cells. Once a pluripotent haemopoietic stem cell becomes committed to differentiation, it ultimately produces a number of red cells, granulocytes, platelets, and lymphoid cells, which thus belong to the same clone. Similarly, each committed granulocyte progenitor (for example) gives rise to a single clone of granulocytes, which is therefore a subclone of the parent pluripotent stem cell.

Box 277.3 Some drugs and other toxic agents causing bone marrow failure*Predictable (dose related)*

- radiation
- cytotoxic drugs
- chloramphenicol

*Idiosyncratic (not dose related)**Agents causing granulocytosis*

- NSAIDs
- co-trimoxazole

Agents causing aplastic anaemia

- chloramphenicol
- phenylbutazone and other NSAIDs
- benzene and derivatives
- gold
- penicillamine
- pesticides

Box 277.4 Causes of aplastic anaemia

- drugs:
 - antibiotics (chloramphenicol, penicillin, cephalosporins, sulfonamides)
 - anti-inflammatory agents (phenylbutazone, indomethacin, penicillamine, gold)
 - hypoglycaemics (chlorpropamide, tolbutamide)
 - antithyroid drugs
 - phenothiazines
 - antimalarials
 - antiepileptics
- chemicals and toxins:
 - pesticides
 - benzene derivatives and related solvent compounds
 - dyes
- radiation
- infections:
 - hepatitis
 - EBV
 - CMV
 - rubella
- pregnancy

From time to time, an individual progenitor sustains genetic damage which alters its potential for growth and differentiation. This may give the cell and its progeny a growth advantage over normal cells, allowing **clonal expansion** of the affected line. The consequences of this will depend upon the nature of the mutant cell, the nature of the damage, and its effect on growth and differentiation. Uncontrolled clonal expansion of this sort is the basis of virtually every malignant neoplastic disorder.

Clonal disorders of haemopoiesis include frank haematological malignancies such as leukaemia and lymphoma, as well as less obviously malignant myelo- and lymphoproliferative disorders (see Box 277.2).

Bone marrow failure

Failure of haemopoiesis usually results from damage to proliferating marrow cells by cytotoxic drugs or radiation, haemopoietic malignancy, or a combination of the two. Much less commonly, damage to one or more cell lines can occur in patients taking other medication, due to immune mechanisms, certain viral infections, or for unknown reasons (see Box 277.3). Marrow replacement by metastatic malignancy may also result in marrow failure.

The result is a varying degree of anaemia, neutropenia, and thrombocytopenia; reduction in all three cell types is known as **pancytopenia**. The term **aplastic anaemia** is reserved for primary marrow failure with pancytopenia that is **not** obviously due to cytotoxic drugs or radiation.

Anaemia

Cessation of erythropoiesis leads to anaemia (see Chapter 279). The normal erythrocyte life span is 120 days, so interruption of production will lead to a fall in haemoglobin of about 1% per day (1 g/dl per week). Infection and bleeding, secondary to neutropenia and thrombocytopenia, are therefore often earlier and more serious manifestations of marrow failure.

Anaemia can be corrected by red-cell transfusions. In general, the aim is to maintain a haemoglobin level compatible with good health, normally above 9 g/dl. Below this level, there is a significant risk of optic fundal haemorrhage, which may occur in any form of anaemia but which can be particularly troublesome if infection and thrombocytopenia are also present.

Transfusion should be with packed red cells or red-cell concentrates, given slowly, and with diuretics if necessary, to avoid circulatory overload.

Neutropenia

Unlike red cells and platelets, neutrophil granulocytes have a predominantly extravascular role, and circulate in the blood for only a few hours, before passing into the tissues. The generation of mature

neutrophils from pluripotent stem cells takes 10–14 days, although the last few days in the marrow are spent in a non-mitotic **maturation compartment** which can be mobilized into the circulation rapidly in response to infection. Neutrophil lifespan in the tissues is only 2–3 days, so neutropenia is usually the earliest and most pronounced feature of marrow failure, reaching a nadir 7–10 days after haemopoiesis has been arrested.

The principal function of the neutrophil is bacterial phagocytosis and, in the steady state, most neutrophils scavenge for normal commensal gut organisms and other organisms which gain access to the body through breaks in the skin or gut mucosa. Bacterial infection is thus the major consequence of neutropenia, and will occur in around one-half of patients with peripheral blood neutrophil counts less than $0.5 \times 10^9/l$, and virtually all those with less than $0.2 \times 10^9/l$, lasting more than 10–14 days.

Gram-negative organisms of bowel origin are most commonly involved but, in hospitalized patients, the normal gut flora is often supplemented by resistant pathogens, such as *Klebsiella* spp. and *Pseudomonas* spp. Gram-positive organisms, such as *Staphylococcus epidermidis*, are commonly associated with the use of implanted central venous catheters for vascular access.

The earliest and often only manifestation of serious infection is fever. Local inflammatory signs are impaired, and focal signs may be minimal. Pulmonary, soft tissue, and urinary infections may occur. Septicaemia is common, although positive blood cultures are obtained in less than one-third of patients with a temperature higher than 38°C .

Suspected infection must be treated promptly, as delay may prove rapidly fatal. If a temperature $>38^\circ\text{C}$ develops, blood and urine cultures should be taken, and a chest radiograph performed. IV broad-spectrum antibiotics should be started immediately, following local protocols which should reflect the local pattern of organisms. Antibiotic therapy may be subsequently modified by the results of cultures.

Modern antimicrobials are capable of curing the majority of bacterial infections in neutropenic patients. Problems occur when neutropenia is particularly prolonged, especially in association with aggressive cytotoxic therapy, which may damage mucosal barriers and impair macrophage, as well as neutrophil production. Deep-seated fungal infections may develop in this situation and are often difficult to diagnose *in vivo*. Empirical IV antifungal therapy (e.g. with amphotericin) is advisable when fever or signs of infection persist, despite broad-spectrum antibiotic cover.

Infection may be prevented in severely neutropenic patients by strict isolation in a sterile environment, together with rigorous decontamination of skin and gut with disinfectants and antibiotics. In general, however, such measures do not improve the overall outcome, and their expense and poor patient acceptability has led most centres to abandon such regimes. Certain oral antibiotics, such as cotrimoxazole, ciprofloxacin, and norfloxacin may reduce the incidence of systemic infection and are often recommended in prolonged neutropenia, although there is potential risk of antibiotic resistance.

Recombinant growth factors (e.g. G-CSF) can reduce the period and severity of neutropenia after cytotoxic therapy, and thereby the morbidity and mortality from infection. Alternatively, by reducing myelotoxicity, they may permit the safe use of higher, and thus perhaps more effective, doses of cytotoxic therapy for malignant disease.

Thrombocytopenia

Platelets survive in the circulation for an average of 9–10 days, but are consumed more rapidly in the presence of bleeding, infection, or fever. The likelihood of abnormal bleeding depends upon the platelet count and the nature of the injury: spontaneous haemorrhage is uncommon unless the count falls below $20 \times 10^9/l$. At levels below this, petechial haemorrhages occur in the skin and mucous membranes, and in the internal organs.

Bleeding is aggravated by minor trauma and is most noticeable in dependent areas (because of hydrostatic pressure) and in pressure areas. The most serious risk from thrombocytopenia is cerebral haemorrhage.

Bleeding can be treated and prevented by transfusion of platelet concentrates. In an average adult, a transfusion of 5–6 units of

platelet concentrate will raise the platelet count by $10\text{--}30 \times 10^9/l$. Transfused platelets have a slightly shorter life span than normal, and 2–3 transfusions weekly may be required—increasing to daily in the presence of active bleeding or infection, both of which increase platelet consumption.

The major problem with repeated platelet transfusions is sensitization to foreign human leucocyte antigens (HLA) and platelet-specific antigens, which may lead to rapid platelet destruction, and ineffectiveness of transfusions from random donors. In this situation, good responses may be obtained by using platelets from HLA-matched donors, often as single-donor transfusions (collected on a cell separator), from the outset of thrombocytopenia to reduce the subsequent risk of sensitization. Since the responsible HLAs are most strongly expressed on leucocytes, an alternative approach is to use high-efficiency in-line filters at the time of transfusion to remove any leucocytes. Despite such measures, however, sensitization to platelet-specific antigens may still occur.

Drug-induced cytopenias

A variety of drugs may damage the marrow (see Box 277.3). Myelotoxicity is a well-recognized (and often intended) dose-dependent effect of the cytotoxic drugs used to treat malignant disease or as immunosuppressants. Other drugs may, on rare occasions, produce a severe reduction in the production of one or more cell types, in a non-dose-dependent or idiosyncratic fashion.

Prompt recovery usually follows withdrawal of the offending drug, provided this is rapidly identified. Prognosis is good except in patients who present with severe infection, and in whom mortality is high. Full supportive measures should be given as outlined in 'Neutropenia'.

Aplastic anaemia

Aplastic anaemia is a rare form of marrow failure leading to pancytopenia with a hypocellular or acellular bone marrow. In the majority of cases, no specific cause can be found, although various factors may be implicated in a minority (see Box 277.4).

Most cytotoxic drugs can produce severe pancytopenia, but this is usually recoverable, as the pluripotent stem cell population is relatively resistant to permanent damage. However, the alkylating agent busulphan, when used carelessly, can lead to prolonged or permanent aplasia, as can high doses of whole-body irradiation. Several drugs and chemicals have been associated with severe aplastic anaemia, presumably through an idiosyncratic and possibly immune-mediated mechanism.

The diagnosis of aplastic anaemia requires demonstration of the severely hypocellular marrow, preferably on two separate trephine examinations. Aplastic anaemia is said to be **severe** when, over a period of at least 3–4 weeks, the following findings are observed:

- the neutrophil count remains less than $0.5 \times 10^9/l$
- platelets are less than $20 \times 10^9/l$
- the **absolute** reticulocyte count (red blood cell count \times per cent reticulocytes) is less than $20 \times 10^{12}/l$

Untreated, severe aplastic anaemia is almost always ultimately fatal, although spontaneous recovery may occur occasionally.

Management involves supportive care, but with particular attention to the risk of sensitization to HLAs by transfusion, as this may impair platelet support and increase the risk of graft rejection if bone marrow transplantation (BMT) is undertaken. BMT is the treatment of choice in patients who are under the age of 50 and who have an HLA-compatible sibling donor. Two-thirds of transplanted patients will be cured permanently; the major problem is graft-vs-host disease, which tends to be less severe in younger patients.

An alternative to BMT is antithymocyte globulin (ATG). This was initially used as an immunosuppressant in the early days of BMT, but apparent early success of BMT in some patients was shown to be due to autologous recovery of the patient's own marrow, following failure of engraftment. Infusion of ATG over 5 days produces a response in about one-half of patients; the response is complete in about one-quarter and is sustained in over two-thirds. Age is not a factor influencing response, and ATG therapy is the treatment of choice over the age of 50, and in younger patients without a marrow donor.

The success of ATG therapy suggests a possible immune basis for aplasia in those who respond, although other non-myelotoxic

immunosuppressive agents, such as corticosteroids and cyclosporin A, have only occasionally produced a response.

Pure red-cell aplasia

Rare causes of severe anaemia occur in which the marrow shows complete absence of erythroid activity, but normal white-cell and platelet production. A congenital form, Diamond–Blackfan anaemia, is apparent at or shortly after birth and is associated with a variety of other, mainly skeletal, deformities in about one-third. There is a reduction in erythroid progenitors, which are also relatively insensitive to erythropoietin.

Acquired red-cell aplasia is thought to be autoimmune, with cytotoxic immune reactions directed against developing erythroblasts or, rarely, autoantibodies to erythropoietin. There is an association with thymoma, and it is worth doing a CT scan of the chest in affected patients, as removal of a thymoma may reverse the red-cell aplasia. Treatment is otherwise with corticosteroids. It is also occasionally seen in patients with chronic lymphocytic leukaemia (see Chapter 287).

Transient erythroblastopenia of childhood is an uncommon condition in which sudden onset of anaemia is associated with the erythropoiesis being temporarily suppressed.

Leukaemia

Leukaemias are clonal malignant proliferations of leukocytes and/or their precursors. **Acute** leukaemias (see Chapter 286) are characterized by uncontrolled growth of immature haemopoietic progenitor cells, at the expense of normal marrow function, and most of the clinical features are therefore those of marrow failure. They are of either myeloid (more common in adults) or lymphoblastic (more common in childhood) origin, and are rapidly fatal if untreated, but potentially curable with appropriate treatment.

Chronic leukaemias are clonal proliferations of haemopoietic cells that have not completely lost the ability to differentiate. Chronic myeloid (granulocytic) leukaemia has features in common with myeloproliferative disorders, while chronic lymphocytic leukaemia is best considered as a form of low-grade non-Hodgkin lymphoma.

Myeloproliferative disorders

The myeloproliferative disorders are a group of clonal disorders arising in haemopoietic or pluripotent stem cells characterized by uncontrolled growth but relatively normal differentiation—predominantly (but not always exclusively) down one of the three main haemopoietic pathways. The result is a significant expansion of red cells, granulocytes, or platelets and their precursors, alone or in combination.

Clinically, the myeloproliferative disorders may be classified according to the predominant cell type:

- **polycythaemia rubra vera:** red cells
- **essential thrombocythaemia:** platelets
- **myelofibrosis:** fibroblasts proliferating in response to growth factors, produced by an immature haemopoietic clone
- **chronic granulocytic leukaemia:** granulocytes

278 Diagnosis and investigation in haematology

Chris Bunch

The full blood count

A routine full blood count performed by the haematology laboratory will include the following parameters (some of these are measured directly, while others are derived by calculation; typical reference ranges are given in Table 278.1):

- **haemoglobin (Hb):** the concentration of haemoglobin in whole blood (expressed as grams per decilitre)
- **red-cell count (RCC):**
 - the concentration of red cells ($\times 10^{12}/\text{l}$)
 - changes in the RCC tend to parallel changes in the haemoglobin and haematocrit
 - a decrease in the RCC is called **anaemia**
 - an increase in the RCC is called **erythrocytosis** or **polycythaemia**
- **mean corpuscular volume (MCV):**
 - the average volume of individual red cells (expressed in femtoliters)
 - a low MCV indicates **microcytosis**
 - a high MCV indicates **macrocytosis**
- **haematocrit, or packed cell volume:**
 - the proportion of red cells in a unit volume of blood, usually expressed as a ratio (e.g. 0.45) or a percentage
 - derived from $\text{MCV} \times \text{RCC}$
- **mean cell haemoglobin (MCH):**
 - the average amount of haemoglobin per cell (expressed in picograms)
 - derived from Hb/RCC
- **mean cell haemoglobin concentration (MCHC):**
 - the mean concentration of haemoglobin per cell (expressed as grams per decilitre of red cells)
 - derived from $\text{Hb}/(\text{MCV} \times \text{RCC})$

- the MCHC tends to remain fairly constant but may be reduced in severe iron deficiency or thalassaemia
- pale (hypochromic) red cells on a blood smear may indicate small red cells (low MCV and MCH) but is more striking when MCHC is also reduced
- **white-cell (leucocyte) count:**
 - the total concentration of leucocytes ($\times 10^9/\text{l}$)
 - an increase is called a **leucocytosis**
 - a decrease is **leucopenia**
- **differential leucocyte count:**
 - either the absolute concentration ($\times 10^9/\text{l}$) or the percentage of each type of white cell
 - this may be derived manually by examination of a stained blood smear or by automated counters which differentiate cells by size, staining, or other characteristics
 - automated counters are potentially more accurate numerically (especially with low counts), but may misclassify some abnormal leucocytes
- **platelet count:** the concentration of platelets ($\times 10^9/\text{l}$)

The blood film or smear

Examination of a stained blood film is one of the key investigations in haematology, as alterations in the appearances of red cells, white cells, and platelets may give clues to the cause of any blood count abnormality, while the presence of abnormal cells, for example immature leucocytes in leukaemia, may be diagnostic (see Tables 278.2–6 and Box 278.1).

Unfortunately, the automation of blood counts has led to blood film examination becoming less routine in many laboratories, but a film should always be requested if a blood count abnormality cannot readily be explained by the clinical context.

The reticulocyte count

The reticulocyte count can give valuable information about the dynamics of erythropoiesis. In the normal, steady state, 1%–2% of red cells are reticulocytes. A normal marrow will respond to anaemia by increasing red-cell production and, thereby, the proportion of reticulocytes. This effect is most marked when red-cell lifespan is also reduced, as in haemolysis.

Because anaemia implies a reduction in the absolute RCC, a small increase in reticulocyte percentage does not necessarily indicate a healthy marrow response to anaemia, and calculation of the absolute reticulocyte count ($\% \text{ reticulocytes} \times \text{RCC}$: normally $25 \times 10^9/\text{l}$ to $85 \times 10^9/\text{l}$) is a more accurate guide.

The erythrocyte sedimentation rate, and plasma viscosity

When anticoagulated whole blood is left to stand, the red cells, white cells, and platelets sediment over time. The rate of red-cell sedimentation is directly proportional to the concentration of macromolecules such as fibrinogen and immunoglobulins in the plasma; so, any condition that increases these will increase the **erythrocyte sedimentation rate (ESR)**. In practice, the ESR is measured by timing the extent of red-cell sedimentation

Table 278.1 Normal values for full blood count

Variable	Normal range
Hemoglobin	Male: 13.5–17.5 g/dl Female: 12.0–16.0 g/dl
Hematocrit	Male: 41–53% Female: 36–46%
Mean corpuscular volume (MCV)	80–100 fl
Red cell distribution width (RDW)	11.5–14.5%
Reticulocyte count	0.5–2.5% red cells
White blood cell count	$4.5\text{--}11.0 \times 10^9/\text{L}$
Neutrophils	40–70%
Lymphocytes	22–44%
Monocytes	4–11%
Eosinophils	0–8%
Basophils	0–3%
Platelet count	$150\text{--}350 \times 10^9/\text{L}$

Data from Bain, B.J. Diagnosis from the blood smear. *N Engl J Med* 2005; 353: 498–507; and Tefferi, A. et al. How to interpret and pursue an abnormal complete blood cell count in adults. *Mayo Clinic Proc* 2005;80: 923–36.

after 1 hour in a standardized calibrated tube, and the result is expressed in millimetres per hour. The upper limit of normal is age- and sex-dependent, ranging from 17 mm/h in men aged 17–50, and 30 mm/h in men over 70, with acceptable values being 5–10 mm/h higher in women.

The ESR is most commonly raised in infections and inflammation, reflecting predominantly increased levels of fibrinogen, an 'acute phase reactant'. In this respect, it gives information similar to that provided by C-reactive protein (CRP) levels. However, it is a very non-specific test and may be raised in a range of underlying disorders, including malignancy. It will usually be higher than normal with significant anaemia (reflecting the reduced haematocrit).

The ESR can be significantly elevated when immunoglobulin levels are high, as in polyclonal hypergammaglobulinaemia (suggestive of chronic infection or inflammation), or monoclonal paraproteinaemia due to myeloma. Very high ESR levels (>100 mm/h) are highly suggestive of myeloma, Waldenström's macroglobulinaemia, tuberculosis, or vasculitic conditions, such as polymyalgia rheumatica or giant cell arteritis. The CRP level can sometimes help differentiation, as it is elevated in 'acute phase' conditions (inflammation or infection) but is usually unaffected by monoclonal paraproteinaemia.

The ESR is simply an indirect measure of plasma viscosity, which is increased by the same macromolecules, and some laboratories offer plasma viscosity measurements by preference. The information obtained is the same, and just as non-specific.

Iron, vitamin B₁₂, and folate studies

Iron-deficient erythropoiesis occurs when the iron supply to developing erythroblasts is reduced, typically due to iron deficiency or the anaemia of chronic disorders (ACD) and results in anaemia with a reduced MCV (microcytosis). Serum iron estimation alone is insufficient, as it is reduced in both cases, and proper evaluation requires serum ferritin and transferrin levels and/or transferrin saturation as well. In iron deficiency, ferritin is low and transferrin high; in ACD, transferrin is normal or low, and ferritin normal or raised (ferritin is also an 'acute phase reactant').

Serum vitamin B₁₂ and folate levels are required to determine the cause of megaloblastic anaemia and to elucidate macrocytic anaemia generally. Low folate levels in dietary folate deficiency can be rapidly reversed by refeeding, and the diagnosis missed. If this is suspected, then red-cell folate estimation may be helpful, as low levels recover much more slowly.

Vitamin B₁₂ levels are often requested in the investigation of dementia, but the interpretation of low levels in the absence of anaemia or typical neurology is a matter of some debate. Low levels may be associated with increased risk of falls in the elderly. High vitamin B₁₂ levels are seen in patients receiving intramuscular vitamin B₁₂ replacement, and in some myeloproliferative disorders, but are not diagnostic.

Radioisotopic studies

Radiation protection regulations have severely limited the availability of radioisotopes for haematological investigation. Traditional uses include blood volume estimations (red cells labelled with ⁵¹Cr; plasma with ¹²⁵I), red-cell survival (⁵¹Cr-labelled red cells), and the Schilling test for pernicious anaemia (absorption of ⁵⁷Co- or ⁵⁸Co-labelled cobalamins, with and without bound intrinsic factor).

Bone marrow examination

Although the nature of many haematological disorders can be determined from the blood count and film, examination of the bone marrow is essential to the proper evaluation and diagnosis of many disorders (see Box 278.2). The simplest form of marrow examination involves needle aspiration of marrow cells from the posterior iliac crest, after infiltrating the skin and periosteum with local anaesthetic. Smears are made and stained in the same way as a blood film and allow quantitative and qualitative assessment of the developing blood cells. Marrow can also be biopsied for histological examination, by using a special trephine biopsy needle. This can be performed at the same time as marrow aspiration from the iliac crest.

A marrow aspirate is usually sufficient to diagnose qualitative and quantitative defects in blood cell precursors, although it must be recognized that it only provides a 'snapshot' of a dynamic process. On occasions, marrow cells cannot be aspirated, and the attempt yields just a 'dry' or 'blood' tap. This may occur in myelofibrosis with a

Table 278.3 Microcytic anaemia (mean corpuscular volume <78 fl)			
Cause	Clues from full blood count and film	Other blood results	Causes/comment
Iron deficiency	Increased red-cell distribution width Anisocytosis Increased platelet count	Low iron Increased transferrin Low ferritin	Commonest cause of microcytic anemia, caused by inadequate dietary intake, malabsorption (e.g. celiac disease) or blood loss
Anemia of chronic disease (ACD)	Film usually unremarkable	Low iron Low/normal transferrin Normal/increased ferritin	~20% ACDs are microcytic: causes include Hodgkin disease and renal cell carcinoma
Thalassemia	Polychromasia Target cells	Normal ferritin Hemoglobin electrophoresis normal in alpha-thalassemia trait, and abnormal in beta-thalassemia trait and other thalassemia syndromes	Hematocrit usually >30% and MCV <75 fl in beta-thalassemia trait
Sideroblastic anemia	Siderocytes may be seen: hypochromic red cells with basophilic stippling that stain positive for iron (Pappenheimer bodies)	Increased ferritin	Rare Hereditary and acquired forms

Abbreviations: MCV, mean corpuscular volume.

Box 278.2 Indications for examination of bone marrow

- haematological malignancy, including leukaemia, lymphoma, myeloma, chronic granulocytic leukaemia, and myelodysplasia
- pancytopenia, or selective thrombocytopenia or neutropenia, where cause otherwise is not evident
- refractory anaemias (those not due to or responding to iron, vitamin B₁₂, folate replacement, or to obvious red-cell production disorders, such as thalassaemia)
- unexplained protracted fever; may rarely demonstrate tuberculosis, kala azar, or underlying malignancy
- leucoerythroblastic anaemia; to detect metastatic carcinoma, or myelofibrosis
- to confirm megaloblastic anaemia (rarely necessary)

hypercellular or ‘packed’ marrow—as in some cases of leukaemia or other haematological malignancies—or if the marrow is severely hypocellular. Trephine biopsy is necessary in these circumstances and is also helpful if marrow infiltration with metastatic malignancy is suspected. Where haematological malignancy is suspected or being investigated, a sample for cytogenetics may be taken for karyotyping and/or molecular studies.

Marrow aspirate and biopsy are invasive and unpleasant procedures and should not be undertaken lightly. It is important to consider carefully what information is being sought and to plan the samples and sample handling accordingly. Formal consent should be obtained: although the risks are low, occasional fatalities have occurred; extensive bleeding may occur in patients with recognized or unrecognized coagulation, or platelet function abnormalities, and inadvertent puncture of internal organs or blood vessels may occur if an unduly long biopsy needle is used. Particular care should be taken in the elderly, who may have a degree of osteopenia.

279 Deficiency anaemias

Chris Bunch

Definition

Erythropoiesis requires an adequate supply of iron for haem formation, as well as vitamin B₁₂ and folic acid (folate) to support high levels of DNA synthesis, and a lack of any of these will result in anaemia. Iron-deficient anaemias are typically microcytic, while a deficiency in vitamin B₁₂ or folate results in megaloblastic haemopoiesis and a macrocytic anaemia.

Aetiology

Iron deficiency

When iron loss exceeds iron intake, the body stores of iron are mobilized for haemoglobin production. As the stores become depleted, the ability to absorb iron from the diet is increased, and serum ferritin falls. As stores are further depleted, the serum iron level falls, and the total iron binding capacity (transferrin) rises. If a negative iron balance continues, the stores become exhausted, and tissue iron deficiency and anaemia will develop.

Iron deficiency will result from poor dietary iron intake, poor absorption, increased demands, blood loss, or combinations of these.

Diet

The bioavailability of iron in the diet is low for many people worldwide, although poor diet is rarely the sole cause of iron deficiency in Western societies, except in the very poor and the elderly. Even in populations whose diet is largely vegetarian and is poor in available iron, deficiency may only develop at times of increased losses or physiological demands.

Increased physiological demands

Increased physiological demands will commonly lead to a degree of iron deficiency in infants (6–24 months), adolescents (especially at the time of the growth spurt and puberty), and in menstruating women who are also childbearing. The additional requirements during pregnancy, amounting to about 500 mg, include iron supply to the fetus, the expanded maternal red-cell volume, and blood losses at delivery.

Blood loss

Menstruating women form the largest group of people who suffer sufficient blood loss to cause iron deficiency. Losses of up to 80 ml a month may be tolerated by increased absorption, provided the diet is adequate. However, worldwide, this is often not the case and, with the additional stresses of pregnancy, menstruating women are frequently iron deficient. Even in Western societies, where only 5% of women are overtly iron deficient as assessed by haemoglobin measurements, some 30% may respond to iron supplementation with a rise in haemoglobin.

Gastrointestinal bleeding accounts for the majority of other cases involving blood loss. The normal insensible loss in the gastrointestinal tract amounts to 1 ml/day. Since tests for occult bleeding are insensitive below about 20 ml/day, and bleeding is often intermittent, even moderate intestinal bleeding cannot always be documented. The most important benign causes of gastrointestinal bleeding are:

- haemorrhoids
- hiatus hernia
- NSAID use
- diverticulosis
- peptic ulceration
- angiodysplasia (especially in the elderly)

The possibility of occult bowel malignancy is always a major concern in postmenopausal women and adult males. Such patients should have upper gastrointestinal endoscopy and colonoscopy, or barium studies if these are not available. Hookworm infestation is a major cause of blood loss in developing countries, and should always be considered in recent immigrants.

Malabsorption

Malabsorption of iron occurs in coeliac disease, and may be its only manifestation, although there is usually also folate deficiency. Iron deficiency secondary to gastric atrophy is common in association with pernicious anaemia, but simple atrophic gastritis may respond to iron therapy, and thus be a result, rather than a cause, of iron deficiency.

Megaloblastic anaemias

Megaloblastic haemopoiesis produces a macrocytic anaemia with a slow and pernicious onset. This allows time for compensatory mechanisms to develop, and symptoms may not be apparent until the haemoglobin is very low, often below 6 g/dl. The principal complaint is therefore of progressive lassitude, with shortness of breath. Angina pectoris may occur in patients with coexistent impairment of myocardial function or coronary blood flow. Increased bilirubin production, associated with ineffective erythropoiesis and a shortened red-cell survival, may give rise to mild jaundice which, combined with extreme pallor, gives rise to a 'lemon-yellow' appearance.

Anaemia due to vitamin B₁₂ deficiency

Vitamin B₁₂ is synthesized only by microorganisms, and is obtained in man by ingestion of other animal products, or from bacterially contaminated vegetable matter. Pure dietary deficiency is therefore rare, and seen only in strict vegans.

Dietary vitamin B₁₂ binds to R factor in saliva and gastric juices. In the duodenum, it dissociates from R factor, and binds to intrinsic factor (IF) in the presence of pancreatic enzymes. The IF–B₁₂ complex is taken up by receptors (cubilin) in the terminal ileum and then released into plasma, bound to transcobalamins TC I, II, or III. Vitamin B₁₂ enters cells by receptor-mediated endocytosis and is metabolized into two coenzymes: adenosylcobalamin and methylcobalamin.

The usual cause of severe vitamin B₁₂ deficiency in Western countries is an autoimmune atrophic gastritis, in which there is a loss of gastric parietal cell numbers and an absence of intrinsic factor production, which effectively prevents vitamin B₁₂ absorption. This is the classical **pernicious anaemia**, and it is often seen in association with other autoimmune disorders, such as myxoedema (hypothyroidism), Addison's disease (hypoadrenalism), and vitiligo.

Vitamin B₁₂ deficiency may result from infestation with the fish tapeworm *Diphyllobothrium latum*. More rarely, it may result from total gastrectomy; surgery or disease (e.g. Crohn's) affecting the terminal ileum, or congenital deficiencies of intrinsic factor, cubilin (the IF–B₁₂ receptor), or transcobalamins.

Anaemia due to folate deficiency

Folate deficiency may result from a poor diet, from malabsorption, or when demand for folate is increased, for example during pregnancy or with increased haemopoiesis in haemolytic anaemias or myeloproliferative disorders.

Dietary sources of folate are varied, with high amounts in liver, kidney, green vegetables, yeast, nuts, and fruit. Cooking at high temperatures and in large volumes of water largely destroys it. Alcoholics

whose caloric intake is in large part derived from ethanol are particularly prone to folate deficiency.

Folate malabsorption occurs in gluten-sensitive enteropathy (coeliac disease), and most untreated patients will have low serum and red-cell folate levels. Clinical anaemia is more often due to combined iron and folate depletion, but folate deficiency may be sufficiently severe to lead to pure megaloblastic anaemia. Dermatitis herpetiformis may also be associated with folate malabsorption. Less common causes are jejunal resection; partial gastrectomy; extensive Crohn's disease involving the small bowel; lymphoma; and severe systemic infection. Tropical sprue is an important cause on a worldwide basis.

Typical symptoms of the disease, and less common symptoms

The symptoms and signs of anaemia due to deficiency in iron, vitamin B₁₂ or folate are principally those of any associated anaemia—tiredness, fatigue, pallor—and may occasionally presage the development of anaemia. Deficiency of iron or folate is associated with slowed growth and impaired cognitive development in infants and young children, and with premature birth and low birthweight in pregnancy. In addition, folate deficiency is linked to neural tube defects.

Severe iron deficiency may also be associated with pica (an abnormal appetite for non-nutritional substances such as clay, or for food ingredients such as raw meat or vegetables), mucous membrane inflammation affecting the tongue (glossitis) and sometimes the pharynx and oesophagus (Plummer–Vinson/Paterson–Brown–Kelly syndrome), brittle, ridged nails (koilonychia), or hair loss.

Severe vitamin B₁₂ deficiency may be complicated by a symmetrical peripheral neuropathy, with predominant signs in the lower limbs. A classical and often irreversible complication of vitamin B₁₂ deficiency is **subacute combined degeneration of the spinal cord**. Psychiatric disturbance and optic atrophy may also occur. Recently, low blood levels of vitamin B₁₂ have been linked to postural hypotension and falls in the elderly in the absence of anaemia. The biochemical basis of these neurological complications is unclear. Low vitamin B₁₂ and folate levels have also been linked to depression.

Folate in the 5-methyltetrahydrofolic acid form is a cosubstrate for methionine synthase in the conversion of homocysteine to methionine; consequently, homocysteine accumulates in folate deficiency and is strongly associated with atherosclerotic vascular disease such as coronary artery disease and stroke.

Demographics of the disease

Demographics of iron deficiency

Iron deficiency is a worldwide problem, reflecting the heavy physiological demands for iron and its limited bioavailability in many diets. Overall, more than 500 million people are thought to be affected. Even in 'advanced' Western societies, around 10% of infants, adolescents, and menstruating women are iron deficient, with anaemia evident in around a quarter of these. Both chronic blood loss and poor diet play a part.

Demographics of folate deficiency

Like iron deficiency, folate deficiency is a worldwide problem associated with inadequate nutrition. Dietary lack may be aggravated by previous gastric or abdominal surgery, gastrointestinal disorders such as chronic tropical sprue, and chronic inflammatory conditions, such as rheumatoid arthritis and chronic infections, which appear to inhibit absorption. Pure dietary deficiency may also occur in infants fed goats' milk (which is very low in folate) as a substitute for mother's or cows' milk.

Since 1998, food fortification with folic acid has been compulsory in the US, and this has been accompanied by a reduction in the prevalence of low serum folate levels from 16% to 0.5%

Demographics of vitamin B₁₂ deficiency

Nutritional vitamin B₁₂ deficiency is much less common than iron or folate deficiency, reflecting the widespread availability of vitamin B₁₂ in all but the strictest vegan diets. However, the risk of developing vitamin

B₁₂ deficiency increases with age for a number of reasons, including cognitive dysfunction, social isolation, mobility limitations, and poverty.

Pernicious anaemia, which is vitamin B₁₂ malabsorption due to a lack of gastric intrinsic factor, is the commonest form of vitamin B₁₂ deficiency. It is most common in Caucasians of Northern European descent, affecting up to 3% of individuals over 60.

Natural history and complications of the disease

Deficiency anaemias are progressive until the deficiency is corrected. As the onset is usually slow, adaptive mechanisms can mitigate the symptoms of anaemia, which in extreme cases may only become symptomatic at very low haemoglobin levels (2–4 g/dl). However, anaemia is likely to aggravate coexisting coronary or cerebrovascular disease.

Approach to diagnosing the disease

Iron deficiency should be considered in any anaemia that is microcytic, and vitamin B₁₂ or folate deficiency in any anaemia that is macrocytic. The aim of investigation is to establish whether or not a deficiency exists, as well as the underlying cause. The former can usually be achieved by laboratory tests. The latter depends on the clinical picture, so a full clinical history, covering diet as well as bleeding history, together with a full clinical examination (including neurology) is important and will dictate subsequent investigation.

Other diagnoses that should be considered

Causes of red-cell microcytosis and macrocytosis are given in Table 279.1.

'Gold-standard' diagnostic test

The diagnosis of deficiency anaemias is made on the basis of the clinical and haematological picture, together with measurement of serum levels of iron, ferritin, and transferrin (iron deficiency); serum and red-cell folate levels (folate deficiency); and serum vitamin B₁₂ levels (vitamin B₁₂ deficiency). A bone marrow aspirate stained for iron has long been considered the gold-standard test for iron deficiency, but it is invasive, painful, and rarely justified for this purpose alone. On the other hand, while the blood film may reveal features of megaloblastic anaemia (e.g. macrocytosis, circulating megaloblasts, hypersegmented neutrophils), a bone marrow aspirate may occasionally be necessary to confirm the presence of megaloblastic haemopoiesis in vitamin B₁₂ or folate deficiency, if these features are not unequivocally present.

Acceptable diagnostic alternatives to the gold standard

Acceptable diagnostic alternatives to the gold-standard test for iron deficiency

A low serum iron and ferritin, with a raised serum transferrin, is virtually diagnostic of iron deficiency. In practice, the ferritin level is more useful than iron or transferrin levels, although it is an acute phase

Table 279.1 Causes of red-cell microcytosis and macrocytosis

Microcytic	Macrocytic
Iron deficiency	Alcohol
Anaemia of chronic disease	Pregnancy
Thalassaemias (alpha and beta)	Reticulocytosis
Abnormal haemoglobins (haemoglobin C, S/C, or E)	Liver disease
	Hypothyroidism
	Liver disease
	Myeloma
	Myelodysplasia
	Cytotoxic drugs
	Vitamin B ₁₂ deficiency
	Folate deficiency

reactant and is raised in the presence of infection or inflammation. In the presence of microcytic anaemia, a ferritin of $<15 \mu\text{g/l}$ confirms iron deficiency, while a level of $>100 \mu\text{g/l}$ virtually excludes it.

Acute or chronic inflammation, infection, or malignancy can confuse the picture, as these may cause a mild-to-moderate anaemia that is normocytic to microcytic with a reduced serum iron but, typically, a raised ferritin and normal or low transferrin—the **anaemia of chronic disease**. For this reason, a trial of oral iron therapy should be considered in anaemic patients with a serum ferritin of $<40 \mu\text{g/l}$, or $<70 \mu\text{g/l}$ in the presence of infection, inflammation, or malignancy.

Acceptable diagnostic alternatives to the gold-standard test for folate deficiency

Folate status is normally assessed by measurement of serum and red-cell folate concentrations. A normal serum folate more or less excludes significant folate deficiency, but a reduced level does not in itself make a diagnosis of deficiency. This is because serum folate levels reflect recent folate intake and may be depressed after a short period of inadequate intake, while red-cell folate reflects folate status over the previous 2–3 months, and a low level is a more reliable indicator of tissue folate depletion. As a single meal can improve a low serum folate level within a few hours, red-cell folate should be measured in patients who have been admitted to (and fed in) hospital.

Low folate levels reflect poor dietary intake or absorption, while high levels may be associated with blind loop syndrome (bacterial production), active liver disease (release of stored folate), or folate supplementation.

Acceptable diagnostic alternatives to the gold-standard test for vitamin B₁₂ deficiency

Serum vitamin B₁₂ levels in megaloblastic anaemia due to vitamin B₁₂ deficiency are usually significantly reduced, and the diagnosis is then straightforward. More difficult to interpret are marginally reduced vitamin B₁₂ levels in the absence of significant anaemia or macrocytosis. This is a fairly common situation in the elderly, who are also prone to falls, a condition which is thought by many to be a consequence of mild, subclinical deficiency.

A diagnosis of pernicious anaemia (vitamin B₁₂ malabsorption due to gastric atrophy and intrinsic factor deficiency) as the cause of anaemia due to vitamin B₁₂ deficiency normally rests on the demonstration of a reduced absorption of radioactive vitamin B₁₂ administered orally, and increased absorption when the dose is combined with intrinsic factor—the **Schilling test**. However, tougher regulation of medical radioisotope use has all but completely eliminated the availability of this test, and the diagnosis rests on probabilities. The presence of other autoimmune conditions such as thyroid disease and adrenal insufficiency (Addison's disease), as well as the presence of gastric parietal cell antibodies or intrinsic factor antibodies, are strong pointers to pernicious anaemia being the cause.

Other relevant investigations

Less commonly available investigations that may be helpful in diagnosing the presence of deficiency anaemias include:

- circulating transferrin receptor levels, which parallel tissue receptor levels and are increased in iron deficiency
- serum or urinary hepcidin levels, which are low in iron deficiency but raised in anaemia of chronic disease
- methylmalonic acid and homocysteine levels, which may be useful in the evaluation of slightly reduced or low-normal vitamin B₁₂ or folate levels; a raised methylmalonic acid and/or homocysteine level gives some support to the diagnosis of vitamin B₁₂ and folate deficiency

Prognosis

Deficiency anaemias are usually easily correctable by replacement of the missing substance, so the main determinant of prognosis is the underlying cause.

Treatment and its effectiveness

Treatment for iron deficiency

In most cases, iron deficiency responds well to oral replacement: ferrous sulfate 200 mg or ferrous fumarate 300 mg daily, raising to twice, and then three times daily if tolerated. In uncomplicated iron deficiency, a rise in haemoglobin of 1 g/dl per week may be expected. Treatment should continue for 6 months after the anaemia is corrected, in order to replenish iron stores. If this is not done, the risk of recurrence is high.

Response to iron therapy may be suboptimal in the presence of infection, inflammation, renal impairment, cancer, or continuing blood loss. Oral iron commonly causes gastrointestinal symptoms such as nausea, epigastric pain, and diarrhoea; in addition, iron supplementation turns the stools black, so that they are commonly mistaken for melaena. Ideally, for maximal absorption, iron should be taken between meals, although side effects are likely to be worse. Concomitant administration of vitamin C improves absorption of a given dose. Alternative oral preparations (liquid, slow release) may cause fewer side effects but are less effective because they contain less iron and/or release most of it beyond the duodenum and upper jejunum, where iron is absorbed.

In rare cases of complete intolerance or refusal to take oral iron, it may be given intravenously. Earlier IV iron preparations were high-molecular-weight carbohydrate complexes (e.g. iron dextran) and were associated with serious (and sometimes fatal) side effects. Newer preparations such as iron sucrose appear to be more effective and safer.

Treatment of folate deficiency

Folate is easily replaced orally in a dose of 5–15 mg of folic acid daily, with no side effects. IV replacement is necessary, only in patients receiving total parenteral nutrition.

Treatment of vitamin B₁₂ deficiency

Vitamin B₁₂ is usually replaced by regular intramuscular injection of hydroxocobalamin, which is available in 1 mg ampoules. This is about 1000 times the normal daily requirement, but this is not a problem as the vitamin is inexpensive and safe, and most of it is excreted in the urine. For this reason, initial treatment should be 1 mg on alternate days for a fortnight and then monthly thereafter.

Indications for blood transfusion

There is sometimes a temptation to perform a blood transfusion on a patient with severe or even moderate anaemia that is clearly due to a deficiency in iron, vitamin B₁₂, or folate. This temptation should be resisted in most instances, and is usually only justified if there is ongoing bleeding, when iron replacement may be insufficient to correct the anaemia. Indeed, transfusion may be dangerous: deficiency anaemias usually develop gradually over weeks or months, giving plenty of time for adaptive mechanisms to develop. Such red cells, that are circulating, are actually highly attuned to optimal oxygen delivery. Transfused red cells are the opposite: they have been refrigerated, are metabolically inert, and have lost much of their 2,3-diphosphoglycerate, shifting the oxygen-dissociation curve in favour of retaining rather than delivering oxygen.

280 Haemolytic anaemia

Chris Bunch

Introduction

Haemolytic anaemias occur when the rate of red-cell breakdown is increased and exceeds the marrow's capacity to generate new cells. The normal red-cell lifespan averages 120 days: by this time, the cells' metabolic activity is no longer able to maintain membrane integrity, resulting in removal by macrophages, predominantly in the spleen. Increased red-cell destruction, or **haemolysis**, may occur for a variety of reasons (Box 280.1). Some involve intrinsic defects in the red cell itself; in others, the red cells are normal but subjected to external factors which lead to premature destruction. Many of the intrinsic defects are due to inherited disorders affecting the red-cell membrane, its enzymes, or haemoglobin. Some of these represent major worldwide health problems.

The marrow can normally compensate for moderate haemolysis by increasing red-cell production up to tenfold. Only when haemolysis is severe and the red-cell lifespan is reduced to less

than about 15 days, or the marrow is unable to compensate, will anaemia occur.

General features of haemolysis

The clinical effects of haemolysis can be divided into those of increased red-cell breakdown, and those related to compensatory marrow activity. The breakdown of haemoglobin generates bilirubin, which is transported to the liver, where it is conjugated with glucuronic acid and excreted in the bile. The conjugation pathway is easily saturated, leading to mild jaundice due to increased levels of circulating unconjugated bilirubin. This is sometimes called **acholuric jaundice** (literally, 'no bile in the urine' jaundice).

In most cases, haemolysis is **extravascular**: the red cells are destroyed after phagocytosis by fixed macrophages lining the sinusoids of the spleen, liver, and bone marrow. Less commonly, red-cell destruction is **intravascular**, with release of haemoglobin into the circulation.

Free haemoglobin binds to circulating haptoglobins, and the complex is removed by the liver. Haptoglobins can normally bind 100–140 mg of haemoglobin per 100 ml of plasma: a fall in haptoglobin level is thus a sensitive indicator of intravascular haemolysis, although some reduction usually also occurs in severe extravascular haemolysis. Large amounts of haemoglobin may exceed the binding capacity of haptoglobin, so that free haemoglobin appears in the circulation, is filtered by the glomerulus, and appears in the urine. Small amounts are reabsorbed and metabolized by the tubular cells to haemosiderin, which may be detected in a urine deposit due to shedding of tubular cells. This is a particularly sensitive measure of chronic intravascular haemolysis.

Anaemia occurs in severe haemolysis or when the marrow is unable to compensate normally. The appearance of the red cells may give some clue to the nature of the haemolysis. For example, there may be spherocytes, sickle cells, deposits of precipitated haemoglobin (**Heinz bodies**), and so on.

Increased red-cell production is reflected by a **reticulocytosis** greater than the normal level of 2%. This produces polychromasia (the reticulocytes stain with a bluish tinge on routine blood smears) and a mild macrocytosis, as reticulocytes are larger than mature red cells. The marrow shows erythroid hyperplasia. In long-standing or severe haemolysis, increased folate utilization may lead to deficiency, with superadded megaloblastic change.

Patients with haemolytic anaemia may suffer sudden and profound falls in haemoglobin in association with human parvovirus infection; such events are termed '**aplastic crises**'. The virus infects erythrocyte progenitors in the marrow, and red-cell production ceases completely for 48–72 hours. The effect is insignificant in normal individuals but, with haemolysis, when red-cell survival is very short, sudden failure of compensation produces catastrophic anaemia with reticulocytopenia. The leucocyte and platelet counts may be affected to a lesser degree. The infection is self-limiting, but transfusion may be needed.

Red-cell membrane disorders

The red-cell membrane has important functions in maintaining the cell shape and deformability, in controlling the osmotic equilibrium of the cell by energy-dependent cation transport systems, and in governing the permeability and other properties of the cell via the structural organization of its proteins, lipids, and terminal sugar residues. Interference with any of these functions increases red-cell fragility and can lead to haemolysis. This is usually the result of an inherited structural or metabolic defect.

Box 280.1 Causes of haemolysis

Intrinsic red-cell defects

Red cell membrane disorders

- hereditary spherocytosis
- other rare inherited membrane disorders (e.g. hereditary elliptocytosis, stomatocytosis, hereditary pyropoikilocytosis, acanthocytosis)
- paroxysmal nocturnal haemoglobinuria
- other acquired membrane disorders (e.g. myelodysplasia, lipid defects)

Red cell metabolic disorders

- abnormalities of the pentose phosphate pathway (e.g. glucose-6-phosphate-dehydrogenase deficiency)
- abnormalities of the glycolytic pathway (e.g. pyruvate kinase deficiency)
- abnormalities in glutathione metabolism
- acquired abnormalities (e.g. in myelodysplasia)

Haemoglobin disorders

- disorders of globin chain synthesis: the thalassaemias
- structural globin chain variants: sickle cell disease, haemoglobin E, etc.

Extrinsic factors causing haemolysis

Immune haemolysis

- alloimmune haemolysis
- autoimmune haemolysis
- drug-induced haemolysis

Haemolysis secondary to red-cell damage

- damage from infections (e.g. malaria, toxoplasmosis, *Clostridium welchii*)
- damage from drugs or chemicals (e.g. phenylhydrazine, dapsone, sulfasalazine, arsine, chlorate)
- damage from mechanical trauma (e.g. artificial heart valves, march haemoglobinuria, microangiopathic haemolytic anaemia)
- damage from other causes (e.g. fibrinoid necrosis, vasculitis, tumour cell invasion (especially from mucin-secreting carcinomas), burns (from direct heat damage and, secondarily, disseminated intravascular coagulation))

Hereditary spherocytosis

Hereditary spherocytosis (HS) is characterized by red cells that are spherical rather than biconcave and have increased osmotic fragility and a shortened life span. The condition is heterogeneous both in clinical severity and in terms of the underlying defect. In the majority of cases, the defect is inherited in an autosomal dominant fashion, although recessive forms are also recognized. It is the commonest form of haemolytic anaemia due to a red-cell membrane abnormality, and the commonest inherited haemolytic anaemia in Northern Europeans, affecting 1:5000 of this population.

Aetiology of HS

HS results from a molecular defect in one or other of the membrane cytoskeleton proteins (e.g. spectrin, actin, band 3 protein, protein 4.2). The cell is unable to maintain its normal biconcave shape and becomes spherical and prone to early destruction, predominantly in the spleen.

Clinical features of HS

The severity of HS is variable but is often similar in the affected members of a given family. It usually presents in childhood, sometimes as neonatal jaundice but, in mild cases, may only be recognized in an adult after identification of an affected offspring or grandchild, or when pigment gallstones are found at cholecystectomy.

In HS, anaemia is mild (haemoglobin levels of 8–12 g/dl) or absent. The reticulocyte count is elevated and the blood film shows spherocytes and polychromasia. Mild jaundice is common, with bilirubin levels of 16–20 mmol/l, which may be accentuated at times, such as during infection, when haemolysis increases. A high bilirubin turnover can lead to the formation of pigment gallstones. The spleen is usually just palpable.

Diagnosis of HS

The diagnosis of HS is confirmed by an **osmotic fragility test**, in which cell lysis is assessed in solutions of differing osmotic strength. In spherocytosis, the fragility curve characteristically shows two cell populations, with a 'tail' of fragile cells.

Management of HS

Splenectomy markedly reduces the rate of haemolysis in HS and produces almost complete reversal of the anaemia. It is recommended in symptomatic patients, especially if recurrent transfusion has been required. However, its role is more debatable in asymptomatic patients with a well-compensated low-grade haemolysis, and the risks of post-splenectomy infection must be borne in mind. The risk of infection is much greater in children, and splenectomy should therefore be delayed as long as possible. The spleen should be removed at the time of cholecystectomy in patients with gallstones.

Other inherited membrane disorders

Haemolytic anaemia is associated with a variety of other rare red-cell membrane disorders. These include:

- **hereditary elliptocytosis:**
 - this is a fairly common but mild defect with autosomal dominant inheritance
 - it is rarely a clinical problem
 - some forms are linked to the rhesus D group loci
 - occasional homozygotes may have severe disease
- **stomatocytosis:** in this disorder, the membrane defect gives the cell a characteristic 'stoma', or mouth-like appearance
- **hereditary pyropoikilocytosis:** in this disorder, the red-cell membrane is unusually temperature sensitive, which leads to red-cell fragmentation
- **acanthocytosis:** in this disorder, a membrane lipid defect produces cells with characteristic 'spiky' projections, which can be seen on a fresh blood film

Paroxysmal nocturnal haemoglobinuria

Definition of paroxysmal nocturnal haemoglobinuria

Paroxysmal nocturnal haemoglobinuria (PNH) is a rare acquired haemolytic disorder characterized by exquisite sensitivity of

the red cells to intravascular lysis by complement, resulting in haemoglobinuria. Sufferers also have an increased tendency to thrombosis.

Aetiology of PNH

The abnormality in PNH arises from a mutation in a haemopoietic stem cell: it is thus a clonal disorder which affects red cells, white cells, and platelets, although the most obvious clinical manifestations arise from red-cell lysis. The abnormal clone coexists with normal cells, with the proportion of abnormal cells determining the severity of the disease.

The defect is caused by the absence of glycosyl-phosphatidylinositol (GPI)-anchored proteins which normally protect against complement-mediated lysis. The absence of two of these proteins, CD55 and CD59, is fundamental to the pathophysiology of PNH. The enzyme phosphatidylinositol glycan A (PIG-A), which is needed for GPI synthesis, is deficient in PNH. The gene for PIG-A resides on the X chromosome: in males, cells contain only one X chromosome while, in females, there is random inactivation of one of each pair at an early stage of development. Thus, just a single PIG-A mutation is required to disrupt the GPI anchor.

The thrombotic tendency is thought to be due to a similar membrane defect in platelets.

Clinical features of PNH

PNH classically presents with early morning haemoglobinuria, as haemolysis is more active during sleep. There may also be exacerbations during infection or following surgery. In many patients, however, the brief paroxysms of haemoglobinuria go unnoticed, and the condition presents as unexplained anaemia or jaundice. For this reason, several years may ensue from the first onset of symptoms to eventual diagnosis. In some patients, the disease comes to light because of thrombotic complications: these often involve unusual sites, such as the mesenteric and hepatic veins (Budd–Chiari syndrome), or the intracranial venous sinuses.

A PNH clone, and other features of the disease, may appear in some patients with aplastic anaemia. Most patients with PNH have a degree of pancytopenia at some stage in their illness, and recurrent infections may occur. Recurrent haemoglobinuria commonly leads to iron deficiency.

Diagnosis of PNH

The major barrier to the diagnosis of PNH is not thinking of the disorder in the first place. It should be considered in patients with unexplained pancytopenia, bizarre thromboses, or jaundice. The diagnosis is confirmed by the demonstration of reduced membrane CD55 and CD59 in red or white cells by flow cytometry, or by the fluorescein-labelled proaerolysin test (proaerolysin binds to GPI.) Screening the urine for haemosiderin is a useful indicator of low-grade chronic intravascular haemolysis.

Treatment of PNH

Many PNH patients require no treatment. Transfusion may occasionally be necessary but can precipitate haemolysis unless the red cells are washed free of plasma before transfusion. Patients who have experienced thrombosis should take oral anticoagulants for life. Steroids may be of benefit in acute exacerbations but are not indicated in the long term. Oral iron supplements should be given if iron deficiency occurs. Marrow transplantation should be considered in severe cases, especially in those with predominant pancytopenia.

Recently, use of the monoclonal antibody eculizumab has been advocated for the management of PNH. Eculizumab is directed against the complement protein C5, which inhibits terminal activation, and it is effective in preventing intravascular haemolysis in PNH. However, its precise role has not yet been determined.

Prognosis of PNH

Most patients with PNH survive for many years. The major hazards are thrombotic events, and pancytopenia, which tends to progress with time. Acute myeloid leukaemia may occasionally occur, reflecting clonal evolution of the abnormal clone. Many years of chronic haemoglobinuria may eventually lead to renal failure.

Other acquired membrane disorders

Alterations in the red-cell environment can lead to the development of abnormal membrane characteristics, which then result in mechanical destruction of the cell and a shortened lifespan. **Lipid disorders** and **liver disease** may alter the red-cell lipid content by passive exchange. **Zieve's syndrome** is a severe haemolytic anaemia with abdominal pain, cirrhosis, hyperlipidaemia, and jaundice, seen in chronic alcoholics. **Vitamin E deficiency** in the newborn allows auto-oxidation of the membrane lipids and haemolysis.

Haemolysis is a feature of a number of acquired haematological dysplasias. It may arise because of ineffective erythropoiesis with defective cell formation, or because of clonally acquired red-cell membrane defects due to inherited disorders such as PNH. Both **megaloblastic anaemia** and **iron-deficiency anaemia** are associated with ineffective erythropoiesis and a slightly shortened red-cell lifespan. In the **myelodysplasias**, acquired abnormalities of red-cell shape, metabolism, or surface components may reduce the red-cell lifespan.

Red cell metabolic disorders

The red cell is nucleate and lacks most intracellular structures such as ribosomes and mitochondria. It cannot replace lost or damaged proteins or use oxidative phosphorylation as an energy source. It therefore relies on anaerobic glycolysis and the hexose monophosphate shunts to provide its energy and reducing power. Consequently, abnormalities in these pathways are associated with haemolysis.

The enzymes most commonly implicated in haemolytic anaemia are glucose 6-phosphate dehydrogenase (G6PD) and pyruvate kinase (PK).

G6PD deficiency

G6PD deficiency is by far the most important red-cell enzyme deficiency worldwide; as many as 100 million people carry a mutation leading to this deficiency. The deficiency is inherited as an X-linked characteristic which is only fully expressed in males, with females having varied expression depending upon the random X-chromosome inactivation in the red-cell precursor population. The condition is particularly prevalent in the populations of Africa, the Mediterranean, the Middle East, and South East Asia, probably because carriers of mutant G6PD alleles are afforded some protection from falciparum malaria.

Pathophysiology of G6PD deficiency

G6PD deficiency results from the inheritance of one of the 400 or so known variant forms of the enzyme. Only two of these occur with any frequency: the unstable A⁻ variant in the African population, and the structural Mediterranean variant. The precise mechanism by which G6PD deficiency causes haemolysis is not completely understood. In outline, there is failure to reduce glutathione which allows oxidative damage to haemoglobin, leading to its precipitation as Heinz bodies. Haemolysis is most apparent in the presence of oxidant drugs and chemicals, which would normally be adequately dealt with by the cells' reducing capacity.

Clinical features of G6PD deficiency

G6PD deficiency has the following clinical features:

- drug-induced haemolysis
- favism
- neonatal jaundice
- chronic haemolysis

Drug-induced haemolysis

In G6PD-deficient individuals, intravascular haemolysis can occur within a few days of ingestion of an oxidant drug. The pattern and severity of the haemolysis depend upon the drug, its dose, and the G6PD variant in question. Anaemia and jaundice develop rapidly and, in severe cases, are associated with shivering, backache, and the passage of dark urine. In the A⁻ variant, G6PD levels are lowest in older red cells, and the episode may be self-limiting, as the

reticulocytes produced in response to the haemolysis have relatively normal amounts of the enzyme. On the other hand, G6PD activity is virtually absent in the Mediterranean type, and haemolysis may be progressive and fatal.

Favism

Favism refers to a severe haemolytic reaction that occurs in individuals with the Mediterranean G6PD deficiency when they are exposed to the fava bean (*Vicia faba*) or its pollen. It is not known how the haemolysis is precipitated or why some individuals are spared while others have recurrent attacks or only have an attack after multiple exposures.

Neonatal jaundice

Neonatal jaundice, occasionally leading to kernicterus, is seen in some individuals with G6PD deficiency. However, other factors seem to be involved, as the haemolysis observed does not fully account for the clinical picture.

Chronic haemolysis

Chronic haemolysis with jaundice and splenomegaly is seen in some G6PD-deficient individuals. In addition, haemolysis can occur or become apparent during an intercurrent illness or infection.

Laboratory diagnosis of G6PD deficiency

Heinz bodies will be detectable in the red cells during period of haemolysis but, in their absence, diagnosis depends on the demonstration of reduced levels of G6PD in red cells. The diagnosis is difficult in a patient with the A⁻ variant during the recovery phase from a haemolytic episode because of the high proportion of reticulocytes containing normal levels of the enzyme. Tests may need repeating in the stable state. More sophisticated analysis is required to identify the G6PD subtype.

Treatment of G6PD deficiency

Avoidance of drugs precipitating acute episodes is most important. Supplementary folic acid should be given in chronic haemolysis, and transfusion may be required during acute haemolysis, with exchange in the neonatal period.

PK deficiency

Although deficiencies of each of the enzymes in the Embden–Meyerhof pathway have been described, the only clinically important deficiency is PK deficiency. PK deficiency is a relatively rare disorder, with autosomal recessive inheritance, and shows considerable molecular heterogeneity. PK catalyses the final reaction in the glycolytic pathway: deficiency slows the overall glycolytic rate, reduces levels of ATP, and leads to accumulation of all metabolic intermediates including 2,3-bisphosphoglyceric acid. Haemoglobin oxygen affinity is thereby reduced, ameliorating to some extent the clinical effects of the anaemia.

Clinical features of PK

Most patients present in the neonatal period or in infancy with a moderate-to-severe anaemia (haemoglobin levels of 4–10 g/dl) that is relatively well tolerated. The spleen may be enlarged and there is jaundice. Haemolysis may increase during intercurrent infection; aplastic crises and gallstones may also occur.

Management of PK

In patients with PK, transfusion should be reserved for times of stress, such as infection or pregnancy. Splenectomy is indicated occasionally and can lead to an overall clinical improvement associated with a marked rise in the reticulocyte count. Folic acid should be given to prevent secondary deficiency.

Deficiencies of enzymes in the glutathione cycle

The glutathione cycle is important in the oxidoreductive balance of the red cells, and there is a link between its reactions, the reduced NADPH of the hexose monophosphate pathway, and the oxidation reactions affecting haemoglobin and the red-cell membrane. Deficiencies of glutathione synthetase and glutathione reductase are both rare causes of haemolytic anaemia.

The only other important red-cell defect—although not associated with haemolysis—is **NADH:methaemoglobin reductase deficiency**. In homozygotes, this causes congenital methaemoglobinemia, with cyanosis from birth. It is important to differentiate the condition from other causes of cyanosis which may need intervention. Heterozygotes may be unusually susceptible to the action of drugs known to cause methaemoglobinemia.

Acquired red-cell metabolic disorders

As mentioned in 'Other acquired membrane disorders', in the myelodysplasias, an acquired abnormality of red-cell metabolism may reduce red-cell lifespan.

Haemoglobin disorders

The haemoglobins are a family of molecules with a basically similar structure consisting of two pairs of globin chains, each associated with a haem moiety. Normal adult haemoglobin (Hb A) is formed from two alpha globin chains and two beta globin chains. Interactions between the amino acid side chains lead to complex folding of the globin molecule to give a quaternary structure, with the haem molecules tucked inside the folds of the chains.

Other normal human haemoglobins consist of an alpha chain or the alpha-like zeta chain, combined with one of the beta-like chains: epsilon or gamma (there are two gamma chains: gamma G (which is predominant at birth) and gamma A). The first haemoglobins to appear in the embryo are haemoglobin Gower 1, which is made up of two zeta chains and two epsilon chains; haemoglobin Portland, which is made up of two zeta chains and two gamma chains; and haemoglobin Gower 2, which is made up of two alpha chains and two epsilon chains. These are replaced in the fetus by fetal haemoglobin (Hb F), which is made up of two alpha chains and two gamma chains. Shortly before birth, production switches to Hb A, which largely replaces Hb F by the end of the first year of life. In postnatal life, a minor adult haemoglobin, haemoglobin A₂ (Hb A₂), which is made up of two alpha chains and two delta chains, accounts for less than 2.5% of total haemoglobin. The switch from fetal to adult haemoglobin is affected by some of the molecular lesions responsible for the thalassaemias and may lead to continued or increased production of Hb F, with some amelioration of the expression of the disease.

The genes for the alpha chains are found on Chromosome 16, together with the embryonic zeta chain gene. The alpha gene is duplicated on each haploid chromosome so, in each individual, there are four copies of the alpha gene. The non-alpha genes are clustered on Chromosome 11, closely linked and in order of developmental expression: their order is, from 3' 5', epsilon, gamma G, gamma A, delta, and beta. These genes are sequentially activated and then repressed during fetal development, to ensure the appropriate developmental changes in haemoglobin production. Alpha and non-alpha chain synthesis is synchronized, with haem being incorporated into each chain by a separate pathway before the chains are combined to form the complete haemoglobin molecule.

The genetic control of haemoglobin production has several important consequences. First, abnormalities affecting individual globin genes may be inherited from one or both parents (heterozygosity and homozygosity, respectively). Second, different abnormalities can be inherited from each parent (double heterozygosity). Third, abnormalities affecting the beta chain will not become apparent until after the first 3–6 months of life, when beta chain synthesis supercedes gamma chain production. On the other hand, disorders affecting alpha chain production may become apparent during fetal life, although duplication of the alpha chain gene affords protection from limited abnormalities.

The thalassaemias

The term 'thalassaemia' comes from the Greek *θαλασσα*, meaning 'the sea', and refers to a group of genetic anaemias that was first recognized in patients of Mediterranean origin. It has subsequently become clear that the thalassaemias are heterogeneous disorders with a worldwide distribution and which result from a reduced rate of production of one or other of the two globin chains of the haemoglobin molecule. Study of these conditions has made a major

contribution to our understanding of cellular and molecular biology and genetics, both of haemoglobin and more generally.

Molecular genetics of thalassaemia

The thalassaemias are classified according to which globin chain genes are affected and by how much globin production is reduced (Table 280.1). A wide variety of molecular lesions have been uncovered and complex interactions can occur. In beta thalassaemia, most of the molecular lesions are small—often single base-pair changes—which may interfere with RNA transcription, post-translational modification of RNA, or its translation into protein. In alpha thalassaemia, deletion mutations are more common. The clinical effects depend upon whether synthesis of the particular globin chain is completely or partially suppressed, and whether or not the switch from fetal to adult haemoglobin production is affected.

Pathophysiology of the thalassaemias

Beta thalassaemia is the more important disorder clinically, and results from reduction (beta⁺ thalassaemia) or failure (beta⁰ thalassaemia) of beta chain synthesis. This only comes to light a few months after birth, when Hb A production takes over from Hb F production.

Failure of beta chain production leads to an excess of alpha chains, which cannot be incorporated into Hb A and so precipitate in the cell, producing large inclusion bodies. These interfere with cell maturation of the cell and may lead to cell death in the marrow (ineffective erythropoiesis) or to premature destruction of the cells which have been released into the circulation (shortened red-cell lifespan). Both factors contribute to the anaemia, which stimulates erythropoietin production, leading to expansion of the erythropoietic marrow to an extent that may produce gross skeletal deformities. Peripheral red-cell destruction leads to splenomegaly, and this may further exaggerate the anaemia and also cause thrombocytopenia.

Those cells which continue to produce some gamma chains are able to 'mop up' some of the excess alpha chains to make Hb F. These cells have fewer inclusion bodies and thus a survival advantage, leading to a relative increase in Hb F levels. A similar effect leads to increased levels of Hb A₂, unless the molecular lesion extends to the delta gene (delta beta thalassaemia).

Table 280.1 Classification of thalassaemias

Type of thalassaemia	Findings in homozygote	Findings in heterozygote
α ⁰	Hb Bart's hydrops	Thalassaemia minor
α ⁺ (deletion)	Thalassaemia minor	Normal blood picture ²
α ⁺ (nondeletion)	Hb H disease ¹	Normal blood picture ²
β ⁰	Thalassaemia major ^{3,4} Hbs F and A ₂	Thalassaemia minor Raised Hb A ₂
β ⁺	Thalassaemia major ^{3,4} Hbs F, A, and A ₂	Thalassaemia minor Raised Hb A ₂
δβ	Thalassaemia intermedia Hb F only	Thalassaemia minor Hb F 5–15%; Hb A ₂ normal
(δβ) ⁺	Thalassaemia major or intermedia	Thalassaemia minor
(Lepore)	Hbs F and Lepore	Hb Lepore 5–15%; Hb A ₂ normal
εγδβ	Not viable	Neonatal haemolysis Thalassaemia minor in adults, with normal Hbs F and A ₂

Abbreviations: Hb, haemoglobin.

¹Haemoglobin H disease more commonly results from the compound heterozygous inheritance of α⁰ and either variety of α⁺ thalassaemia.

²There may be very mild red-cell hypochromia.

³Occasionally have thalassaemia intermedia phenotype.

⁴Many patients with thalassaemia are compound heterozygotes for different molecular forms of β⁰ or β⁺ thalassaemia.

In alpha thalassaemia, alpha chain production is reduced or absent, and there is relatively excess production of gamma chains during fetal life, and of beta chains after birth. Above a certain level of chain imbalance, gamma and beta chains can form tetramers, producing haemoglobin Barts (Hb Barts), which consists of four gamma chains, and haemoglobin H (Hb H), which consists of four beta chains, respectively. If all four copies of the alpha chain gene are affected, the fetus is unable to make any alpha chains and only Hb Barts is formed: this is physiologically useless, and severe anaemia leading to hydrops fetalis and fetal loss results. In milder forms of alpha thalassaemia—involving one, two, or three of the four copies of the alpha chain gene—alpha chain synthesis is reduced rather than absent. Excess non-alpha chains form Hb Barts in infancy, and Hb H in adult life. There is, therefore, less globin chain precipitation in the marrow cells than in beta thalassaemia, and less ineffective erythropoiesis and marrow expansion. However, there is some precipitation of excess globin, leading to a degree of haemolysis in all the alpha thalassaemia variants.

Geographical distribution of the thalassaemias

Some beta thalassaemia occurs sporadically in all populations, but the high incidence zones lie in a band from the Mediterranean and North and West Africa through the Middle East and Indian subcontinent to South East Asia. The highest incidences (up to 30% gene frequency) are seen in South East Asia.

Severe forms of alpha thalassaemia only occur with any frequency in South East Asia, in some parts of the Middle East, and in isolated Mediterranean populations. Mild alpha thalassaemia has a high incidence in West Africa, and in some immigrant populations originating from this area.

The high frequencies of thalassaemic alleles in these populations seems to have resulted from a relative protection of heterozygote carriers from falciparum malaria, and population genetic studies clearly show that the allelic frequency reflects changing malaria endemicity. How this protection may be afforded by thalassaemia alleles is not clearly understood.

Beta thalassaemia

The beta thalassaemias fall into two groups: those with no beta chain production (beta⁰), and those with some beta chain production (beta⁺). The beta⁺ thalassaemias are extremely heterogeneous, with beta chain production ranging from being virtually absent to being near normal levels. The clinical phenotype usually depends on the amount of beta chain synthesized, although this may be modified in patients who have also inherited other forms of thalassaemia or one of the haemoglobinopathies. In practice, three broad clinical phenotypes are recognized:

- beta thalassaemia major: this is a homozygous or compound heterozygous state, with severe, transfusion-dependent anaemia
- beta thalassaemia intermedia: this is also a homozygous or heterozygous state, but with mild-to-moderate moderate anaemia requiring only occasional transfusion
- beta thalassaemia minor or trait: this is the heterozygous state; it is usually asymptomatic, but affected individual may have a severely affected child

Beta thalassaemia major

Beta thalassaemia major is clinically the most important form of thalassaemia. It presents in the first year of life, with failure to thrive, poor feeding, and intermittent fever. The infant is usually pale and has splenomegaly. There is severe anaemia with small misshapen red cells. The bilirubin is raised and haptoglobins are reduced, because of haemolysis. Haemoglobin electrophoresis shows only Hb F and Hb A₂ in beta⁰ thalassaemia, with variable amounts of Hb A in beta⁺ thalassaemia.

Untreated or inadequately treated children progressively fail to thrive and have reduced growth rate and slow development. The spleen enlarges massively and hypersplenism leads to exaggeration of the anaemia and additional thrombocytopenia. The expansion of the bone marrow leads to disfiguring deformities, and bossing of the skull and expansion of the zygomata lead to a typical facial appearance. Radiologically, there is a fine, lacy trabecular pattern to the

long bones, and the classical 'hair-on-end' appearance of the skull. The long bones are fragile, and fractures are common, while the skull deformities can be complicated by malocclusion and poor sinus drainage, with infection and deafness.

Reduced resistance to infection leads to further chronic malaise and intermittent additional falls in the haemoglobin. The massive expansion of the marrow with the ineffective erythropoiesis puts the children into a hypermetabolic state leading to folic acid depletion, hyperuricaemia, and gout. A bleeding tendency from liver abnormalities adds to the thrombocytopenia secondary to hypersplenism.

Without transfusion, death occurs in the first year of life. Those who receive inadequate transfusions will often succumb to overwhelming infection in early childhood.

With early diagnosis and adequate transfusion, early growth and development is normal. However, transfusional iron overload is inevitable by the end of the first decade unless long-term iron chelation is undertaken. Iron overload produces endocrine, hepatic, and cardiac complications, with growth spurt failure, diabetes, hypothyroidism, adrenal insufficiency, progressive liver failure, and cardiac failure. The commonest mode of death is either sudden arrhythmia or intractable cardiac failure, which occurs in the teens or the early twenties.

Intensive chelation therapy may avoid these complications and should be introduced as early as is practicable. A subcutaneous infusion of desferrioxamine for five or six nights a week, started early and maintained indefinitely, may prevent iron overload altogether. However, compliance may be poor, especially in teenage children.

Beta thalassaemia minor

In heterozygous beta thalassaemia, excess alpha chains are readily degraded, and damage to the developing red cells is minimal. Affected persons are usually asymptomatic, although symptomatic anaemia may develop during pregnancy or at other times of stress. Anaemia is mild or absent (haemoglobin levels of 9–12 g/dl), but the blood film shows hypochromia and microcytosis with moderate anisocytosis and some target cell change. The amount of Hb that is Hb A₂ is elevated to 4%–6%, and the amount that is Hb F to 1%–3%. Diagnosis can be difficult if there is concomitant iron deficiency, in which case iron supplementation, monitoring of the serum ferritin, and repeat haemoglobin electrophoresis and quantitation may be necessary.

It is important to recognize beta thalassaemia trait so that the patient can be counselled about the risk of having a severely affected child if their partner is also a carrier. Once the diagnosis is established, further investigation and unnecessary iron therapy can be avoided.

Beta thalassaemia intermedia

There are various ways in which the severity of homozygous beta thalassaemia is ameliorated in some way, giving rise to a less severe or intermediate clinical phenotype with reduced or absent transfusion requirement. These include the production of large amounts of Hb F, the co-inheritance of an alpha thalassaemia allele which reduces the degree of chain imbalance, or a variety of other situations. These patients usually maintain haemoglobin levels of 6–10 g/dl, although anaemia may become more severe during intercurrent illness or during pregnancy. Iron absorption is increased, and loading can occur. Chelation may be required.

Beta thalassaemia interactions with haemoglobin variants

The beta thalassaemia allele and the alleles for structural haemoglobin variants (e.g. beta^s, which encodes the beta chain in sickle haemoglobin (Hb S); beta^c, which encodes the mutant beta chain leading to the formation of haemoglobin C (Hb C); beta^d, which encodes the mutant beta chain leading to the formation of haemoglobin D (Hb D); and beta^e, which encodes the mutant beta chain leading to the formation of haemoglobin E (Hb E); see 'The haemoglobinopathies') occur at high frequencies in similar populations, so co-inheritance of a different abnormality from each parent is not infrequent. Three interactions are clinically important:

- sickle cell beta thalassaemia
- Hb C thalassaemia
- Hb E thalassaemia

Sickle cell beta thalassaemia produces a variable picture depending upon whether the beta thalassaemia allele is beta⁺ (as it is in many

of African descent) or beta⁰. The clinical picture in the former may be almost normal or be that of a mild sickling trait. The red-cell indices will be hypochromic and microcytic, and the film will show anisopoikilocytosis with target cells and occasional sickle cells. Hb S will account for about 70% of the haemoglobin, and Hb A for about 25%. The level of Hb A₂ will be raised. Sickle cell beta thalassaemia is clinically indistinguishable from sickle cell anaemia (see 'Sickle cell disease'). Haemoglobin electrophoresis shows a complete absence of Hb A, with Hb S and raised levels of Hb A₂ and Hb F.

Hb C thalassaemia is a mild disorder that is similar to Hb C disease (see 'The haemoglobinopathies'). There is mild anaemia and splenomegaly, and the blood film shows thalassaemic changes with large numbers of target cells. Haemoglobin electrophoresis shows predominantly Hb C, with some Hb F and Hb A₂ and variable amounts of Hb A. Hb C thalassaemia is largely restricted to West Africans, with occasional North African and Mediterranean cases.

Hb E thalassaemia is the commonest severe thalassaemic syndrome in South East Asia and India. The inefficiency of production of the Hb E structural haemoglobin variant leads to a severe beta thalassaemia major syndrome when the allele for this variant is co-inherited with the beta⁰ thalassaemia allele. The overall spectrum of disease varies greatly. Haemoglobin electrophoresis shows only Hb E and Hb F.

Delta beta thalassaemias

The delta beta thalassaemias comprise a group of disorders involving reduction or absence of synthesis of both delta and beta chains. The molecular defects at the genetic level may be very varied. Clinically, homozygotes present with thalassaemia intermedia, although in homozygotes for one variant, haemoglobin Lepore, the disease behaves more like thalassaemia major. Hb F is the only haemoglobin detectable. Heterozygotes are asymptomatic but have raised level of Hb F (5%–15%) with a normal Hb A₂ level.

Another African variant is characterized by a failure to switch off gamma chain synthesis, producing homozygotes that have a normal haemoglobin level consisting only of Hb F, and heterozygotes with 20%–30% Hb F and a normal Hb A₂ level. This disorder is known as **hereditary persistence of fetal haemoglobin**.

Alpha thalassaemia

Four different alpha thalassaemia phenotypes are recognized, depending on how many of the four copies of the alpha gene are affected:

- **single gene deletion:**
 - a single copy of the alpha gene is affected
 - this produces a 'silent' carrier state
 - affected persons are clinically and haematologically normal
- **alpha thalassaemia trait:**
 - two copies of the alpha gene are affected
 - there is a mild microcytic hypochromic anaemia
- **Hb H disease:**
 - three copies of the gene are affected
 - excess beta chains produce Hb H, which can be demonstrated after precipitation by brilliant cresyl blue
 - there is a variable degree of anaemia, with splenomegaly and a typical thalassaemic blood picture
 - haemoglobin electrophoresis shows Hb A with variable amounts of Hb H and some Hb Barts
- **Hb Barts hydrops syndrome**
 - this occurs when all four alpha chain genes are affected
 - it is a common cause of stillbirth in South East Asia
 - the absence of alpha chain production leads to severe anaemia, with haemoglobin consisting mainly of the beta chain tetramer Hb Barts
 - hydrops fetalis, with gross oedema, splenomegaly, and extra-medullary haemopoiesis occurs, and affected babies are still-born at 36–40 weeks gestation
- **haemoglobin Constant Spring thalassaemia:**
 - this form of thalassaemia occurs when a single base mutation in the termination codon for haemoglobin leads to the (rather inefficient) formation of elongated alpha chains and, consequently, an abnormal haemoglobin, haemoglobin Constant Spring (Hb CS)

- co-inheritance of this abnormality with the alpha thalassaemia trait can lead to a disorder that is similar to Hb H disease
- the heterozygous state is clinically and haematologically silent, apart from the presence of trace amounts of Hb CS

The haemoglobinopathies

Whereas thalassaemias result from a reduced rate of production of the globin chains that make up the haemoglobin molecule, the haemoglobinopathies are disorders resulting from a structural abnormality of the haemoglobin molecule. A large number of structural haemoglobin variants have been described. Some are without obvious effect, while others may impair the integrity of the red cell and lead to haemolysis.

The most common abnormal haemoglobin is Hb S, which causes haemolytic anaemia in homozygotes or when co-inherited with another abnormal haemoglobin or a thalassaemic trait. The only other relatively common abnormal haemoglobins are Hb C, Hb D, and Hb E, although several rare unstable haemoglobins are known. Inheritance of a single abnormal haemoglobin gene is not usually associated with significant problems.

Sickle cell disease

The generic term 'sickle cell disease' refers to the disease that occurs when the sickle beta chain (beta^s) allele is inherited from one parent, and an allele for another abnormal beta chain (e.g. a second beta^s or a beta^c, beta^d, or beta^f allele) or one of the forms of beta thalassaemia is inherited from the other parent. Heterozygote carriers of beta^s do not, in the main, suffer the recognized consequences of the disease, but are important as potential parents of affected children.

Pathophysiology of sickle cell disease

Hb S results from a single base substitution leading to the replacement of glutamic acid by valine at Position 6 in the beta globin chain. Hb S has unusual solubility properties, forming liquid crystals—'tactoids'—when it becomes deoxygenated. These further aggregate into parallel rod-like structures. The end result is that the cells become rigid and distort into a sickle shape (sickling). Initially, this is reversible on reoxygenation, but repeated cycles of sickling and unsickling lead to a loss of membrane and membrane permeability and, eventually, to irreversible sickling.

Sickled erythrocytes have a shortened lifespan resulting from increased mechanical fragility. They also tend to form aggregates, especially in the microcirculation; these increase blood viscosity and reduce flow, causing hypoxia (which aggravates sickling) and, eventually, tissue infarction.

The presence of other haemoglobins may affect the behaviour of Hb S. For example, Hb C, Hb D, and Hb E will all form tactoids with Hb S, while Hb A, Hb A₂, and Hb F inhibit tactoid formation. These differences explain the involvement of the haemoglobins in the first group in the sickling syndromes, and the protective effect of those in the second group, especially Hb F.

Clinical features of sickle cell disease

Sickle cell disease is a chronic haemolytic anaemia with a course that is punctuated by painful crises and other less common manifestations. It may run a variable clinical course in any individual and is occasionally undiagnosed into adulthood. This variability is related in some degree to factors such as climate, socio-economic status, and the level of Hb F present, but still remains largely unexplained. Hb S has a low oxygen affinity, so anaemia is well tolerated, with most patients asymptomatic at their steady state level (6–10 g/dl).

Children with sickle cell disease are well at birth because of the protective effect of the high levels of Hb F, but will present in infancy with anaemia, jaundice, susceptibility to infection, and recurrent painful crises. The **hand-foot syndrome** of painful dactylitis resulting from multiple microinfarcts in the digital bones is a classic feature of sickle cell disease in childhood (and may lead to permanent shortening if the epiphyses are affected).

Sickle cell trait (which occurs when the patient is heterozygous for beta^s) rarely causes any clinical problems. Extremes of anoxia, such as those encountered when flying in unpressurized aircraft, when scuba diving or, occasionally, during anaesthesia, can, rarely, precipitate a

crisis. Some individuals may also experience renal papillary necrosis, reflecting the relative hypoxia deep in the renal medulla.

Complications of sickle cell disease

Most patients with sickle disease will experience complications at some point, although the nature of the complication will vary with factors such as the specific defect and the age of the patient. Complications include those seen in any chronic haemolytic state, such as jaundice, gallstones, and aplastic crises. Those specifically related to the sickling process include:

- painful veno-occlusive episodes
- sequestration syndromes
- stroke
- priapism
- infection

Painful veno-occlusive episodes result from tissue infarction caused by the sickling of cells in the microvasculature. Painful crises may be precipitated by cold, dehydration, and infection. In the younger child, they tend to affect the long bones but, later, they appear more often in the axial skeleton. The episodes are characterized by severe pain, fever, and tachycardia. Treatment involves adequate pain control (often requiring opiates) and maintenance of hydration, intravenously if necessary. Antibiotics may be required, as the fever of crisis is not easily distinguished from that of infection.

Sequestration syndromes are the most serious and immediately life-threatening of the sickling complications. All are associated with massive 'sequestration' of sickle cells into some part of the circulation, leading to a rapid fall in haemoglobin. The cause is not known but, if they are unrecognized, the patient may deteriorate rapidly and succumb in a surprisingly short time. Sequestration of sickled red cells in the spleen usually occurs in young children in association with severe infection. There is rapid enlargement of the spleen and a life-threatening fall in the haemoglobin. The mortality is high. In older children and young adults with splenic atrophy, sequestration into the liver may occur, with rapid enlargement and progressive anaemia. Lung sequestration produces the 'sickle chest syndrome', in which there is acute breathlessness with back or chest pain; initial patchy lung consolidation may progress extremely rapidly and is accompanied by a rapidly falling haemoglobin and platelet count, increasing hypoxia, and possibly infection. Sequestration may also involve the circulation of the gastrointestinal tract, sometimes with involvement of the lungs and the liver—the 'girdle syndrome'. The abdomen is painful, distended, and often silent. Differentiation from other causes of abdominal catastrophe is difficult. All the sequestration crises are medical emergencies and require intervention with intensive supportive therapy, hydration, oxygen, antibiotics, and exchange transfusion.

Cerebral thrombosis and the signs of acute stroke may be seen in up to 7% of affected children. The treatment is with exchange transfusion, and subsequent regular transfusion to maintain Hb S at a low level for 3 years to cover the highest risk period for recurrence.

Priapism presents in adult males as a painful erection, occurring either as multiple brief episodes or as a major attack. Initial treatment of the stuttering phase with cyproterone may prevent a major attack, which will require exchange transfusion and sometimes surgical intervention. Subsequent impotence is common.

Infection is commonly seen in patients with sickle cell disease, as they have an increased susceptibility for it. This may relate to splenic malfunction in some manner, but the reasons are not fully understood. Overwhelming pneumococcal infection is particularly common in young children, and penicillin prophylaxis is recommended at least until early adulthood. Septicaemias with salmonella, *E. coli*, and/or *Staphylococcus aureus* are common and may be accompanied by osteomyelitis.

Other complications specifically related to sickle cell disease include:

- **aplastic crisis:** infection with parvovirus may lead to transient erythropoietic arrest and a dramatic fall in haemoglobin levels
- **splenomegaly:** this is present in most children with sickle cell disease but, usually, progressive infarction leads to splenic atrophy by the age of 10; in a minority of patients who are homozygous for beta^s, and a larger number of patients who carry one copy of beta^s

and one copy of beta^c (termed 'Hb SC patients'), splenomegaly will persist into adult life

- **proliferative retinopathy:** this is common in the sickling syndromes, particularly in Hb SC patients; regular review by an ophthalmologist, together with laser treatment, may prevent many severe complications
- **renal problems:** sickle cell disease patients frequently lack renal concentrating ability and so can be susceptible to enuresis in childhood and have a predisposition for rapid dehydration, which may aggravate sickling crises; in addition, urinary tract infections, papillary necrosis, nephrotic syndrome, and chronic renal failure are all common in these patients
- **growth problems and delayed puberty:** most children with sickle cell disease will be thin and grow relatively poorly in comparison to normal siblings; in addition, puberty in patients with sickle cell disease is usually delayed, although complete failure of puberty rarely occurs

Fertility is usually normal in patients with sickle cell disease. However, pregnancy may lead to an increase in the frequency of crises and there is an excess of miscarriage and stillbirth. Many babies are also small for gestational dates. Regular transfusion during pregnancy will often reduce the maternal complications, but the evidence for any significant alteration in the outcome for the fetus is scanty.

Diagnosis of sickle cell disease

The diagnosis of sickle cell disease is made in adults and older children based on the results from a full blood count, the blood film, the solubility test (which demonstrates the presence of Hb S in a sample but does not differentiate between heterozygosity and homozygosity), and haemoglobin electrophoresis.

In disease resulting from two copies of beta^s, there will be a partially compensated haemolytic anaemia, with a haemoglobin level of 6–10 g/dl, reticulocytosis of 10%–20%, sickled red blood cells on the blood film, a positive sickle test, and an electrophoresis showing only Hb S.

The other sickling syndromes are variable in the degree of anaemia, the appearance of the blood film, the haemoglobin electrophoresis, and clinical features.

Management of sickle cell disease

It is important that sickle cell disease patients and their relatives understand the nature of the disease and its complications. The manoeuvres that can be used to avoid crises or curtail minor ones should be explained. The signs that a major event is occurring should alert those concerned that hospital admission is needed.

Minor surgery may be safely performed if there is careful attention to hydration and the maintenance of oxygenation. However, major procedures should only be performed after transfusion, to reduce the proportion of Hb S cells to less than 30%. Some operations, particularly orthopaedic operations, may require maintenance transfusion post-operatively to allow adequate healing.

Simple blood transfusion will be required to correct the profound anaemia of an aplastic crisis or a sequestration syndrome but should probably be avoided at other times. Exchange transfusion can be used preoperatively and may be necessary in some crises in order to reduce the percentage of sickle haemoglobin rapidly. Hypertransfusion may be used for limited periods to avoid crises or allow healing but should not be continued indefinitely because of the dangers of iron overload, and sensitization to red-cell antigens.

Immune haemolysis

Immune haemolysis occurs when antibodies or complement are bound onto the red-cell membrane. The Fc portion of the IgG antibody and the C3d component of the complement system induce phagocytosis of the red cells by fixed macrophages in the spleen, liver, and bone marrow. IgM antibodies may lead to complement binding and activation, which produces direct intravascular red-cell lysis in addition to stimulating removal of the red cells by phagocytosis.

Antibodies bind to red cells by a variety of mechanisms; there may be specificity for red-cell membrane antigens themselves, or the antibody may bind to complexes formed between certain drugs and the

red-cell membrane. Damage may also occur following passive binding of certain immune complexes.

Immune haemolysis may occur with allo- or autoantibodies to red cells.

Alloimmune haemolysis

Alloantibodies are responsible when haemolysis follows transfusion of plasma or red cells, for example when Group O blood containing anti-A antibodies is transfused into a Group A individual or when Kell-positive red cells are transfused into a previously sensitized patient, who will have anti-Kell antibodies. Alloantibodies are also involved in haemolytic disease of the newborn when maternal immune IgG antibodies cross the placenta and cause haemolysis in the fetus.

Autoimmune haemolysis

Haemolytic anaemias due to autoantibodies directed against normal red-cell constituents may be idiopathic or associated with lymphoproliferative malignancy or other immune disorders such as SLE and rheumatoid arthritis. Such haemolytic anaemias may be further classified according to antibody type, the complement-fixing ability of the antibody, and whether the antibody is more active at body temperature (a 'warm antibody') or reduced temperatures (a 'cold antibody'), as follows:

- Ig-mediated autoimmune haemolytic anaemia
- paroxysmal cold haemoglobinuria
- chronic cold haemagglutinin disease
- acute cold haemagglutinin disease

IgG-mediated autoimmune haemolytic anaemia

IgG-mediated autoimmune haemolytic anaemia usually involves a 'warm' IgG autoantibody that is most active at 37°C. It is associated with low-grade lymphoproliferative malignancies such as non-Hodgkin lymphoma and chronic lymphocytic leukaemia, and also with other autoimmune disorders. Initially idiopathic cases may in fact precede the development of an associated condition, sometimes by many years. The incidence increases with age, probably reflecting the increase in the incidence of the associated lymphoid malignancies.

The onset is usually insidious, with progressive anaemia and mild jaundice, but it may occasionally be fulminant. The spleen is usually moderately enlarged. There is anaemia and reticulocytosis, with spherocytosis and, in extreme cases, nucleated red cells in the blood film. The direct antiglobulin test shows IgG and sometimes C3d bound to the membrane.

Treatment is aimed at reducing haemolysis and correcting anaemia. Haemolysis may cease when any underlying condition is treated, and idiopathic cases may 'burn out' after a time. Symptomatic cases are treated with prednisolone, 1 mg per kilogram of body weight initially, tailing after 2–3 weeks to a maintenance dose. Transfusion may be necessary in severe cases provided compatible blood can be found. Refractory cases may be managed with rituximab with or without azathioprine or cyclophosphamide. Splenectomy may also be considered, but is successful in only half of cases. Folic acid supplementation should also be given.

Paroxysmal cold haemoglobinuria

Paroxysmal cold haemoglobinuria, which is a rare condition, is caused by an IgG antibody with peculiar thermal characteristics: the Donath-Landsteiner antibody. It was once typically associated with congenital syphilis but is now more commonly seen after certain viral infections, usually in childhood. There is acute intravascular haemolysis, with haemoglobinuria, on exposure to cold. The condition is usually self-limiting and the patient should be kept in a warm environment until remission occurs. Blood transfusion, when required, should be given through a warmer.

Chronic cold haemagglutinin disease

Chronic cold haemagglutinin disease is usually a primary disorder affecting older patients, although it is occasionally associated with lymphoma. There may be chronic intravascular haemolysis which is aggravated by a cold environment, but the main problem is often a painful peripheral acrocyanosis due to stasis and agglutination in the cold extremities. There is striking red-cell agglutination in the

specimen tube and blood film; this may produce an artificially high mean corpuscular volume unless the blood is tested at 37°C. The direct antiglobulin test is positive with complement only. The antibody is always an IgM monoclonal kappa paraprotein with anti-I activity. Treatment is directed at avoiding haemolysis by keeping the patient (and especially their hands and feet) warm and, if necessary, lowering the level of antibody with chlorambucil. Steroids and splenectomy are not useful in this condition. Transfusions should be given using a blood warmer.

Acute cold haemagglutinin disease

Acute cold haemagglutinins are seen as transient phenomena after certain infections in patients of any age, most commonly mycoplasma pneumoniae or infectious mononucleosis.

Drug-induced immune haemolysis

A number of drugs have been associated with immune haemolysis (true autoimmune mechanisms are uncommon, and the red cells are usually damaged in some indirect way.)

Immune complex formation

Drug-induced haemolysis associated with immune complexes was originally described with stibophen but has been seen on occasion with a large number of drugs. The antibody is directed against the drug, or a complex of the drug and a plasma component, and the antibody–drug complex then binds to the red cells. The antibody is IgG or IgM and fixes complement, leading to brisk intravascular haemolysis on second and subsequent exposures to the drug. This mechanism has been described as an 'innocent bystander' effect. The direct antiglobulin test is positive with complement alone, and the antibody is only lytic in the presence of the drug.

Hapten-membrane-induced antibodies

Hapten-membrane-induced antibodies are responsible for the haemolysis occasionally seen with penicillin administration. The drug is bound covalently to the cell membrane, and an IgG antibody against the complex is responsible for the haemolysis. The antibody will only bind to red cells in the presence of the drug. The direct antiglobulin test is positive with IgG, and the haemolysis ceases on withdrawal of the drug.

'Autoimmune' drug-induced haemolysis

Therapy with methyl dopa, and sometimes levodopa and mefenamic acid, leads to the development of a positive direct antiglobulin test in up to 20% of users. The antibody involved is an IgG which is directed against red-cell membrane constituents, most often in the rhesus system, and is thus a true autoantibody. In a minority of cases, haemolysis will occur, which ceases on withdrawal of the drug, although the direct antiglobulin test may remain positive for some time.

Diagnosis of immune haemolysis

Antibody or complement bound to the red-cell surface may be detected by the direct (Coombs) antiglobulin test, while free antibody in the serum may be detected by an indirect antiglobulin test. Antibody bound to the red cell may be eluted for further investigation of its nature and specificity. For a complete diagnosis, the class of the antibody, its thermal amplitude, and its activity in the presence of any suspect drug must also be assessed.

Haemolysis secondary to red-cell damage

Haemolysis may result from red-cell damage secondary to infections, the oxidative effects of drugs or chemicals, or by physical or mechanical means.

Damage from infections

Malaria causes haemolysis as the parasites burst out of the red cells. Falciparum malaria occasionally causes acute massive intravascular haemolysis (blackwater fever) or disseminated intravascular

coagulation. **Toxoplasmosis** may cause a severe haemolytic anaemia in congenitally infected newborns. **Bacterial infection** with Gram-negative organisms which produce endotoxin may lead to disseminated intravascular coagulation with intravascular haemolysis. *Clostridium welchii* septicaemia is associated with the production of a lecithinase which can directly damage red cells. This results in an intense haemolysis with microspherocytes and red-cell fragments in the blood film.

Damage from drugs or chemicals

Drugs or chemicals which are powerful oxidizing agents may overcome the red cell's normal reducing capacity. These effects are exaggerated in persons with deficiencies of these enzymes systems. The clinical effects produced will reflect the nature of the oxidant substance and the dose administered. Acute intravascular haemolysis and renal failure will result from exposure to strongly oxidizing substances such as arsine or chlorate, but there will be less intense responses with drugs such as phenylhydrazine (which was once used to treat polycythaemia). Chronic intravascular haemolysis is seen in association with the use of dapsone and sulfasalazine used in the treatment of inflammatory bowel disease.

Damage from mechanical trauma

Certain conditions lead to the physical breakup of the red cell by mechanical trauma. For example, **artificial heart valves** cause fragmentation of the red cells when there is turbulent flow in relation to prosthetic inserts. This rarely occurs with homografts and is more common with aortic than mitral prostheses. The basis is usually a small leak around the attachment of the valve, allowing a high-pressure jet to flow from the ventricle to the atrium. When it arises, it may be aggravated by conditions increasing cardiac output and turbulent flow. Anaemia of varying degree results and the blood film shows fragmented and distorted red cells and spherocytes. Haemolysis is intravascular, and haemosiderin may be detected in the urine, and iron deficiency may develop. Surgical correction may be required in severe cases. Haemolysis in association with endocarditis on a valve needs to be distinguished from simple fragmentation haemolysis.

March haemoglobinuria is a benign condition seen usually in young men after vigorous exercise. It is usually asymptomatic but may be associated with loin discomfort through an unknown mechanism. The condition appears to be due to fragmentation of the red cells on a hard surface and can be avoided by the use of shoes with a springy sole, which cushions the impact of the ground on the feet and actually reduces red-cell breakup.

Microangiopathic haemolytic anaemia is a term used to describe the red-cell fragmentation seen in a variety of conditions in which the underlying defect is probably damage to the microvasculature. This may be due to microthrombi, fibrinoid necrosis, necrotizing arteritis, or invasion by malignant cells. The precise means by which any of these conditions lead to red-cell fragmentation are poorly understood. The clinical features will reflect the underlying cause, and the presence of haemolysis (anaemia, jaundice, low serum haptoglobins). The blood film shows fragmented red cells and microspherocytes, and the direct antiglobulin test is negative. There may also be thrombocytopenia, especially when microangiopathy is associated with disseminated intravascular coagulation, haemolytic-uraemic syndrome, or thrombotic thrombocytopenic purpura). The treatment of microangiopathic haemolysis is directed primarily at the underlying cause, with red-cell transfusion to correct the anaemia if required.

Damage from other causes

Other situations which may produce red-cell fragmentation and haemolysis include

- **fibrinoid necrosis** from malignant hypertension and pre-eclampsia
- **vasculitis** in SLE, Wegener's granulomatosis, and polyarteritis nodosa
- **invasion** of small blood vessels by tumour cells; this occurs especially with mucin-secreting carcinomas
- **burns**, following direct heat damage to the red blood cells and, secondarily, from disseminated intravascular coagulation

281 Normal platelet function

Nicola Curry and Raza Alikhan

Introduction

The platelet is a small (2–4 μm in diameter), discoid, anucleate cell that circulates in the blood. In health, it plays a vital role in haemostasis, and in disease it contributes to problems with bleeding as well as thrombosis.

Platelets are produced from the surfaces of megakaryocytes in the bone marrow. Each megakaryocyte has the ability to produce 2000–3000 platelets over its lifetime. The number of platelets produced in the body is under tight homeostatic control, and is regulated by the cytokine thrombopoietin. Thrombopoietin binds to its receptor, c-Mpl, which is found on the megakaryocyte, and platelet surfaces and is then internalized by these cells. It acts to stimulate megakaryopoiesis, and platelets are released into the blood stream. A normal platelet count lies between 150×10^9 platelets/l and 450×10^9 platelets/l.

Platelets have a lifespan of approximately 7–10 days, and they usually circulate in the bloodstream in a quiescent state. Intact,

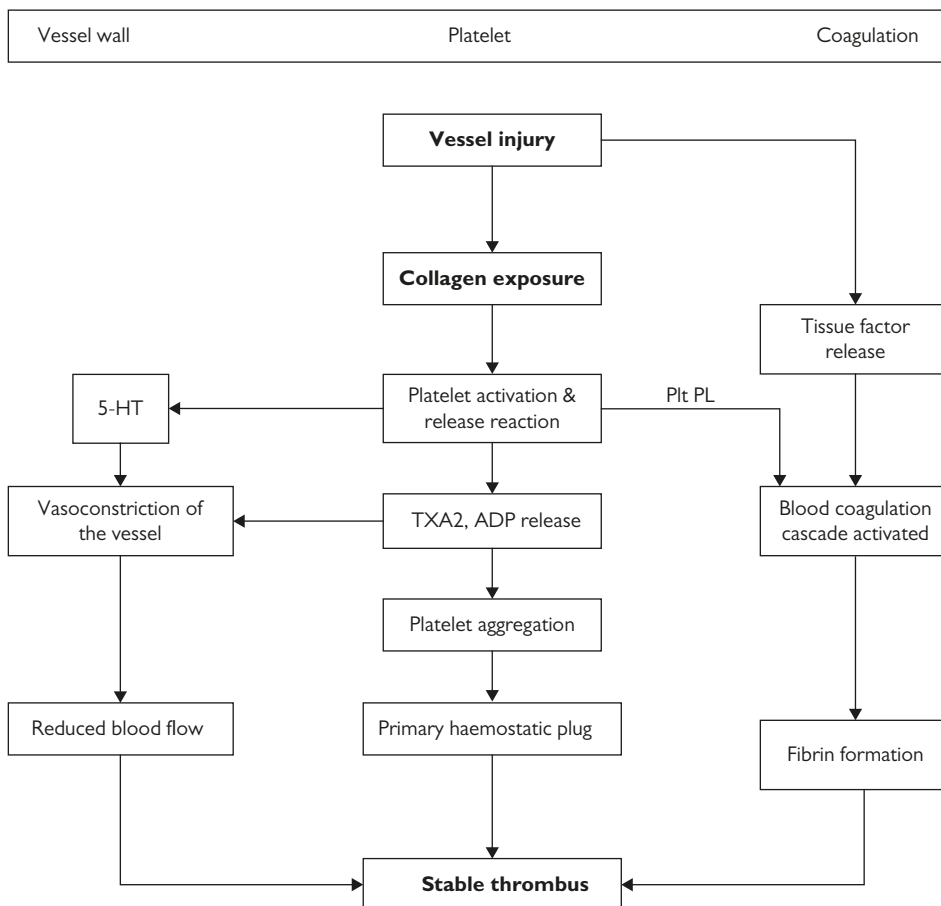

undamaged vessel walls help to maintain the platelets in this inactive state by releasing nitric oxide, which acts both to dilate the vessel wall and to inhibit adhesion, activation, and aggregation of the platelet.

However, after a traumatic insult to the blood vessel wall, the platelet becomes activated (see 'Platelet physiology'). The activated platelet then acts in concert with coagulation factors and the endothelium to form a stable clot. The single aim is to minimize blood loss (see Figure 281.1).

Structure of the platelet

The platelet can be thought of as a bag stuffed full with goodies which enable it to rapidly transform from a resting to fully activated state. There are several components that help this process:

- specialized membrane receptors
- a phospholipid-rich outer membrane

Plt PL: platelet phospholipid surface supports coagulation

Figure 281.1 The central role of the platelet in the blood-clotting process. The platelet phospholipid surface supports coagulation; ADP, adenosine diphosphate; 5-HT, serotonin; Plt PL: platelet phospholipid; TXA₂, thromboxane A₂.

- the platelet's canalicular system
- specialized storage granules
- adaptations in the platelet's cytoskeleton

Platelet membrane receptors

Platelet integrins are membrane receptors made up of glycoproteins (GPs) that enable the platelet to adhere to the endothelium, as well as to other platelets. They include:

- the GPIa/IIa complex (receptor for collagen)
- GPIb (receptor for von Willebrand factor (vWF); deficiency in this causes Bernard–Soulier syndrome)
- the GPIIb/IIIa complex (receptor for fibrinogen; deficiency in this causes Glanzmann thrombasthenia)
- GPVI (another receptor for collagen)

Phospholipid-rich outer membrane

The platelet membrane is rich in phospholipids, and this helps to support the assembly of several important procoagulant complexes—namely factor tenase (which contains factors VIIIa and IXa, which convert factor X to factor Xa) and prothrombinase (made up of factors Va and Xa, which convert factor II to factor IIa (thrombin)). The end result is the generation of thrombin right at the site of injury. Thrombin has two roles: first, to convert fibrinogen to fibrin and, second, to provide positive feedback to the platelets by encouraging further activation.

The importance of the phospholipid membrane in assisting coagulation can be seen in the autosomal recessive bleeding disease known as Scott syndrome. In this syndrome, the ability of platelets to promote tenase and prothrombinase activity is significantly reduced, and patients present with a moderately severe bleeding disorder.

Canalicular system

The platelet surface has extensive invaginations, collectively known as the canalicular system, which connect the inside of the platelet to the external environment. This interconnecting network of small tubes enables rapid secretion of platelet granule contents to the outside, as well as easy access for plasma proteins to the inside of the platelet.

Platelet granules

There are three main storage granules found in the platelet:

- alpha granules
- dense granules
- lysosomes

Alpha granules

Alpha granules are the most numerous (approximately 80 per platelet), and are important both in haemostasis and host defence. They contain fibrinogen, factors V and VIII, fibronectin, vWF, and platelet factor 4, as well as many other important factors. Deficiency leads to grey platelet syndrome, Quebec platelet disorder, and Paris–Trousseau syndrome.

Dense granules

Dense granules, of which there are usually less than ten per platelet, contain the nucleotides ADP and ATP, as well as calcium and serotonin. Their role is to support platelet activation and to contribute to vasoconstriction of the surrounding vessel, thereby aiding reduction of blood loss. Deficiency leads to delta storage pool disease, Hermansky–Pudlak syndrome, and Chediak–Higashi syndrome. Deficiency of both alpha and dense granules leads to alpha delta storage pool disease.

Lysosomes

Lysosomes are the third type of granule in platelets. They act as part of the host defence mechanisms against invading microorganisms

Platelet cytoskeleton

The cytoskeleton is made up of a circumferential band of microtubules (containing spectrin and actin fibrils), which respond to

changes in the intracellular calcium concentration in the platelet. The cytoskeleton enables the platelet to change shape during the process of activation.

Platelet physiology

Vessel injury initiates a set of highly regulated and specialized responses from the platelet. These include adhesion, activation, granule release reactions, and platelet aggregation. The process is complex, but a simplified schematic of it is shown in Figure 281.1.

When a vessel is damaged, the resultant exposure of subendothelial matrix proteins, such as collagen, starts the process of platelet activation. First, vWF, which normally circulates in the blood and which is also released from damaged endothelial cells, quickly binds to the exposed collagen. Platelets then can bind to vWF using the GPIb receptor.

Platelets are able to make initial contact with vWF because of their small size and discoid shape, both of which enable them to circulate in the bloodstream in a position that is close to the periphery of the blood vessel. Platelets will bind under conditions of high shear stress to vWF, using the platelet glycoprotein receptor GPIb. This forms a weak bond, but one that enables the platelet to slow down in the blood vessel. In conditions of low shear, such as in the venous system, platelets can bind directly to collagen and fibrinogen.

Once the platelet has slowed down, it can bind to collagen using another glycoprotein; the GPVI receptor. This is of importance, because it results in conformational changes to two of the important glycoproteins, namely GPIIb/IIIa and GPIa/IIa. Once these protein receptors have changed shape, they are able to bind avidly to the subendothelial matrix, binding to vWF and collagen, respectively. This is vital, since these bonds are very strong and anchor the platelet more firmly.

The next step in platelet activation is the granule release reaction. This happens after agonists such as ADP, thrombin, and thromboxane A₂ (which are in the surrounding plasma milieu) bind to their respective platelet surface membrane receptors. Many of these platelet receptors are coupled to G proteins, and activation results in changes in intracellular platelet calcium concentrations. The contents of the granules are released when calcium levels rise within the platelet. (Conversely, granule release is inhibited by substances that lead to increased cAMP platelet activity, such as prostacyclin.)

The contents of the alpha and dense granules are released into the canalicular system to enable rapid delivery of the contents. The granules contain many important factors (see 'Structure of the platelet'), the majority of which support ongoing haemostasis, and provide positive feedback to the platelet.

At the same time that the granule release reaction occurs, the platelet undergoes a shape change. This is again facilitated by alterations in calcium levels within the platelet and the resulting activation of enzymes that regulate myosin activity. The cytoskeleton affects the shape changes.

The changes in shape enable platelets to adhere more easily to the endothelial surfaces and also to each other. In addition, agonists in the plasma, in particular ADP and thromboxane A₂, encourage more platelets to adhere to the site of injury, resulting in platelet aggregation. Platelets are said to aggregate when they bind to each other, using fibrinogen as the glue. (The platelets bind to fibrinogen with the GPIIb/IIIa receptors.)

The end product is the formation of a thrombus which is rich in platelets and fibrinogen. During these latter stages, fibrinogen is converted to fibrin under the action of thrombin, and this increases the stability of the platelet plug. Finally, the clot undergoes retraction, which helps the clot to withstand high shear forces within the blood vessels.

The platelet therefore contributes heavily to the formation of a stable clot at the site of vessel injury, a process often called primary haemostasis. Under normal circumstances, this whole process takes approximately 3–5 minutes.

Wider roles of the platelet

The platelet not only is important in the formation of the thrombus but also plays several other important roles which highlight the close relationship seen between coagulation and inflammation. These include:

- promotion of vessel constriction, brought about by release of serotonin from dense granules (this helps reduce blood loss)
- vessel wall repair

- leucocyte recruitment
- promotion of inflammatory processes, in particular atherosclerosis

282 Platelet disorders

Nicola Curry and Raza Alikhan

Definition of the disease

The term 'platelet disorder' covers a very large and heterogeneous group of diseases that have a multitude of causes. Platelet disorders are either inherited or acquired, and are due to:

- an abnormality of platelet number (quantitative disorder; see Box 282.1 and Box 282.2; e.g. thrombocytopenia (platelet count $<150 \times 10^9/l$) and thrombocytosis (platelet count $>450 \times 10^9/l$)
- an abnormality of platelet function (qualitative disorder; see Table 282.1 and Box 282.3)
- a combination of quantitative and qualitative abnormalities

Aetiology of the disease

For the aetiology of the disease, see Boxes 282.1–282.3 and Table 282.1.

Typical symptoms of the disease, and less common symptoms

The symptoms of a platelet disorder include:

- mucosal surface bleeding, i.e.:
 - bleeding into the skin: easy or spontaneous bruising, ecchymoses, purpura
 - petechial haemorrhages
 - gum bleeding
 - epistaxis
 - menorrhagia
 - gastrointestinal bleeding
- immediate and continued bleeding after injury (in contrast to bleeding due to coagulation factors, which is often delayed)

There may be no symptoms at all until a patient bleeds excessively after a haemostatic challenge such as surgery, dental extraction, or childbirth. Less commonly, a patient may present with symptoms of anaemia, due to continued occult blood loss and the development of iron deficiency.

Approach to diagnosing the disease

The most important part of the assessment is to take a detailed history, particularly focusing on:

- family history (to look for evidence of an inherited disease)
- bleeding history

Box 282.1 Inherited disorders of platelet number

Thrombocytopenia

- small platelets (mean platelet volume <7 fl)
 - Wiskott–Aldrich syndrome
 - X-linked thrombocytopenia
- normal-sized platelets (mean platelet volume 7–11 fl)
 - thrombocytopenia with absent radii
 - congenital amegakaryocytic thrombocytopenia
- large platelets (mean platelet volume >11 fl)
 - MYH9 disorders: May–Hegglin anomaly, Fechtner syndrome, Epstein syndrome, Sebastian syndrome
 - velocardiofacial/DiGeorge syndrome
 - grey platelet syndrome
 - Bernard–Soulier syndrome

Thrombocytosis

- familial essential thrombocytosis

Box 282.2 Acquired disorders of platelet number

Thrombocytopenia

- autoimmune
 - immune thrombocytopenia purpura
 - connective tissue disease
 - lymphoproliferative disease
- drugs
 - heparin (heparin-induced thrombocytopenia)
 - quinine
 - co-trimoxazole
 - gold
 - cytotoxic drugs
- infection
 - viral: HIV, hepatitis C, CMV, parvovirus
 - severe sepsis
- microangiopathic diseases
 - thrombotic thrombocytopenia purpura
 - haemolytic–uraemic syndrome
 - disseminated intravascular coagulopathy
- alloimmune thrombocytopenia
 - neonatal alloimmune thrombocytopenia
 - post-transfusion purpura
- bone marrow infiltration
 - many haematological diseases such as leukaemia
- malignancy
- pregnancy related
 - pre-eclampsia
 - HELLP syndrome
- liver disease
- aplastic anaemia
- radiation
- vitamin B₁₂ deficiency
- folate deficiency
- massive transfusion

Thrombocytosis

- bleeding
- infection
- inflammation
- splenectomy
- malignancy
- iron deficiency
- myeloproliferative diseases:
 - essential thrombocythaemia
 - polycythaemia rubra vera
 - chronic myeloid leukaemia
 - myelofibrosis

It must be remembered that a bleeding history is a very subjective method of assessment, and mild platelet disorders can be difficult to distinguish from normality.

There are some standardized guides, or 'bleeding questionnaires', that can improve the accuracy of taking a bleeding history: such as the ISTH bleeding assessment tool (BAT). In women with menorrhagia, pictorial menstrual blood loss charts are a useful method of quantifying bleeding.

Inherited or acquired disease

A patient is more likely to have an inherited disease if they give a positive family history of bleeding or they present at a young age.

Box 282.3 Acquired disorders of platelet function**Drugs****NSAIDs**

- aspirin
- ibuprofen
- indometacin
- naproxen

Anticoagulants

- heparin

Cardiovascular drugs

- propranolol
- furosemide
- calcium-channel antagonists
- angiotensin-converting enzyme inhibitors

Antimicrobials

- beta-lactam antibiotics

Psychotropics

- haloperidol
- amitriptyline
- chlorpromazine

Chemotherapy

- daunorubicin
- mitomycin

Conditions

- uraemia
- liver disease
- myeloma
- leukaemia
- myelodysplasia
- myeloproliferative disorders: polycythaemia vera, essential thrombocythaemia
- cardiopulmonary bypass

Previous platelet counts can prove invaluable as they may provide evidence of a long-standing thrombocytopenia, suggesting an inherited disease, or may show a rapid recent fall in a platelet count more in keeping with an acquired problem.

Remember, some of the inherited platelet disorders are autosomal recessive, and you should ask if the patient's parents are in a consanguineous relationship.

Disease severity

Questions that relate to the severity of disease are important. The following points are suggestive of more severe disease:

- mucosal bleeding taking a significant length of time to stop, i.e. >30 minutes, and/or requiring intervention such as packing, pressure dressings, etc.

Table 282.1 Inherited disorders of platelet function

Platelet abnormality	Defect	Disorder
Platelet receptors	Glycoprotein IIb/IIIa Glycoprotein Ib/IX/V	Glanzmann thrombasthenia Bernard–Soulier syndrome
Platelet granules	Dense granules Alpha granules Combined defects	Hermansky–Pudlak syndrome Chediak–Higashi syndrome Delta storage pool disease Grey platelet syndrome Quebec platelet disorder Paris–Trousseau syndrome Alpha delta storage pool disease
Platelet membrane phospholipids	Inability to support coagulation proteases	Scott syndrome

- bleeding following routine surgery or childbirth, sufficient to require a blood transfusion
- a single or repeated episode of iron deficiency, due to recurrent bleeding
- significant bleeding at one site on three separate occasions

Mild bleeding disorders are more likely to present at a later stage in life, and often only become apparent after invasive procedures.

In patients with thrombocytopenia, spontaneous bleeding is rare with counts that are greater than $50 \times 10^9/l$, and bleeding only tends to become a problem when counts fall below $20 \times 10^9/l$. However, platelet dysfunction in combination with a reduced number of platelets may mean that a patient will bleed with a much higher platelet count.

Drug history

It is important to take a full drug history and, specifically, to ask about over-the-counter medicines, that may contain aspirin or other anti-platelet agents, such as NSAIDs, the use of which is one of the most common reasons for an acquired platelet abnormality.

Other diagnoses that should be considered

von Willebrand's disease presents with symptoms that are indistinguishable from platelet disorders and should therefore be excluded during your investigation. It is important to remember that von Willebrand's disease is much more common than many of the inherited platelet disorders.

Connective tissue disorders such as Ehlers–Danlos syndrome can present with problematic bruising and should at least be considered in the differential.

Purpura is a presenting feature of vasculitis, but the purpura is palpable. Purpura in platelet disorders is not palpable.

'Gold-standard' diagnostic test

Although platelet aggregometry is said to be the gold-standard test to assess platelet function, there is no single diagnostic test that informs a clinician which platelet abnormality is affecting their patient. This is partly due to the diversity of the underlying causes, but is also because the tests are unable to look at all of the functions of the platelet in one go.

Therefore, a group of tests will often need to be requested for patients under investigation. Many of the tests are specialized, and can only be performed at certain laboratories. One should consider whether the patient would benefit from referral to a haemostasis specialist centre.

Acceptable diagnostic alternatives to the gold standard**Routine laboratory tests****Full blood count and blood film**

A full blood count should be performed and a blood film examined, to determine the platelet count, the mean platelet volume, and the haemoglobin concentration (see Table 282.2). It is best to look at the

Table 282.2 Full blood count and blood film

Test	Uses	Limitations
Platelet count	Usually accurate, unless count very low	Unusually large platelets may be counted as red blood cells Red-cell fragments may be counted as platelets Platelet clumps
Mean platelet volume	Platelet size (high in immune thrombocytopenic purpura)	
Haemoglobin concentration	Associated anaemia	

Box 282.4 Bleeding time**Test**

- bleeding time

Use

- screen for severe platelet disorders

Limitations

- painful
- operator dependent
- affected by low haematocrit, skin laxity, subject age
- leaves a scar
- will not pick up mild disease; therefore, it cannot be used as a standalone screening test

results of as many full blood count tests as possible for a patient, as trends often provide clues to the underlying problem.

Coagulation screen

The activated partial thromboplastin time, prothrombin time, thrombin time, and Clauss fibrinogen assays should be performed. These will provide information about the coagulation factors, and whether the bleeding abnormality is more complex than an isolated platelet problem. For example, disseminated intravascular coagulation (DIC) may cause bleeding, and tests will demonstrate a thrombocytopenia, as well as prolonged clotting results.

von Willebrand testing

von Willebrand's disease must be excluded. To do so the following tests should be taken:

- factor VIII:Ag assay
- von Willebrand factor:Ag assay
- von Willebrand factor ristocetin cofactor assay
- ristocetin induced platelet aggregation (RIPA)

Bleeding time

Methods such as the 'Ivy' or the 'template' bleeding time can be used to assess primary haemostasis (the interaction between the platelet and the vessel wall; see Box 282.4). This test is rarely used nowadays – a blood pressure cuff is wrapped around the upper arm, and inflated to 40 mm Hg. Using a special blade to cut the skin, often on the forearm, incisions are made to a specified depth and length. The puncture sites are blotted with absorbent gauze every 30 seconds, until bleeding stops. The bleeding time depends slightly on the method used, but averages between 1 and 9 minutes. Greater than 15 minutes is recognized as abnormal.

Platelet function analyser-100

The platelet function analyser-100 test goes some way to replacing the bleeding time and providing an automated means of assessing primary haemostasis, but again it cannot be used to exclude a platelet disorder when used as a standalone test (see Box 282.5). Two cartridges are used for each test; an ADP/collagen cartridge, and an epinephrine/collagen cartridge. Both of these cartridges have a small hole or aperture in the centre of them, and the patient's blood flows through these holes

Box 282.5 Platelet function analyser-100 test**Test**

- PFA-100

Use

- severe platelet disorders

Limitations

- will not pick up mild disease
- affected by haematocrit, thrombocytopenia, diet, aspirin
- cannot therefore be used as a single screening test

under shear stress. The cartridges activate the platelets in the blood sample, and the time taken for the holes in the cartridges to be closed by a platelet plug is measured. This time is called the 'closure time'.

More specialized tests

The following tests are usually performed in specialist coagulation laboratories. Tests that look at platelet function should be performed within 2 hours from the time of venepuncture. This is because the platelets can undergo *in vitro* activation or desensitization if left in blood bottles.

Platelet aggregation

This test involves analysing the response of a patient's platelets to the addition of a variety of known platelet agonists. The aggregometer monitors changes in light transmission through a sample of platelet rich plasma over time. Light transmission increases as platelet aggregation increases.

The following are commonly used as platelet agonists:

- ADP
- collagen
- ristocetin
- arachidonic acid
- epinephrine

Typical patterns of aggregation are found with various platelet disorders.

Platelet nucleotide testing

The nucleotides ADP and ATP are found in the dense granules of the platelet. Assessment of platelet ADP and ATP levels may be useful in helping in the diagnosis of storage pool disorders.

Platelet flow cytometry

Flow cytometry can be used to assess several areas of the platelet, but it is most commonly used to measure numbers of glycoproteins found on the surface of the platelet. For example, Glanzmann's thrombasthenia is caused by a deficiency in glycoprotein IIb/IIIa receptors in the platelet membrane. Flow cytometry is able to detect this deficiency.

Electron microscopy

Electron microscopy can be used to assess platelet granule defects and other changes in the structure of the platelet. For example, the platelet in a patient with Hermansky–Pudlak syndrome contains no dense granules.

Molecular analysis

Families with inherited disorders of platelets may benefit from molecular analysis to determine their underlying genetic defect. This information may then be used for antenatal diagnosis. There is an increasing interest in the genetics of platelet disorders, helped by the introduction of Next Generation Sequencing and GWAS, which has led recently to the elucidation of many new causative mutations being discovered.

Treatment and its effectiveness**Acquired platelet disorders**

Once a cause for the platelet dysfunction is found, any bleeding symptoms are likely to improve when treatment of the underlying condition commences. For example, dialysis improves the bleeding from platelet dysfunction associated with uraemia. On the other hand, if bleeding is caused by drugs such as NSAIDs, they should be discontinued where possible and alternative medication prescribed.

Bleeding in patients with acquired platelet dysfunction can be treated in a variety of ways (see Table 282.3). When making decisions as to which therapy to use, you must take into consideration the risks of the bleeding and weigh this against the benefits and risks of the treatment. Many of the more common acquired disorders of platelets will not require any treatment at all. For example, there would be no reason to treat a patient with mild thrombocytopenia but who has no bleeding symptoms. If you are in any doubt, a haematologist will be able to provide advice.

Table 282.3 Management options for bleeding due to platelet disorders

Therapy	Dose	Precautions
Tranexamic acid	Orally: 15–25 mg/kg three times per day IV: 10–15 mg/kg three times per day Mouthwash: 10 ml of a 5% solution four times per day	Care in patients with increased thromboembolic risk Reduce dose with renal failure Contraindicated with haematuria (risk of clot retention)
Desmopressin	Subcutaneous: 0.3 µg/kg IV: 0.3 µg/kg Intranasal: 300 µg for adults, 150 µg for children Note: tachyphylaxis occurs with repeated doses Doses can be repeated after 12 hours	Can cause fluid retention/hyponatraemia Should not be given to the elderly, or patients with atherosclerosis (increased risk of myocardial infarction) Do not use in children <2 years old, due to risk of hyponatraemia and fits Ask adults to restrict fluids for 24 hours after dose
Platelets	Adult dose: 1 unit of platelets usually, but may depend on indication	Low risk of transfusion-transmitted infection Allergic reaction risk HLA-sensitization; HLA-matched platelets may be given to some patients with hereditary diseases

Inherited platelet disorders

These disorders should be managed within a haemophilia and haemostasis comprehensive care centre, where specialist care can be provided. This is particularly important for management of surgery and pregnancy.

General advice for all patients with platelet disorders

Patients with platelet disorders should:

- avoid aspirin, other antiplatelet agents, and NSAIDs (note: aspirin may be given to patients for whom the benefit outweighs the risk)
- avoid intramuscular injections
- avoid contact sports if they have severe disease

Platelet dysfunction

Mild platelet dysfunction disorders

Most patients with mild platelet disorders are unlikely to bleed spontaneously. They will require treatment for interventional procedures.

For minor surgery or dental extraction:

- care should be taken at the site of surgery; e.g. stitches should be placed for dental extractions, packing for nasal bleeding, etc.
- desmopressin should be given as a single dose prior to surgery; if rebleeding occurs, a patient may be given a second dose 12 hours later
- tranexamic acid may also be used in combination with desmopressin
- mouthwashes are often very effective for oral bleeding

For major surgery:

- desmopressin may not provide adequate cover for major surgery
- platelet transfusion is likely to be required; in the case of inherited disease, these may be HLA-matched platelets
- tranexamic acid should also be considered
- measures local to the operated area should be taken, such as careful suturing, pressure dressings, the use of fibrin sealants if appropriate, etc.

Severe platelet dysfunction disorders

For dental extraction:

- local measures, such as suturing, should be employed
- oral tranexamic acid should be commenced 24 hours prior to a procedure and continued for 5–7 days afterwards
- if bleeding persists, consider the use of platelets or, in the case of Glanzmann's thrombasthenia, NovoSeven® may be used; these cases should be discussed with a haematologist

For minor surgery:

- NovoSeven® may be used for patients with hereditary platelet disorders, in particular Glanzmann's thrombasthenia, but this must be discussed with a haematologist
- if bleeding persists, platelets should be given
- platelets may be considered for patients with acquired disease
- tranexamic acid should be given in addition

For major surgery:

- platelets are the mainstay of treatment
- tranexamic acid should be given in addition

Thrombocytopenic disorders

For those patients **without** platelet dysfunction, management of invasive procedures is dependent upon the platelet count. Follow the guidance in Table 282.4

Notable exceptions

Several specific acquired platelet conditions require different management to that outlined; these include immune thrombocytopenia (ITP), thrombotic thrombocytopenic purpura (TTP), DIC, and heparin-induced thrombocytopenia (HIT). If you think that your patient may have one of these diseases, contact your haematologist for further advice.

ITP

ITP is one of the commoner acquired platelet disorders, and may have an acute or chronic onset. The important thing to remember with ITP is that platelet transfusion should be avoided, unless the patient is bleeding, and treatment is most often with oral corticosteroids.

TTP

TTP is an uncommon microangiopathic disorder, with a high mortality rate. The mainstay of treatment for these patients is plasma exchange. Again, platelet transfusion should be avoided.

HIT

HIT is due to an immune response to a neoantigen formed by heparin and PF4. The result is platelet destruction and thrombocytopenia. It typically occurs 5–10 days after starting heparin, and platelet counts usually fall by greater than 50% from the baseline. HIT often leads to thrombosis, and treatment involves discontinuation of the heparin and anticoagulating the patient with an alternative agent, such as lepirudin or danaparoid.

Table 282.4 Recommended minimum platelet counts for invasive procedures

Procedure	Recommended platelet count ($\times 10^9/l$)
Dental extraction	>30
Minor operations, i.e. <ul style="list-style-type: none"> • liver biopsy • laparotomy • central venous catheter insertion 	>50
Major surgery	Variable recommendations >50 to >80
Surgery on the eye or brain	>100

DIC

DIC is a clinicopathological diagnosis that requires evidence of a disease process that is known to predispose to DIC, and laboratory tests to support this diagnosis. Treatment for patients who are bleeding involves treating the underlying disease, and transfusing fresh frozen plasma, platelets, and cryoprecipitate as necessary.

283 Normal haemostatic function

Raza Alikhan

Introduction

Humans have evolved an intricate system that maintains blood in a fluid state. This relies on an intact vascular endothelium modulating vascular tone and forming a barrier between blood components and reactive subendothelial components. It also involves the production of inhibitors of both blood coagulation and platelet aggregation. In addition, haemostatic systems are primed to convert blood from its fluid state to a solid state, to allow the formation of a haemostatic plug, following vessel injury, to stem the flow of blood from or within a blood vessel.

It is convenient to divide these haemostatic processes into:

- primary haemostasis:
 - vasoconstriction
 - platelet activation and aggregation at the site of vessel injury
- secondary haemostasis:
 - stimulation of protein serine enzyme coagulation pathways, resulting in thrombin generation, and formation of a fibrin clot at the site of vessel injury
- fibrinolysis:
 - a process whereby the size of the fibrin clot is initially limited to the site of injury, by plasmin, and is then broken down once vessel wall healing has occurred

It is important to remember that these processes often occur simultaneously, rather than in a stepwise manner.

These haemostatic systems exist in a dynamic state of equilibrium in the majority of people, but disturbances in this balance may result in bleeding disorders (see Chapter 284) or thrombotic disorders (see Chapter 285).

Endothelium

The normal vascular endothelium maintains blood fluidity by producing inhibitors to platelet aggregation and blood coagulation, by promoting fibrinolysis, and by regulating vascular tone.

The endothelium inhibits platelet aggregation by releasing:

- prostaglandin I₂ (PGI₂, or prostacyclin)
- nitric oxide (NO)

The endothelium inhibits blood coagulation by synthesizing and secreting:

- thrombomodulin
- heparin sulphate

The endothelium promotes fibrinolysis by synthesizing and secreting:

- tissue plasminogen activator
- urokinase plasminogen activator
- plasminogen activator inhibitor

In addition to their effects on platelet aggregation, both PGI₂ and NO (also known as endothelium-derived relaxing factor) exert vasodilatory effects on smooth muscle cells in the vessel wall, to modulate vascular tone and help to maintain blood flow.

Platelets

Following injury to the blood vessel wall, platelets become activated and begin to aggregate, forming a haemostatic plug to stem the flow of blood. In addition, the platelet phospholipid membrane provides a surface for the assembly of the procoagulant complexes tenase and prothrombinase, which are central to the production of thrombin

and the fibrin clot. Chapter 281 describes normal platelet synthesis and function, including their roles in haemostasis (see Figure 283.1).

Coagulation

Historically, the coagulation system has been divided into an extrinsic pathway (tissue factor–factor VIIa complex) and an intrinsic pathway (contact factors). However, such a division does not occur in vivo. There are essentially two linked phases of coagulation: an initiation phase and a propagation phase (see Figure 283.2).

Initiation of clotting arises when tissue factor, expressed on damaged endothelium or activated monocytes, comes into contact with the active form of the vitamin K-dependent factor VII, factor VIIa. Approximately 1%–2% of factor VII circulates in the active form. The tissue factor–factor VIIa complex converts two other vitamin K-dependent factors, factor IX and factor X, to factor IXa and factor Xa, respectively. Factor Xa cleaves prothrombin and generates a small amount of thrombin, which activates factors V, VIII, and XI. These activated factors are crucial to the development of the tenase and prothrombinase complexes and the propagation phase of coagulation.

Tenase complex

Once factor VIIIa is formed, factor IXa, generated by the tissue factor–factor VIIa complex, combines with factor VIIIa on the platelet phospholipid membrane, in the presence of calcium, to form ‘factor Xase’. This ‘tenase’ complex is the major activator of factor X.

Prothrombinase complex

Factor Xa binds to factor Va (which is generated by the small amount of thrombin during the initiation phase). In the presence of calcium and membrane-bound phospholipids, the ‘prothrombinase’ complex is formed. This prothrombinase complex is 300 000-fold more active than factor Xa alone in catalysing the conversion of prothrombin and results in a ‘thrombin burst’ that is responsible for more than 95% of the thrombin activity generated.

Thrombin has a number of roles in haemostasis. The primary role of thrombin is to cleave fibrinogen to form a fibrin clot. This clot is further stabilized by cross linkage in the presence of factor XIII, which is activated by thrombin. Thrombin activation of factors V, VIII, and XI allow formation of the tenase and prothrombinase complexes.

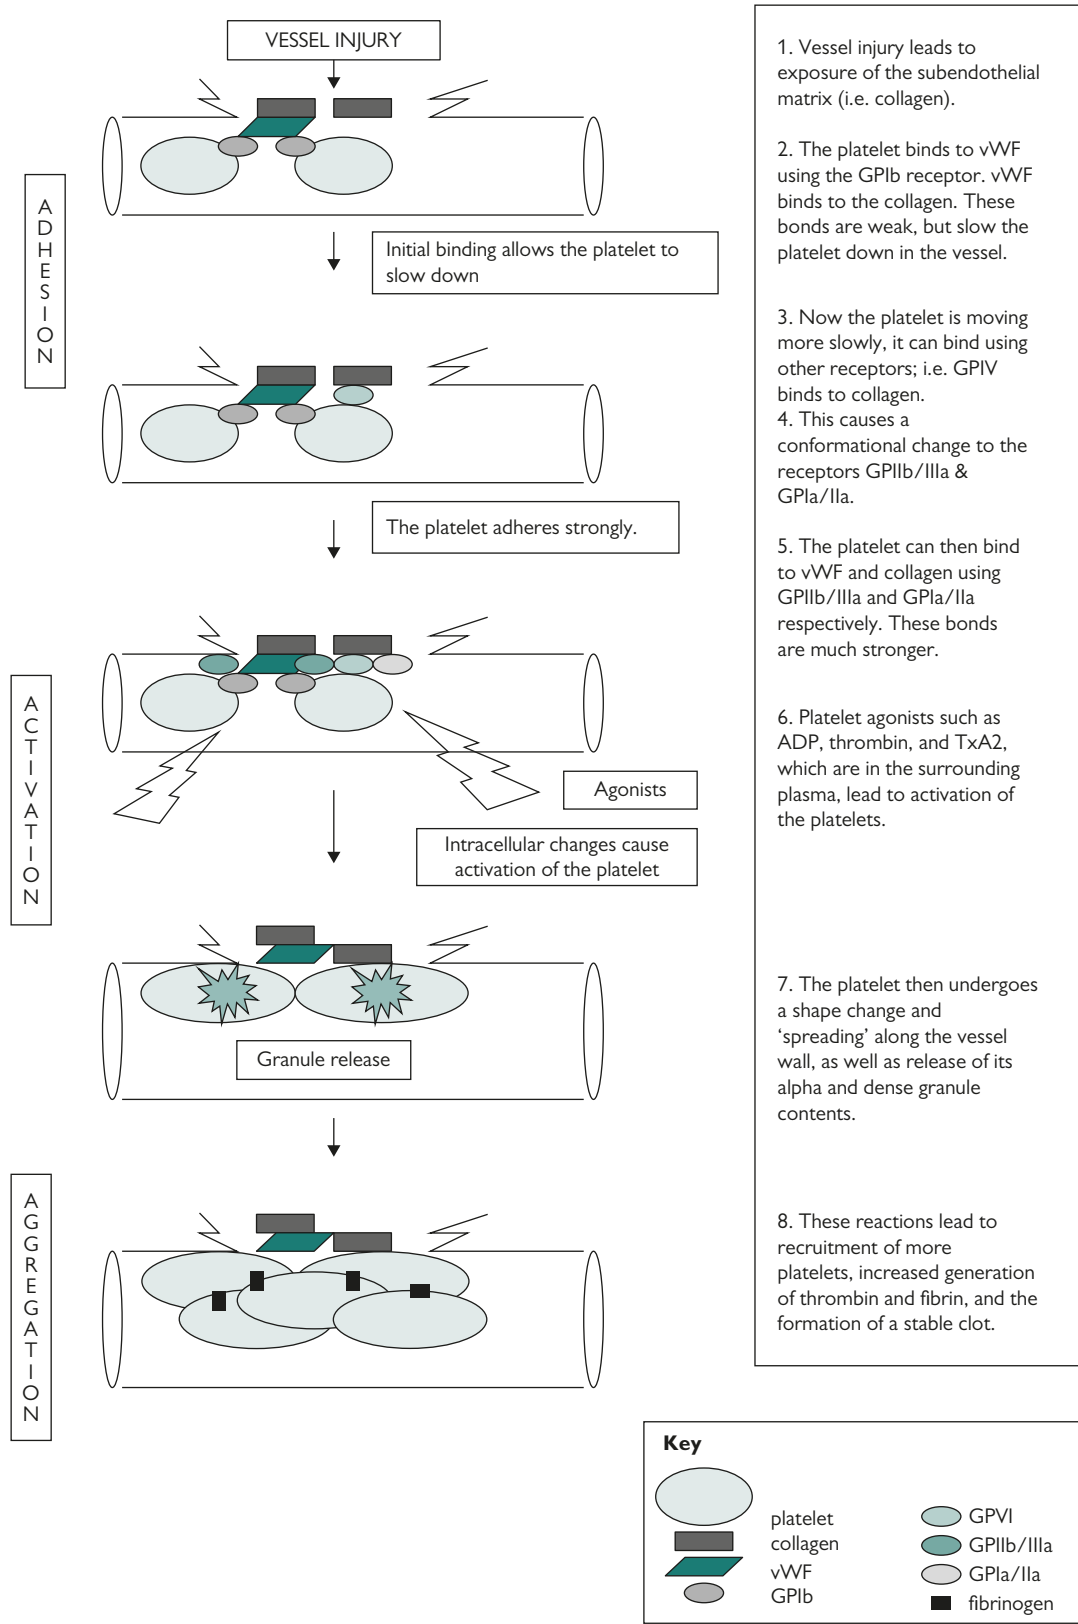

Inhibition of coagulation

The presence of natural anticoagulants regulates and localizes the formation of the haemostatic plug to the site of endothelial damage.

Antithrombin (AT), also known as heparin cofactor I, is a serine protease inhibitor (or serpin) that inactivates the serine proteases thrombin (factor IIa) and factors IXa, Xa, and XIa. AT binds irreversibly, via an arginine residue in its active site, to the active serine site of the serine proteases. In the presence of heparin or vessel wall heparan sulphate, a conformational change of AT results in potentiation of its inhibition of thrombin. Congenital deficiency of AT results in a significantly increased risk of venous thromboembolism (VTE; see Chapter 285).

Heparin cofactor II, another serpin, can also be activated by heparin or dermatan sulphate and selectively inhibits thrombin (but not factor Xa).

Protein Z, a vitamin K-dependent protein, is a cofactor for the inhibition of factor Xa by Z protease inhibitor.

1. Vessel injury leads to exposure of the subendothelial matrix (i.e. collagen).
2. The platelet binds to vWF using the GPIb receptor. vWF binds to the collagen. These bonds are weak, but slow the platelet down in the vessel.
3. Now the platelet is moving more slowly, it can bind using other receptors; i.e. GPIV binds to collagen.
4. This causes a conformational change to the receptors GPIIb/IIIa & GPIa/IIa.
5. The platelet can then bind to vWF and collagen using GPIIb/IIIa and GPIa/IIa respectively. These bonds are much stronger.
6. Platelet agonists such as ADP, thrombin, and TxA₂, which are in the surrounding plasma, lead to activation of the platelets.
7. The platelet then undergoes a shape change and 'spreading' along the vessel wall, as well as release of its alpha and dense granule contents.
8. These reactions lead to recruitment of more platelets, increased generation of thrombin and fibrin, and the formation of a stable clot.

t-PA –tissue plasminogen activator, u-PA –urokinase plasminogen activator,
PAI –plasminogen activator inhibitor, TAFI –thrombin-activatable fibrinolysis inhibitor

Figure 283.3 The fibrinolysis pathway; PAI, plasminogen activator inhibitor; TAFI, thrombin-activatable brinolysis inhibitor; t- PA, tissue plasminogen activator; u-PA, urokinase plasminogen activator.

Thrombomodulin forms a complex with thrombin and enhances thrombin's activation of protein C.

Protein C, a vitamin K-dependent protein, is activated by thrombomodulin to activated protein C (APC) and inhibits factors Va and VIIIa. Hereditary resistance to APC (factor V Leiden) arises due to a mutation in factor V, which prevents APC from inactivating factor Va. This results in a procoagulant state and is associated with an increased risk of VTE (see Chapter 285).

Protein S, a vitamin K-dependent protein, is a cofactor for activated protein C. Protein S deficiency is also associated with an increased risk of VTE (see Chapter 285).

Tissue factor pathway inhibitor (TFPI) inhibits both the tissue factor–factor VIIa complex and the conversion of factor X to factor Xa. TFPI may serve a potentially crucial role in maintaining the endothelium in a thromboresistant state. However, unlike the case with the other natural anticoagulants, an inherited deficiency of TFPI with an increased risk of VTE has not yet been described.

Alpha-2 antiplasmin is the primary inhibitor of plasmin. It limits the fibrinolytic response and allows the haemostatic plug to remain intact until healing has occurred. Deficiency of alpha-2-antiplasmin results in dissolution of the haemostatic plug before healing is complete and results in a haemorrhagic disorder.

Alpha-2-macroglobulin is a secondary or backup inhibitor for plasmin and thrombin. No clinical disorder of alpha-2-macroglobulin deficiency has yet been described.

The fibrinolytic system

The fibrinolytic system contributes to the localization of the haemostatic plug to the site of vessel injury and ensures that the clot is removed once healing has occurred.

During the initial period of haemostatic plug formation, platelets and endothelial cells release plasminogen activator inhibitors 1 and 2, alpha-2 antiplasmin, alpha-2 macroglobulin, and thrombin activatable fibrinolysis inhibitor, which facilitate fibrin formation by inhibiting both the conversion of plasminogen and the action of plasmin (see Figure 283.3).

By a poorly understood but timely orchestrated process, tissue plasminogen activator and, to a much lesser extent, urokinase plasminogen activator convert plasminogen to the serine protease active form, plasmin, by cleavage of a single peptide bond.

Both fibrinogen and fibrin are substrates for plasmin, leading to the production of specific fragments collectively known as fibrinogen/fibrin degradation products. Cleavage of fibrinogen produces transient X fragments, which degrade into D and E fragments. Cleavage of fibrin leads to a different pattern of fragments, because of the cross linkage of fibrin by factor XIIIa. These fragments, DY, YY, and DD (D-dimer), are characteristic of fibrin breakdown.

The measurement of D-dimer levels has been incorporated into clinical decision models for the diagnosis of VTE. Normal D-dimer levels in a patient with a low clinical probability of VTE can be used to exclude the presence of deep vein thrombosis or pulmonary embolism, without the need for further investigation.

284 Bleeding disorders

Raza Alikhan

Introduction

From the rabbinical writings in the second century AD, to the spread of haemophilia within the royal families of Europe, there have been reports of bleeding disorders throughout history. The most common inherited bleeding disorders are haemophilia and von Willebrand's disease. There are also a number of rarer inherited bleeding disorders, which are summarized in Table 284.1.

Haemophilia

Definition of haemophilia

Haemophilia, from the Greek *haima* ('blood'), and *philia* ('friend'), is the most common of the severe bleeding disorders. Haemophilia A and B arise as a result of deficiencies of factors VIII and IX, respectively, and are inherited in an X-linked recessive fashion.

Aetiology of haemophilia

The factor VIII gene, F8, is located on the long arm of the X chromosome (Xq28). It is a large gene, spanning 186 000 base pairs of DNA, and is comprised of 26 exons. This accounts for its greater risk of mutation, compared with the gene for factor IX, F9, which is also

located on the long arm of the X chromosome (Xq27), but is only 34 000 base pairs long. A number of mutations have been described in F8. The most common is the Intron 22 inversion mutation, which occurs in 20% of haemophilia A patients, and always produces severe disease, accounting for up to 50% of cases of severe haemophilia A.

Typical symptoms of haemophilia, and less common symptoms

Affected haemophiliac males suffer from joint and muscle bleeds, as well as easy bruising, the severity of which is closely related to the concentration or level of activity of the affected coagulation factor (see Table 284.2). Haemophilia A and B have an identical presentation, and can only be distinguished by measuring the specific factor levels.

Although factor VIII or IX deficiency is present at birth, spontaneous bleeding during the neonatal period is uncommon. Children with severe haemophilia tend to present this within the first year of life. In contrast, those suffering with mild or moderate haemophilia may not present with symptoms until adolescence or adulthood. The most common presenting symptoms are oral bleeding, either when teeth begin to erupt at age 6–9 months, or associated with a bitten tongue or lip. Bleeding from the frenulum of the upper or lower lip is

Table 284.1 Rare coagulation disorders

Deficiency	Diagnosis	Treatment	Prevalence	Genetics
Factor I (fibrinogen)	↑ PT ↑ APTT ↑ TT ↓ Fibrinogen	Fibrinogen concentrate Cryoprecipitate	1 in 1 000 000	Autosomal recessive Chromosome 4
Factor II (prothrombin)	↑ PT ↑ APTT ↓ Factor II	Prothrombin complex	1 in 2 000 000	Autosomal recessive Chromosome 11
Factor V	↑ PT ↑ APTT Normal TT ↓ Factor V	Fresh frozen plasma	1 in 1 000 000	Autosomal recessive Chromosome 1
Combined Factor V + Factor VIII	↑ PT ↑ APTT ↓ Factor V ↓ Factor VIII	Fresh frozen plasma + Factor VIII concentrate	1 in 1 000 000	Autosomal recessive Chromosome 18
Factor VII	↑ PT Normal APTT ↓ Factor VII	Recombinant Factor VIIa (Novoseven)	1 in 500 000	Autosomal recessive Chromosome 13
Factor X	↑ PT ↑ APTT Normal TT ↓ Factor X	Prothrombin complex	1 in 1 000 000	Autosomal recessive Chromosome 13
Factor XI	Normal PT ↑ APTT Normal TT ↓ Factor XI	Factor XI concentrate	1 in 1 000 000	Autosomal recessive Chromosome 4
Factor XIII	Normal PT Normal APTT ↓ Factor XIII	Factor XIII concentrate	1 in 1 000 000	Autosomal recessive Chromosome 6

Abbreviations: APTT, activated partial thromboplastin time; PT, prothrombin time; TT, thrombin time.

Severity of haemophilia	Activity of coagulation factor	Presentation
Severe	<1 IU/dl	Spontaneous bleeds
Moderate	1–5 IU/dl	Bleeds after mild trauma
Mild	>5 to <40 IU/dl	Bleeds after surgery or trauma

also common, often caused by the child chewing or exploring objects with his mouth.

Once the child becomes mobile and begins crawling or walking, they are prone to hitting their heads against various objects, such as tables or chairs, causing large bruises of the forehead, often out of keeping with the severity of the injury. While learning to walk, children tend to fall into a sitting position, possibly onto hard objects such as toys, resulting in haematomas of the buttocks. These haematomas may be painful and extend into the scrotum or perineum.

Spontaneous joint bleeds (haemarthroses) are a classic feature of severe haemophilia. This usually starts at age 18 months and continues intermittently, sometimes as often as once or twice a week if untreated, throughout the patient's life. The common sites for bleeding are ankles, knees, and elbows and, less frequently, hips and shoulders.

Muscle bleeds are also characteristic of severe haemophilia, commonly affecting the flexor muscles of the limbs, as well as the calf, gluteal, and iliopsoas muscles. In addition to causing pain, swelling, and loss of function, muscle bleeds may press on important blood vessels and/or nerves and result in compartment syndrome.

Demographics of haemophilia

Haemophilia A affects approximately 1 in 5000 live male births, and haemophilia B affects approximately 1 in 30 000. Haemophilia is inherited in an X-linked recessive fashion. However, approximately one-third of cases has no family history and arises due to de novo mutations in F8 or F9.

All daughters of a man with haemophilia will be obligatory carriers of haemophilia, whereas all sons will be unaffected (see Figure 284.1).

The children of a haemophilia-carrier woman have a 50:50 chance of being either unaffected or affected by haemophilia if male, and a 50:50 chance of being unaffected or a carrier if female (see Figure 284.2). When an affected male has children with a carrier female, all children born will have a 50% chance of having haemophilia. This, therefore, is one of the rare situations where a female may present with haemophilia.

Natural history of haemophilia, and complications of the disease

Intracranial haemorrhage (ICH), although uncommon, is a serious complication of haemophilia and may be precipitated by mild trauma, but can also occur spontaneously. ICH is the most common cause of death in children with severe haemophilia.

Figure 284.1 Inheritance of haemophilia when father has haemophilia and mother is unaffected.

Figure 284.2 Inheritance of haemophilia when father is unaffected and mother carries the haemophilia gene.

Recurrent haemarthroses result in the deposition of haemosiderin into synovial tissue, and results in the formation of new vessels in the subsynovial layer and proliferation of the synovium. This results in inflammation of the synovium (synovitis). The friable and highly vascular synovium is more susceptible to further bleeding, and becomes progressively hypertrophic. In addition to synovial proliferation, iron deposition from blood results in destruction of the articular cartilage. The thickened synovium and damaged cartilage lead to bony erosions, which eventually lead to arthropathy. Haemophilic arthropathy is characterized by joint stiffness, chronic pain, and a reduced range of movement in the affected joint.

Calf muscle bleeds may result in shortening of the Achilles tendon and subsequent equinus deformity of the ankle. Iliopsoas muscle bleeds clinically present with pain in the groin, hip flexion, and loss of sensation across the anterior thigh, and may result in femoral nerve palsy, and weakness and wasting of the quadriceps muscle.

Approach to diagnosing haemophilia

If a patient presents with unusual bruising or bleeding, particularly into the joints or muscles, a diagnosis of haemophilia should be considered. Equally, when faced with an unusual pattern of bleeding that is out of context with the precipitating injury, or, more importantly, when faced with a serious condition such as ICH in a neonate, a bleeding disorder should be considered as part of the differential diagnosis.

It is important to document the patient's bleeding history, and any family history of bleeding that may suggest the presence of an inherited bleeding disorder. A family history of haemophilia is an indicator for referral and further investigation.

First-line tests include a full blood count, prothrombin time, activated partial thromboplastin time (APTT), and liver function tests. If the APTT is prolonged, a mixing test with pooled normal plasma should be performed. Correction of the APTT with normal plasma implies a deficiency of a clotting factor or fibrinogen. Further tests should include a fibrinogen concentration and factor assay(s).

Factor assays and mutation testing is generally performed in affected males, and then confirmed or excluded in female relatives. Prior to genetic testing it is advisable that counselling is provided by a healthcare professional experienced in the management of haemophilia.

Other diagnoses that should be considered aside from haemophilia

If there is no family history and only a mild reduction in the factor level, it is important to test the ABO blood group and measure von Willebrand factor (vWF) levels and activity. Patients with Group O blood have lower levels of factor VIII and vWF than those with non-Group O blood.

It is also important to exclude von Willebrand's disease, in particular, type 2N von Willebrand's disease. These patients have low levels of factor VIII, and may be misdiagnosed as having mild haemophilia A (see 'Approach to diagnosing von Willebrand's disease').

In a patient with a bleeding history, a prolonged APTT which corrects on mixing, and normal levels of factor VIII and IX, it is important to measure factor XI levels. The bleeding manifestations in factor

XI deficiency, which is sometimes referred to as haemophilia C, are much less predictable than those in haemophilia A or B.

'Gold-standard' diagnostic test for haemophilia

DNA sequencing is the gold-standard test for mutation detection. A candidate mutation is first identified in a male haemophiliac, and then DNA sequencing can be used to determine the presence or absence of an abnormality in at-risk family members.

Acceptable diagnostic alternatives to the gold-standard test for haemophilia

The F8 Intron 22 inversion can be detected by Southern blotting or by a long-PCR-based protocol. The long-PCR method allows results to be obtained within 24 hours and only uses small amounts of DNA. This is an important consideration when performing prenatal diagnosis on a limited quantity of chorionic villus biopsy material.

Prognosis of haemophilia, and how to estimate it

In the 1920s, the median life span for a boy with haemophilia was approximately 10 years; however, by the 1980s, this had been extended to 55 years. However, this has not been without cost, as highlighted by the tragic infection of haemophiliac patients with hepatitis and HIV, and the chronic morbidity and mortality that has resulted. In the new millennium, the expected lifespan of a newly born haemophiliac is close to that of the general population.

Treatment of haemophilia, and its effectiveness

The goals of modern haemophilia management are to minimize joint disease, and maximize quality of life. The common standard of care falls into one of two categories:

- 'on-demand' treatment: this involves treating bleeding episodes once they arise
- prophylaxis: many patients with severe haemophilia receive regular prophylactic infusions of factor VIII or factor IX to prevent bleeding episodes; this is based on the observation that patients with moderate haemophilia (factor level >1%) suffer from significantly less spontaneous bleeds; the aim of prophylactic treatment is to maintain trough factor levels above 1 IU/dl

Once bleeding has started, it is important to raise factor VIII or factor IX to a haemostatic level, with the appropriate factor replacement concentrate, to arrest bleeding and prevent complications. Factors VIII and IX are currently available as both plasma-derived and recombinant factor concentrates. For patients presenting with a joint bleed, the aim of treatment is to raise the level of factor VIII or factor IX to above 50 IU/dl; for a major bleed, such as ICH, the aim is to raise factor levels above 100 IU/dl.

In addition to factor replacement, the 'PRICE regime' is recommended following an acute bleed:

- P (protection): reduced weight bearing on the affected joint or muscle for the first 24–48 hours
- R (rest): the affected area should initially be rested completely; this allows swelling to settle and prevents further bleeding
- I (ice): helps to reduce swelling, prevents further bleeding, and eases pain
- C (compression): due to increased volumes of fluid, the more swollen an affected area, the more painful it becomes; compression reduces swelling and eases pain
- E (elevation): this also helps to reduce swelling and reduces blood flow to the affected area

von Willebrand's disease

Definition of von Willebrand's disease

von Willebrand's disease is a bleeding disorder caused by inherited defects in the concentration, structure, or function of vWF. vWF has two essential functions:

- primary haemostasis: vWF enables platelets to adhere to injured vascular endothelium, and then to form platelet aggregates

- secondary haemostasis: vWF binds to and stabilizes factor VIII; in the presence of vWF, the half-life of factor VIII is 8–12 hours; in its absence, it is <1 hour

Aetiology of von Willebrand's disease

The vWF gene is located on the short arm of Chromosome 12 (12p13.2). Mutations in this gene result in quantitative or qualitative defects of vWF. The current international classification of von Willebrand's disease is as follows:

- quantitative classification:
 - type 1 von Willebrand's disease: partial loss of vWF
 - type 3 von Willebrand's disease: total loss of vWF
- qualitative classification:
 - type 2 von Willebrand's disease defects:
 - type 2A: absence of high-molecular-weight (HMW) multimers of vWF
 - type 2B: increased affinity of vWF for platelet glycoprotein Ib (GpIb) causing removal of HMW multimers from plasma, and associated with thrombocytopenia
 - type 2M: defective interaction between vWF and platelets, and no loss of HMW multimers
 - type 2N: defect in the N-terminal region of vWF where the binding domain for factor VIII is located, resulting in reduced binding of vWF to this factor; no loss of HMW multimers

Typical symptoms of von Willebrand's disease, and less common symptoms

Bleeding manifestations are those suggestive of a defect in primary haemostasis:

- easy bruising
- epistaxis
- oral mucosa bleeding
- menorrhagia

Demographics of von Willebrand's disease

von Willebrand's disease is the commonest of the inherited bleeding disorders, with up to 1% of the population having reduced vWF levels commensurate with a diagnosis of von Willebrand's disease. However, only 125 per million of the population has a clinically significant bleeding disorder.

The plasma level of vWF in normal individuals varies between 40 and 240 IU/dl, and is affected by various genetic and environmental factors:

- ABO blood group: people with Group O blood have a lower vWF level than people with non-Group O blood
- ethnicity: Africans appear to have higher vWF levels than Caucasians and Asians do
- age: neonates have a raised vWF level at birth, which falls to baseline by 6 months
- pregnancy: the level of vWF increases during pregnancy in women without von Willebrand's disease, and in most women with type 1 von Willebrand's disease; there is no increase in vWF in women with type 3 von Willebrand's disease, and variable increased levels in women with type 2 von Willebrand's disease
- thyroid disease: vWF levels are raised in hyperthyroidism, decreased in hypothyroidism (acquired von Willebrand's disease), and resolve when the patient is treated and becomes euthyroid

Natural history of von Willebrand's disease, and complications of the disease

The clinical expression of von Willebrand's disease is usually mild in type 1 von Willebrand's disease, with increasing severity in type 2 and type 3.

Approach to diagnosing von Willebrand's disease

A personal and/or family history of bleeding and the pattern of bleeding are central to a diagnosis of von Willebrand's disease. Bleeding events that may suggest von Willebrand's disease include:

- prolonged epistaxis, without a history of trauma and which is not stopped within 20 minutes by compression, leads to anaemia, or requires a blood transfusion

- cutaneous haemorrhage and bruising, with minimal or no apparent trauma
- prolonged bleeding from trivial wounds, lasting >15 minutes
- oral cavity bleeding, such as gingival bleeding, bleeding with tooth eruption, or bites to lips and tongue, that requires medical attention
- heavy, prolonged, or recurrent bleeding after dental extraction, tonsillectomy, or adenoidectomy
- menorrhagia not associated with structural lesions of the uterus

Preliminary investigations include:

- full blood count: the platelet count should always be performed when investigating a suspected bleeding disorder; patients with type 2B von Willebrand's disease may have a moderate thrombocytopenia
- APTT: this is often prolonged in von Willebrand's disease; however, a normal APTT does not exclude a diagnosis of von Willebrand's disease
- prothrombin time, thrombin time, and fibrinogen are all normal in von Willebrand's disease
- PFA-100: this allows a rapid and simple determination of platelet-vWF function; it simulates primary haemostasis in the high shear stress environment that occurs after small vessel injury

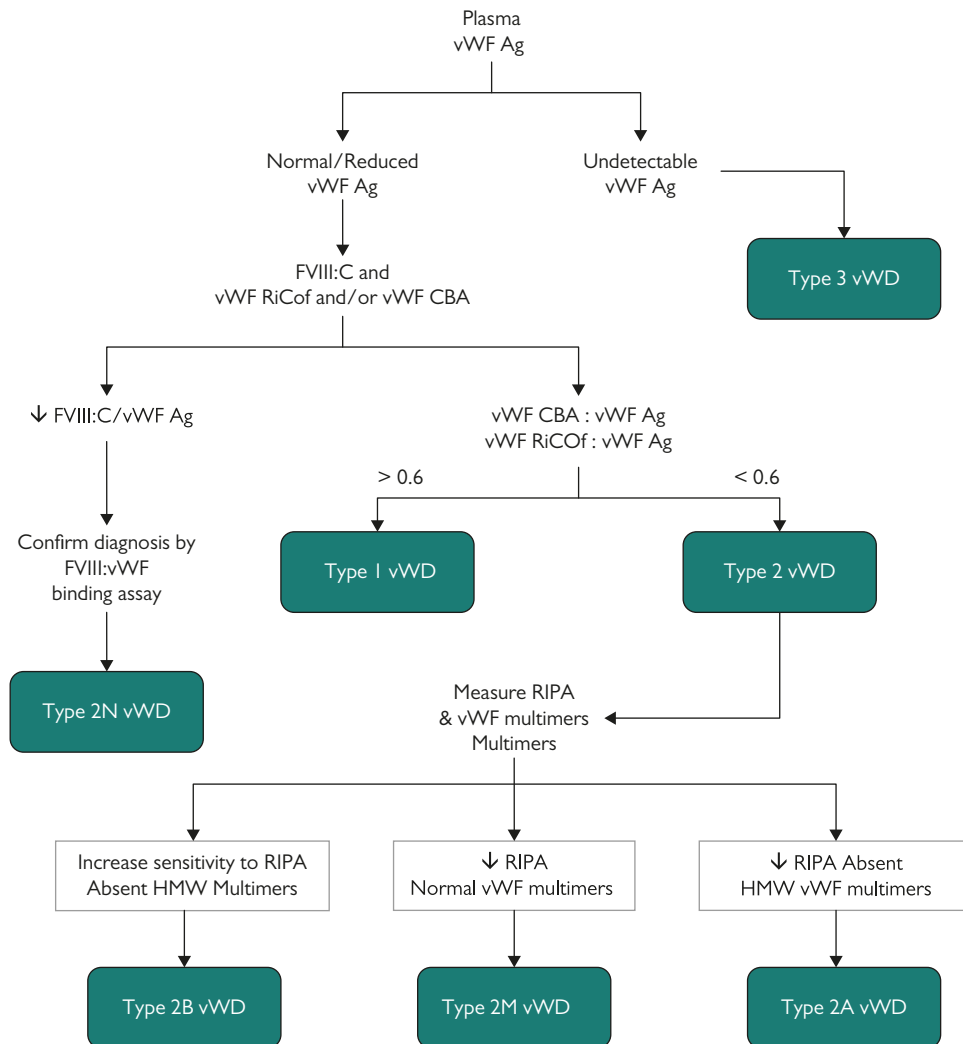

Other diagnoses that should be considered aside from von Willebrand's disease

Platelet-type (pseudo-) von Willebrand's disease is a rare disorder resulting from mutations that affect the platelet glycoprotein Ib/glycoprotein IX receptor complex and causes increased binding between vWF and platelets (i.e. the defect is in the platelets rather than in vWF). Laboratory findings are similar to those found for type 2B von Willebrand's disease (thrombocytopenia, increased ristocetin-induced platelet aggregation (RIPA), and decreased HMW multimers). Therefore, to differentiate type 2B von Willebrand's disease from pseudo-von Willebrand's disease, cryoprecipitate (containing normal vWF) is added to the patient's plasma; it will result in aggregation of platelets in pseudo-von Willebrand's disease, but not in type 2B von Willebrand's disease.

'Gold-standard' diagnostic test for von Willebrand's disease

There is no single diagnostic test for von Willebrand's disease; it requires a series of tests to be performed and interpreted in a step-wise manner, as described in Figure 284.3.

- Factor VIII functional assay: factor VIII is frequently reduced in von Willebrand's disease, as the half-life of this factor is regulated by vWF

vWF: von Willebrand factor, FVIII: factor VIII, RiCof: ristocetin cofactor; CBA: collagen binding activity; RIPA: ristocetin induced platelet aggregation

Figure 284.3 Sequence of tests in the diagnosis of von Willebrand's disease subtypes; Ag, antigen; CBA, collagen-binding activity; FVIII, factor VIII; FVIII:C, factor VIII antigen; HMW, high molecular weight; RiCof, ristocetin cofactor; RIPA, ristocetin-induced platelet aggregation; vWD, von Willebrand's disease; vWF, von Willebrand factor.

- vWF antigen (vWF:Ag): vWF antigen levels are measured by immunological methods, such as ELISA assays
- vWF ristocetin cofactor activity (vWF:RiCof): addition of the anti-biostic ristocetin promotes the binding of vWF to platelet glycoprotein Ib; this is a functional assay, rather than an antigen assay (like vWF:Ag), which only measures the level of vWF present
- vWF collagen-binding activity: this is another functional assay RIPA: in this assay, ristocetin is added at several concentrations (ranging from 0.2 to 1.5 mg/ml) to platelet-rich plasma from the patient, to assess the affinity of vWF for platelets by determining the lowest ristocetin concentration that induces agglutination; aggregation at concentrations <0.5 mg/ml indicates vWF/platelet hyper-reactivity, and is an essential diagnostic criterion for type 2B von Willebrand's disease
- multimeric analysis of vWF: this has a role in the subclassification of von Willebrand's disease
- vWF-factor VIII binding assay: reduced binding of factor VIII to vWF is diagnostic of type 2N von Willebrand's disease
- molecular analyses: in some circumstances, the identification of a molecular defect in the vWF gene can help with diagnosis and classification

Treatment of von Willebrand's disease, and its effectiveness

Desmopressin (1-deamino-8-D-arginine vasopressin; Desmopressin) is a synthetic analogue of vasopressin. It causes vWF to be released from endothelial stores, and increases factor VIII and vWF levels to 3–5 times their baseline level, 30–60 minutes after IV or subcutaneous administration. Side effects include headache, facial flushing, hypotension, and hyponatraemia. It should be avoided in patients with cardiovascular disease, as it has been associated with myocardial infarction and stroke.

Desmopressin (0.3 µg/kg) is most effective in patients with type 1 von Willebrand's disease, where increasing levels by three- to fivefold is sufficient for haemostasis. It is of no use in type 3 von Willebrand's disease. Patients with type 2 von Willebrand's disease have a variable response, and a trial of Desmopressin should be considered in type 2A and 2M von Willebrand's disease. Desmopressin is usually avoided in patients with type 2B von Willebrand's disease, because it appears to exacerbate thrombocytopenia.

Tranexamic acid is an antifibrinolytic agent that binds to the lysine-binding sites of plasminogen and therefore inhibits the binding of

plasminogen to fibrin. Like desmopressin, it is useful for the management of epistaxis and menorrhagia and following dental extraction. It can be given orally (15–25 mg/kg three times per day), intravenously (10 mg/kg three times per day), or as a mouthwash (10 ml of a 5% solution four times per day).

Patients unresponsive to desmopressin require transfusion with vWF/factor VIII concentrates derived from plasma, as there is no recombinant vWF currently available. There are a number of vWF/factor VIII concentrates available: Haemate P, Alphanate, and Fanhdi. The aim of treatment is to raise the vWF:RiCof and factor VIII levels to above 100 IU/dl for a major surgical procedure, or to treat a significant bleed. The vWF:RiCof and factor VIII levels are then maintained above 50 IU/dl until wound healing has occurred.

Rare inherited bleeding disorders

Rare coagulation disorders are outlined in Table 284.1.

285 Prothrombotic conditions

Raza Alikhan

Definition of the disease

The term thrombophilia is used to describe an individual who has a tendency to develop thrombosis. Arterial thrombosis is usually linked with classical risk factors such as age, smoking, hypertension, hyperlipidaemia, or diabetes; a thrombophilia assessment and workup is not usually considered in cases of arterial thrombosis. A clinically useful approach to the diagnosis and management of a patient with a venous thrombotic process is to categorize the disorder as either a primary (inherited) or a secondary (acquired) hypercoagulable state (see Table 285.1).

Aetiology of the disease

Inherited hypercoagulable states

Antithrombin deficiency

Antithrombin (AT) is synthesized by the liver. In addition to inhibiting thrombin, it inhibits the activated clotting factors IXa, Xa, XIa, XIIa, and tissue factor bound VIIa. Two important functional regions have been identified: a heparin-binding domain and a thrombin-binding domain. There are two types of AT deficiency, and both cause a reduction of AT activity:

- type I: due to a quantitative reduction in the AT protein
- type II: due to a qualitatively (functionally) abnormal AT protein; subclassified according to the site of the molecular defect:
 - reactive site (RS): abnormality in the reactive (thrombin-binding) site
 - heparin-binding site (HBS)
 - pleiotropic: abnormality in both the RS and the HBS

Type I and II deficiencies can be differentiated by comparing the results of an immunological assay (quantitative level) with those of a heparin cofactor assay (functional level). The distinction between

subtypes is of clinical relevance, as the incidence of thrombosis is higher with type I and type II RS deficiencies.

Protein C deficiency

Protein C is a vitamin K-dependent protein synthesized in the liver. Activated by a complex of thrombin and thrombomodulin, it inhibits activated clotting factors Va and VIIIa. Activated protein C (APC) requires the presence of a cofactor, protein S, to exert its inhibitory effects. Protein C deficiency is classified into two subtypes on the basis of functional and immunological assays. However, subtyping serves no clinical purpose, as there is no difference in thrombotic risk. Acquired deficiencies of protein C activity occur in patients with disseminated intravascular coagulopathy (DIC), patients with liver disease, and patients on warfarin therapy.

Protein S deficiency

Protein S, another vitamin K-dependent protein synthesized in the liver; is a cofactor for APC. Two-thirds of the plasma protein S is bound to C4b-binding protein; the remaining third, free protein S, is unbound and has functional activity. Three types of protein S deficiency have been described:

- type I, which is due to a quantitative defect (reduced levels of total and free protein S)
- type II, which is due to a qualitative (functional) defect
- type III, which there are normal levels of total protein S but reduced levels of free protein S

Protein S levels are lower in women than in men and fall both during pregnancy and with the use of oestrogen-containing contraceptive pills or hormone replacement therapy. Acquired deficiency of protein S also occurs in patients with DIC, liver disease, antiphospholipid antibodies, or SLE, as well as with warfarin therapy.

APC resistance/factor V Leiden mutation

The majority of patients with inherited APC resistance have the same point mutation (G1691A) in the gene that codes for clotting factor V: the 'factor V Leiden' (FVL) mutation. Acquired APC resistance occurs with advancing age, in the presence of antiphospholipid antibodies, during pregnancy, and in women using oestrogen-containing contraceptive pills or hormone replacement therapy.

APC resistance is measured using an activated partial thromboplastin time (APTT), with samples tested with and without added APC; the resulting clotting time is expressed as a ratio, the APC sensitivity ratio. The FVL mutation can be detected by amplifying the DNA around the mutation site using a polymerase chain reaction (PCR) and then performing a restriction digest with an enzyme. This recognizes the sequence GAGG, which is present in normal factor V but is lost in the FVL form of the protein. The resulting cleaved fragment is then electrophoresed on an agarose gel to separate the fragments and visualized directly after staining. DNA testing clearly identifies those who have the normal form of the gene, those who are heterozygotes for the FVL mutation, and those who are homozygotes for the FVL mutation.

The FVL mutation is the most common inherited cause of thrombophilia, with a prevalence of 5% in Caucasian populations. The FVL mutation is identified in 20% of patients presenting with a first venous thromboembolism (VTE) and in more than 50% with recurrent VTE. Heterozygous carriers have a three- to eightfold increased risk of VTE, and homozygous have an 80-fold increased risk.

Prothrombin G20210A mutation

The prothrombin G20210A mutation is a guanine (G) to adenine (A) base substitution at nucleotide position 20210 in the

Table 285.1 Hypercoagulable states

Inherited (primary) hypercoagulable state	Acquired (secondary) hypercoagulable state

	Myeloproliferative disorders
	<ul style="list-style-type: none"> • polycythaemia vera • essential thrombocythaemia
	Paroxysmal nocturnal haemoglobinuria

Table 285.2 Prevalence of inherited thrombophilia in the general population, and the risk of venous thrombosis

Thrombophilia	Prevalence in population (%)	Relative risk of VTE
Antithrombin deficiency	0.0002	25–50
Protein C deficiency	0.2000	10
Protein S deficiency	0.0800	2–10
FVL heterozygous mutation	5.000	5
FVL homozygous mutation	0.0002	50–80
Prothrombin G20210A mutation	2.000	2–3
Hyperhomocysteinaemia	5.000–10.000	2

Abbreviations: FVL, factor V Leiden; VTE, venous thromboembolism.

3' untranslated region of the prothrombin gene. Following PCR of the target region, the presence of the mutation can be determined by cleaving the fragment with a restriction enzyme. In normal individuals, the PCR product will not be cleaved, while the product from those possessing the mutation will be cleaved. The cleaved material is then electrophoresed on an agarose gel to separate the fragments and visualized directly after staining.

The prothrombin G20210A mutation causes elevated levels of prothrombin, resulting in enhanced thrombin generation and an increased risk of VTE (see Table 285.2). The gain of function mutation is almost exclusively found in Caucasians. As FVL and the prothrombin gene mutation are common, compound heterozygotes are often encountered and they have a 20-fold increased risk of thrombosis when compared to individuals with neither mutation.

Hyperhomocysteinaemia

Elevated homocysteine levels in the blood, hyperhomocysteinaemia, are associated with both arterial disease and VTE. Homocysteine is an amino acid derived from methionine during its metabolism. There are two types of hyperhomocysteinaemia:

- primary hyperhomocysteinaemia: an inherited deficiency affecting one of the following two enzymes:
 - cystathionine beta synthase: a deficiency in this enzyme occurs in 1 in 100 000 live births and leads to the inherited metabolic disorder homocystinuria
 - methylene tetrahydrofolate reductase: this enzyme is involved in the remethylation pathway by which homocysteine is converted to methionine; approximately 10% of the population have a mutation in this enzyme, with resultant elevated homocysteine levels
- secondary hyperhomocysteinaemia: this is acquired and is caused by a deficiency in one of the following three vitamins:
 - folic acid
 - pyridoxine (vitamin B₆)
 - cobalamin (vitamin B₁₂)

Homocysteine increases the activation of procoagulant factors such as tissue factor and factor V and decreases levels of anticoagulant factors such as protein C and thrombomodulin. It also promotes platelet activation and inhibits fibrinolysis. The presence of elevated homocysteine levels in the blood result in a doubling of the risk of VTE and a two- to fourfold increase in the risk of premature arterial disease. However, there is currently no convincing evidence that reducing homocysteine levels reduces either arterial or venous thrombosis.

Acquired hypercoagulable states

Surgery

All patients admitted to hospital should be assessed for risk factors for VTE (see Table 285.2). The type and duration of surgery, in association with additional risk factors for VTE, contribute to the overall thrombotic risk (see Table 285.3).

Age

VTE affects 1 in 1000 individuals annually. The risk of VTE increases steadily with age, affecting approximately 1 in 100 of the population

Table 285.3 Level of thromboembolic risk in surgical patients without thromboprophylaxis

Procedure	DVT %	Clinical PE %	Fatal PE %
<i>Low risk</i>			
Minor surgery in patients <40 years old with no additional VTE risk factors	<10	<1	<0.01
<i>Moderate risk</i>			
Most general, open gynaecological or urological procedures	10–40	1–4	0.1–1.0
<i>High risk</i>			
Major trauma, surgery in patients with multiple VTE risk factors	40–80	1–10	0.1–5.0
Hip arthroplasty	40–60	1–10	0.1–2.0
Knee arthroplasty	40–80	1–10	0.1–2.0
Hip fracture surgery	50–60	3–10	2.0–5.0

Abbreviations: DVT, deep vein thrombosis; PE, pulmonary embolism; VTE, venous thromboembolism.

over the age of 75 years. Although the exact mechanism for this increase in risk is uncertain, there are a number of plausible explanations. The levels of procoagulants increase without a concomitant increase in natural anticoagulant levels; activity decreases, with increased periods of immobility due to illness, and the frequency of acute infections increase as do serious cardiovascular and respiratory conditions. There also appears to be the development of a hypercoagulable state with age, suggested by the rise in levels of D-dimers and prothrombin fragments.

Malignancy

Armand Trousseau first described the association between thrombosis and cancer, stating that 'there appears in the cachexia ... a particular condition of the blood which predisposes it to spontaneous coagulation' (Trousseau, 1865). Cancer and its associated treatments (central venous lines, chemotherapy) increase the risk of VTE by six- to tenfold. Venous thromboembolic events are one of the leading causes of death in patients with cancer.

Tumours shed membrane particles that contain procoagulant activity, including tissue factor, and membrane lipids that propagate the coagulation response. The risk of VTE appears to be highest for tumours affecting the brain, the ovaries, the pancreas, and the lungs. Approximately 10% of patients presenting with idiopathic VTE are diagnosed with malignancy within a year of their thrombotic event.

Pregnancy

Physiological changes in the haemostatic and fibrinolytic systems increase the risk of VTE during pregnancy. There are increased levels of coagulation factors (von Willebrand factor, factor VIII, and fibrinogen). There is also a reduction in protein S levels, and a third of pregnant women acquire resistance to APC. In addition, venous stasis during pregnancy, and endothelial damage of the pelvic vessels during vaginal or operative delivery, contribute to the thromboembolic risk.

Overall, approximately 1 in 1000 pregnancies is complicated by VTE. Pulmonary embolism is one of the most common causes of maternal death. The incidence of antenatal deep vein thrombosis (DVT) is 0.6 per 1000 maternities in women aged less than 35 years of age, and 1.2 per 1000 maternities in women over 35 years of age (see Table 285.3). For post-partum DVT, the incidence is 0.3 per 1000 maternities in women under 35 years of age, and 0.7 per 1000 maternities in women over 35 years of age. The DVT event rate is highest during the 6-week puerperal period. As well as age, obesity appears to be a significant risk factor for VTE during pregnancy.

Demographics	Relative risk	VTE cases per 100 000 women per year
Non-pregnant Not on combined OCP	–	5
Second-generation OCP	3-fold increase	15
Third-generation OCP	5-fold increase	25
Pregnant (age < 35)	12-fold increase	60
Pregnant (age > 35)	24-fold increase	120

Abbreviations: OCP, oral contraceptive pill; VTE, venous thromboembolism.

Hormones

Combined oral contraceptive pill

All combined oral contraceptive pills (OCPs) contain two hormones: oestrogen and progestogen. The different types of OCP are known as second- or third-generation contraceptives, depending on the type of progestogen they contain. Third-generation OCPs contain progestogen in the form of either deogestrel or gestodene. Second-generation OCPs contain progestogen as levonorgestrel or norethisterone. All women taking combined OCPs have a small increased risk of VTE; this risk is greater with third-generation OCPs than with second-generation OCPs (see Table 285.4). There does not appear to be an increased risk of VTE with progestogen-only contraceptive pills.

The presence of an inherited thrombophilia increases the risk of VTE in women who use OCPs. Heterozygous FVL carriers have a 20–30-fold increased risk of VTE and, in homozygous carriers, oral contraceptives confer an even higher risk. Prothrombin G20210A carriers who use OCPs have a 16-fold increased risk, compared with non-users. In addition to the risk of VTE from OCP use, the presence of obesity (BMI >30 kg/m²) or smoking increases the risk of venous thrombosis by a further twofold in those using OCPs.

Progestogen-only contraception

Progestogen-only pills, injectables, levonorgestrel implants, or levonorgestrel-releasing intrauterine devices have not been shown to increase the risk of VTE. In addition, the WHO and UK medical eligibility criteria for contraceptive use state that progestogen-only contraception may be used in patients with a personal or family history of VTE and in patients with an identified inherited thrombophilia.

Hormone replacement therapy

Women with hypo-oestrogenic symptoms may suffer with marked impairment in their quality of life that may be improved with hormone replacement therapy. However, hormone replacement therapy is associated with severe side effects such as stroke, myocardial infarction, and breast cancer. In addition, the risk of VTE in women receiving oral oestrogen appears to be double that of those not receiving oestrogen. The risk is highest in the first year of treatment. However, recent evidence suggests that women receiving transdermal hormone replacement therapy do not appear to be at an increased risk of VTE.

Antiphospholipid syndrome

Antiphospholipid syndrome (APS) is present if at least one of the clinical criteria for it **and** one of the laboratory criteria for it are present (see Table 285.5).

Antiphospholipid antibodies are present in 1%–5% of apparently healthy subjects and in up to 30% of patients with SLE. For healthy subjects, it is uncertain how many will go on to develop a thrombotic or pregnancy-related complication. In contrast, 50% of patients with SLE and antiphospholipid antibodies develop APS.

The pathogenesis of thrombosis, associated with the presence of antiphospholipid antibodies, appears to be multifactorial and includes interference with the natural anticoagulant proteins C and S, inhibition of fibrinolysis, induction of tissue factor, promotion of platelet aggregation, and activation of complement. Thrombosis may affect the arterial system, the venous system, or both. The most common presentation is with lower limb DVT, but other sites such as cerebral

Clinical criteria	Laboratory criteria
<ol style="list-style-type: none"> Vascular thrombosis <ul style="list-style-type: none"> arterial venous small vessel thrombosis Pregnancy morbidity <ul style="list-style-type: none"> one or more unexplained death of a morphologically normal fetus at/or beyond the 10th week of gestation, or one or more premature birth of a morphologically normal fetus before the 34th week of gestation, or three or more unexplained consecutive spontaneous abortions before the 10th week of gestation 	<ol style="list-style-type: none"> Lupus anticoagulant <ul style="list-style-type: none"> present in plasma, on two or more occasions at least 12 weeks apart Anticardiolipin antibody <ul style="list-style-type: none"> IgG and/or IgM in serum/plasma present in medium or high titre (>40 G phospholipids or M phospholipids), on two or more occasions at least 12 weeks apart Anti-beta-2 glycoprotein 1 antibody <ul style="list-style-type: none"> IgG and/or IgM in serum/plasma present on two or more occasions at least 12 weeks apart

veins and abdominal veins (portal, hepatic, mesenteric) may be affected. Arterial thrombosis usually presents as stroke or transient ischaemic attacks and rarely as myocardial infarction.

APS should be considered in all patients who present with unprovoked VTE, in young patients with arterial thrombosis, and following pregnancy complications that fulfil the criteria in Table 285.5.

Nephrotic syndrome

Nephrotic syndrome is characterized by proteinuria (>3.5 g/day), hypoalbuminaemia, hyperlipidaemia, and peripheral oedema. The leaking of protein from the kidney may be associated with the loss of AT, resulting in an acquired AT deficiency. The incidence of VTE in nephrotic syndrome appears to be approximately 20 events per 1000 patient years.

Paroxysmal nocturnal haemoglobinuria

Paroxysmal nocturnal haemoglobinuria (PNH) is an acquired clonal stem cell disorder, characterized by the triad of chronic intravascular haemolytic anaemia, hypercoagulability, and deficient haematopoiesis. It arises due to the loss of the cell membrane protein anchors CD55 and CD59. As a result, there is excessive activation of factor X, increased complement activation of platelets, and impaired fibrinolysis. In addition to lower limb DVT, patients with PNH often present with thrombosis of the inferior vena cava, the portal vein, the sagittal sinus, or the hepatic vein (Budd–Chiari syndrome).

Typical symptoms of the disease, and less common symptoms

The symptoms and signs of VTE depend on the site of thrombosis. The most common site of thrombosis is the lower limb. Less common sites include the upper limbs, the abdominal (splanchnic) veins, and the cerebral vessels. It is important to appreciate that the clinical features suggestive of venous thrombosis may be non-specific and fit a long list of differential diagnoses. Objective testing confirms the presence of DVT in less than a third of patients with suspected thrombosis. However, it is equally important to realize that the diagnosis is often missed or not considered in clinical practice, as indicated by the significant incidence of VTE at post mortem.

What is clear from Table 285.6, which lists the symptoms and signs of VTE, are the non-specific features of venous thromboembolic disease. The clinician needs to have a high index of suspicion and should consider thrombotic events as part of the differential diagnosis of a wide spectrum of disorders.

Approach to diagnosing the disease

The initial investigation of a patient with thrombosis should include the following:

- a full blood count, looking for:
 - elevation of the haematocrit/packed cell volume; if present, consider polycythaemia

Table 285.6 Site-related clinical features of venous thromboembolism	
Symptoms	Signs
Limbs (lower > upper)	
Pain; no specific characteristics; the location of the pain is not necessarily related to the site of thrombosis; it varies from: <ul style="list-style-type: none"> aching to cramping dull to sharp mild to severe Swelling Tender Red skin	Homans' sign: <ul style="list-style-type: none"> pain in the calf on forced dorsiflexion Lowenberg's sign pain in the calf on inflation of cuff to 180 mm Hg at the thigh Moses' sign: <ul style="list-style-type: none"> pain from compression of calf in a forward/backward motion is greater than that from lateral compression Unilateral pitting oedema Tender to palpation Erythema, if associated inflammation
Splanchnic vessels (hepatic, portal, mesenteric veins)	
Upper abdominal pain: <ul style="list-style-type: none"> all patients present with a varying degree of this very non-specific symptom sudden onset of pain/post-prandial abdominal pain is suggestive of mesenteric artery thrombosis gradual onset of pain is more suggestive of venous thrombosis Nausea + vomiting Bloody stools	Abdominal pain + hepatomegaly + ascites: <ul style="list-style-type: none"> need to consider obstruction of the hepatic vein: Budd–Chiari syndrome Splenomegaly <ul style="list-style-type: none"> portal vein thrombosis portal hypertension
Cerebral vein thrombosis	
Headache Lethargy Fits Stroke Coma	Focal neurological signs
Pulmonary embolism	
Chest pain: <ul style="list-style-type: none"> often pleuritic in nature, worse on deep inspiration Dyspnoea: <ul style="list-style-type: none"> subjective experience of hampered breathing Haemoptysis Cough	Circulatory collapse: <ul style="list-style-type: none"> right ventricular dysfunction Tachypnoea: <ul style="list-style-type: none"> objective observation of increased respiratory rate Hypoxia Tachycardia

- elevation of the platelet count; if present, consider essential thrombocythaemia, or a cause of reactive thrombocytosis, such as sepsis or malignancy
- reduction of the platelet count: this may be a feature of drug-induced thrombocytopenia (due to heparin), thrombotic thrombocytopenia purpura (TTP), SLE, or PNH
- a blood film; look for red cell fragments, as these may indicate DIC or TTP
- the following coagulation tests:
 - prothrombin time
 - APTT, using a lupus sensitive reagent; this will provide an initial screen for the presence of a lupus anticoagulant
 - fibrinogen: to screen for dysfibrinogenaemia

The following tests may also be requested, depending on the suspected clinical disorder:

- special coagulation tests, such as:
 - protein C activity (followed by protein C antigen level if the activity is low)
 - protein S activity (followed by free protein S antigen level if the activity is low; the total protein S antigen level may be helpful if the level of free protein S antigen is low)
 - AT activity
 - the APC resistance ratio; if the ratio is abnormal (low), test for the FVL mutation
 - a test for the prothrombin G20210A mutation
- selective special tests, such as:
 - tests for anticardiolipin and anti-beta-2-glycoprotein 1 antibodies (IgG and IgM), to exclude APS
 - tests for platelet anti-PF4/glycosaminoglycan antibodies, to exclude heparin-induced thrombocytopenia

- a test for the JAK2 mutation, to exclude myeloproliferative disorder (portal or splanchnic vein thrombosis)
- a test for plasma ADAMTS13 activity, to exclude acquired or familial TTP
- flow cytometry, to detect PNH

In addition, the following selective general tests may be requested:

- renal function tests
- liver function tests:
 - abnormal results occur in the Budd–Chiari syndrome, which is characterized by ascites, hepatomegaly, and obstruction of the hepatic venous circulation
 - hypoalbuminaemia occurs in nephrotic syndrome
- urinalysis:
 - protein, to exclude nephrotic syndrome
 - bilirubin, to exclude PNH

In addition, if associated symptoms are suggestive of malignancy, the following tests may be requested:

- tests for tumour markers (e.g. prostate-specific antigen, carcinoembryonic antigen, cancer antigen 125)
- imaging:
 - chest X-ray
 - ultrasound of abdomen/pelvis
 - CT abdomen/pelvis

'Gold-standard' diagnostic test

The gold-standard diagnostic test for DVT (upper or lower limb) is venography. The gold-standard diagnostic test for cerebral and splanchnic vein thrombosis is magnetic resonance angiography. The

gold-standard diagnostic test for pulmonary embolism (PE) is pulmonary angiography.

Thrombophilia testing should not be performed during an acute thrombotic episode because interpretation during such an event is difficult, as levels of e.g. protein C or S are affected by the presence of thrombosis and anticoagulants. In addition, note that thrombophilia results do not alter the initial treatment.

Acceptable diagnostic alternatives to the gold standard

Acceptable diagnostic alternatives to the gold-standard test for DVT are Doppler ultrasound and compression ultrasound. MRI is an acceptable diagnostic alternative to the gold-standard test for cerebral vein thrombosis. Acceptable diagnostic alternatives to the gold-standard test for splanchnic vein thrombosis are Doppler ultrasound and CT.

Acceptable diagnostic alternatives to the gold-standard test for PE are CT pulmonary angiography and ventilation/perfusion scintigraphy (also known as a V/Q scan).

Treatment and its effectiveness

The initial treatment of VTE should be with a rapidly acting anticoagulant such as:

- unfractionated heparin (UFH)
- low-molecular-weight heparin (LMWH)
- fondaparinux

Selected patients with extensive acute proximal DVT but who have a low risk of bleeding, and patients with PE and haemodynamic compromise, should be considered for catheter-directed or systemic thrombolysis. Vena caval filters should not be used routinely and are only indicated for patients in whom anticoagulation is contraindicated.

In addition to UFH, LMWH, or fondaparinux, a vitamin K antagonist (e.g. warfarin) or direct-acting oral anticoagulant should be started, with duration of treatment as given in Table 285.7.

Table 285.7 Duration of anticoagulation for specific clinical conditions

Condition	Duration	Target INR (range) for warfarin
First idiopathic VTE: proximal DVT or PE	>3 months*	2.5 (2.0–3.0)
First proximal DVT or PE, with precipitating factors (e.g. surgery, trauma, pregnancy)	3 months	2.5 (2.0–3.0)
First idiopathic calf DVT	3 months	2.5 (2.0–3.0)
First calf vein DVT, with precipitating factors (e.g. surgery, trauma)	6 weeks to 3 months	2.5 (2.0–3.0)
Recurrent VTE	Long term	2.5 (2.0–3.0)
VTE while on warfarin	Long term	3.5 (3.0–4.0)

Abbreviations: DVT, deep vein thrombosis; INR, international normalized ratio; PE, pulmonary embolism; VTE, venous thromboembolism.

*Patients with unprovoked DVT or PE should be treated for a minimum of 3 months. After 3 months, all patients should be evaluated for the risk–benefit ratio of long-term treatment. Patients with unprovoked VTE and in whom risk factors for bleeding are absent and good anticoagulant monitoring is achievable should receive long-term treatment.

286 Acute leukaemia

Graham Collins and Chris Bunch

Definition of the disease

Acute leukaemia is a rapidly progressive, clonal haematopoietic stem cell disorder resulting in the accumulation of immature blood cell precursors (known as blasts) in the bone marrow. There are two main types of acute leukaemia:

- acute myeloid leukaemia (AML), which is defined by the presence of myeloid lineage markers on the blast cells
- acute lymphoblastic leukaemia (ALL), which is defined by the presence of lymphoid markers on the blast cells

Occasionally, the blast cells express markers from both lineages. Such cases are referred to as 'biphenotypic'.

Aetiology of the disease

AML is associated with a number of predisposing factors:

- other haematological conditions such as myelodysplasia or myeloproliferative conditions can transform into AML
- previous chemotherapy agents predispose to AML (e.g. topoisomerase II inhibitors, alkylating agents)
- toxins (e.g. benzene)
- ionizing radiation
- inherited predisposition: Down's syndrome is associated with a significantly increased risk of developing a rare subtype of AML called acute megakaryoblastic leukaemia

Frequently, however, no etiological factors can be identified.

ALL can also arise from chronic myeloid leukaemia and is also associated with Down's syndrome. In the vast majority of cases, no cause can be identified.

Typical symptoms of the disease, and less common symptoms

Acute leukaemia frequently presents with symptoms and signs of bone marrow failure:

- anaemia: fatigue, shortness of breath, headache, palpitations
- leucopenia: bacterial or fungal infections
- thrombocytopenia: purpuric rash, mucosal haemorrhage

In children, a very important symptom of ALL is bone pain, which can often be rather vague and simply present as a limp.

Less commonly, a very high white-cell count can cause symptoms of leucostasis: shortness of breath, retinal haemorrhages, confusion, and priapism. In certain forms of leukaemia, disseminated intravascular coagulation can result in catastrophic haemorrhage and, in other forms, tissue infiltration by blast cells can produce gum hypertrophy, skin lesions (called chloromas), organomegaly, and lymphadenopathy.

Demographics of the disease

Demographics of ALL

ALL is the commonest childhood cancer, although, overall, it is an uncommon disease. ALL accounts for only 20% of adult acute leukaemia. In childhood, there is a clear peak in incidence between 1 and 6 years of age with the highest incidence between ages 2 and 3. In adults, the incidence increases with age. Childhood ALL is 30% more frequent in boys than in girls.

Demographics of AML

The incidence of AML peaks between 60 and 70 years of age; 80% of cases are diagnosed in the over-50 group. It also can occur in children, although it is uncommon in that age group.

Natural history, and complications of the disease

Acute leukaemia is a rapidly progressive condition which rapidly causes deterioration and death if left untreated. Progressive bone marrow failure causes worsening anaemia with subsequent organ failure, increased risk of severe haemorrhage, and a high risk of life-threatening bacterial and fungal infections.

Numerous complications are associated with the treatment of the disease. Potentially curative chemotherapy is intensive and associated with hair loss, fatigue, gastrointestinal disturbances, reduced fertility, and specific organ damage. The most frequent complication encountered is infection. Prolonged episodes of neutropenia result in a high risk of invasive bacterial infections (especially with *Pseudomonas* and other Gram-negative bacteria, although the incidence of Gram-positive sepsis is increasing) and fungal infections (especially with *Aspergillus*). In ALL, high-dose steroids form an integral part of treatment but frequently result in infections, mood swings, and bony avascular necrosis.

In acute leukaemia patients with very high white counts, tumour lysis syndrome (TLS) is a potential complication in which biochemical disturbances caused by rapid cell death, such as hypocalcaemia, hyperkalaemia, hyperuricaemia, and hyperphosphataemia, are seen. Renal failure may ensue unless prompt action is taken. Treatment is focused on prevention by identifying at-risk patients, initiating IV fluids, and using allopurinol or rasburicase (recombinant urate oxidase). Treatment of established TLS is by correcting clinically important biochemical disturbances and possibly initiating renal dialysis.

In some patients, an allogeneic stem cell transplant is offered as part of the treatment strategy. In addition to infection, graft-vs-host disease (GvHD) is an important complication of this procedure. Acute GvHD (within 100 days of the transplant) typically causes a rash, diarrhoea, and jaundice. GvHD is also immunosuppressive and is frequently complicated by bacterial, fungal, and/or viral infections, including reactivation of CMV. Chronic GvHD (after 100 days from the transplant) can result in numerous manifestations such as mouth ulcers, sclerodermatous skin changes, pulmonary involvement, and neuropathies.

Approach to diagnosing the disease

Acute leukaemia should be considered in the following clinical situations:

- rapidly falling blood counts (more than one lineage involvement should raise suspicion further)
- a rapidly rising white-cell count with blasts seen on the blood film
- deterioration of a previously stable haematological condition (e.g. a rapidly enlarging spleen in a patient with chronic myeloid leukaemia or myelofibrosis)
- a child who is non-specifically unwell and has vague bony symptoms or signs (such as a mild limp)

Other diagnoses that should be considered

A serious underlying infection or solid tumour can cause a reactive blood picture associated with circulating immature blood cell precursors, including blast cells. This is called a 'leukaemoid reaction', and care should be taken not to diagnose acute leukaemia in these cases.

Acute viral infections such as infectious mononucleosis frequently result in atypical lymphocytes being seen on a blood film. Occasionally, these can be hard to distinguish from blast cells. A bone marrow aspirate in these cases can also be hard to distinguish from acute leukaemia. Clinicians should have a low threshold for performing a monospot test.

'Gold-standard' diagnostic test

Acute leukaemia is a disorder of the bone marrow, and accurate diagnosis requires a bone marrow biopsy; an aspirate will often suffice, although a trephine may be helpful in some situations. Morphological examination will give a diagnosis of acute leukaemia but immunophenotyping (by flow cytometry or immunohistochemistry) will allow accurate subtyping.

Acceptable diagnostic alternatives to the gold standard

In some cases (particularly when curative treatment is not appropriate), sufficient diagnostic material may be obtained from the peripheral blood. Although superseded by immunophenotyping, cytochemistry is an acceptable alternative to enable accurate subtyping.

Other relevant investigations

Other relevant investigations for acute leukaemia include:

- a full blood count: to determine the extent of bone marrow failure or leucocytosis; a blood film may or may not show circulating blast cells
- a coagulation screen: some acute leukaemias (especially acute promyelocytic leukaemia) may present with disseminated intravascular coagulation
- a blood group and antibody screen: blood transfusion is highly likely due to the disease or its treatment
- biochemistry: patients may be acutely unwell at diagnosis, with renal and/or liver impairment; renal impairment increases the risk of TLS
- serum calcium: may be elevated in a subset of patients
- inflammatory markers: may indicate an underlying infection
- viral serology including monospot: to exclude acute viral infection in the differential
- serum urate: raised levels increase the risk of TLS
- cytogenetics (preferably from a bone marrow aspirate): can provide important prognostic information from molecular testing which looks for certain genetic mutations and is also important in prognostication and in guiding subsequent disease monitoring and treatment
- septic screen, including blood cultures, chest X-ray, urinalysis
- ECG: in preparation for receiving cytotoxic chemotherapy

Prognosis and how to estimate it

When acute leukaemia is diagnosed in a patient who is unfit for potentially curative treatment, life expectancy is in the order of a few months to a few years. In younger adults with acute leukaemia, intensive chemotherapy with or without allogeneic stem cell transplantation results in 5-year survival rates of approximately 40%. In children, intensive treatment of ALL results in long-term remission rates of 80%.

In childhood ALL, a number of parameters indicate prognosis. Factors associated with a worse prognosis include:

- male sex

- age <1 or >9 years of age
- white-cell count at diagnosis of $>50 \times 10^9/l$
- CNS involvement
- certain cytogenetic findings (e.g. Philadelphia chromosome, complex karyotype, low hypodiploidy, t(4:11), t(8:14))
- poor response to initial treatment, as assessed by clearance of blasts from the bone marrow, or failure to eliminate the presence of minimal residual disease, as assessed by molecular techniques

For AML, poor prognostic factors include:

- increasing age and comorbidities
- cytogenetic features (e.g. complex karyotype, monosomy 5 or 7, abnormal 3q)
- antecedent myelodysplastic syndrome or myeloproliferative disease
- specific genetic mutations, such as internal tandem duplications involving the FLT3 gene
- poor response to initial chemotherapy

Treatment and its effectiveness

Wherever possible, patients with any malignancy should be treated within the context of a clinical trial. This is especially true in acute leukaemia, for which national clinical trials are designed to incorporate the broadest possible spectrum of patients, including childhood ALL, adult ALL, adult AML, and elderly AML.

Treatment of ALL

Treatment of ALL typically consists of three main phases:

- remission induction: this uses agents such as corticosteroids (prednisolone or dexamethasone), vincristine, asparaginase, and daunorubicin
- intensification: this involves multidrug chemotherapy regimens, including treatment directed to the CNS; agents used include cyclophosphamide, cytarabine, etoposide, and methotrexate
- maintenance: this phase of treatment lasts for 2 years in girls, and 3 years in boys; typical regimens include daily oral mercaptopurine, weekly oral methotrexate, and occasional IV vincristine

Approximately 80% of children achieve long-term remission, although the figure is much less in adults. Current clinical trials are aimed at using the technique of minimal residual disease (a genetic test which can pick up very small amounts of residual leukaemia) to identify those patients who are responding well to treatment and those that are responding poorly. Poor responders may benefit from intensification of treatment, and good responders may benefit from de-escalation.

Treatment of AML

Potentially curative treatment of AML involves one or two courses of remission induction chemotherapy followed by one or two courses of consolidation chemotherapy. In fit patients with a poor prognosis and with a suitable donor, allogeneic bone marrow transplant may form part of the consolidation. Standard induction chemotherapy generally consists of cytarabine and daunorubicin. Alternative agents include fludarabine and idarubicin.

Induction and consolidation chemotherapy is intense and associated with profound myelosuppression. Most patients have a central venous cannula (such as a Hickman line) to avoid repeated venepuncture and peripheral cannula insertion. Most patients achieve an initial remission with standard chemotherapy, although relapse remains a major problem.

Allogeneic bone marrow transplantation is the most effective strategy for prevention of relapse, as demonstrated by a number of studies. However, the treatment-related mortality of these procedures is high and limits their use to relatively young and fit patients and to those with a suitable donor. Conventional allogeneic transplants involve high-dose chemotherapy, often with total body irradiation. The intensity of the regimen limits its use to those aged under

45. More recent developments include the use of reduced-intensity conditioning transplants which utilize conditioning protocols which are better tolerated. The efficacy of these procedures relies on a graft-vs-leukaemia effect.

In patients unfit for standard chemotherapy, supportive care or low-dose cytarabine are options. The focus of clinical trials is shifting towards targeting specific types of AML, using small molecule inhibitors of deregulating cellular pathways. Alternatively, monoclonal antibodies are being used to deliver chemotherapy in a more targeted way.

287 Chronic leukaemia

Chris Bunch

Definition of the disease

Leukaemia is, in broad terms, a 'cancer of the blood'. However, this is inaccurate, as the malignant process primarily occurs outside of the bloodstream. In acute leukaemias, it occurs in the bone marrow within immature blood-forming cells. In the two forms of chronic leukaemia, leukaemogenesis occurs in two completely different cell types (and possibly even two different anatomical sites), leading to two very different forms of the disease: chronic myeloid leukaemia (CML) and chronic lymphocytic leukaemia (CLL).

CML is best thought of as a myeloproliferative disorder. It is a clonal disorder of the haematopoietic stem cell, leading to overproduction of the myeloid cells: neutrophils and their precursors, basophils and eosinophils.

CLL is best thought of as a low-grade lymphoma. It is a clonal disorder of mature B-lymphocytes (possibly memory B-cells). The site of initiation of this disorder is unclear; it could be within lymph nodes or within the bone marrow.

Aetiology of the disease

Aetiology of CML

A higher incidence of CML is associated with heavy radiation exposure but this applies to the minority of patients. CLL is the only leukaemia that is not associated with radiation exposure and it also shows the strongest degree of familial clustering, although, again, this applies to the minority.

Much is understood of the pathobiology of CML. CML was the first malignant disease in which a recurrent chromosomal translocation was described, between Chromosomes 9 and 22. This forms an abnormal derivative chromosome termed the Philadelphia chromosome. At the molecular level, this leads to the juxtaposition of the 3' end of the *c-ABL* proto-oncogene on Chromosome 9 with the 5' end of the *BCR* gene from Chromosome 22. This fusion gene is transcribed and produces a constitutively active tyrosine kinase. This protein then phosphorylates a number of substrates, leading to changes in cell proliferation, differentiation, adhesion, and survival. Interestingly, mouse models indicate that the Philadelphia chromosome is both necessary and sufficient for the development of CML. The result is an inappropriate expansion of the myeloid component of the bone marrow. This leads to an increasing white-cell count and, often, pronounced splenomegaly.

Aetiology of CLL

The pathobiology of CLL is much less well understood than that for CML. No single chromosomal aberration is found in CLL cells. However, recurrent cytogenetic changes of various types are found in up to 80% of cases, suggesting that the familiar morphology of CLL cells may represent the final state of a number of different acquired genetic anomalies. Some cytogenetic changes define specific clinical groups. For example, deletion of the short arm of 17p (which results in loss of the tumour suppressor gene *p53*) is associated with a clinically aggressive course and resistance to standard chemotherapy agents. Although CLL is a clonal disorder of B-cells, the type of B-cell giving rise to CLL remains a matter of some debate. Genetic analysis of the immunoglobulin genes shows that some cases of CLL have very few mutations affecting these genes, suggesting it has not experienced antigen and traversed the germinal centre. However, other cases show a higher burden of mutations, suggesting a post-germinal centre origin. These do not represent two clear groups, however, as there is a spectrum of mutational events affecting this gene. Also, gene expression profiling experiments suggest that the closest normal cell is actually a memory B-cell, leading some to think that this may be the cell of origin.

Typical symptoms of the disease, and less common symptoms

Symptoms of CML

CML typically presents with one or more of the following:

- systemic symptoms: anorexia, weight loss, sweats
- symptoms of splenomegaly: abdominal bloating, early satiety, haemorrhoids
- symptoms of leucostasis: breathlessness, blurred vision, priapism, confusion, seizures

Patients are usually symptomatic, although a routine blood test may also pick up the condition. It is most common to present in the chronic phase of the disease, although, occasionally, patients may present in blast crisis. Blast crisis is really a form of acute leukaemia and most commonly presents with symptoms and signs of bone marrow failure (anaemia, infections due to leucopenia, and bleeding/bruising due to thrombocytopenia).

Symptoms of CLL

CLL is much more commonly picked up incidentally from a blood test taken for an unrelated reason (40%–50% of cases). In such situations, there is usually a lymphocytosis with a normal haemoglobin and platelet count. Symptomatic patients usually complain of one or more of:

- systemic symptoms: fevers, weight loss, anorexia, night sweats
- lymphadenopathy (e.g. a lump in the neck, axilla, and/or inguinal regions)
- symptoms of bone marrow failure, especially anaemia; it should be borne in mind that CLL is associated with autoimmune haemolytic anaemia and so anaemia should not be immediately ascribed to bone marrow involvement
- symptoms of organomegaly (e.g. abdominal bloating); however, the spleen is rarely as large as that typically seen in CML

CLL is also associated with a number of autoimmune conditions and may present with one of these. Most commonly, this would be autoimmune haemolytic anaemia, although idiopathic thrombocytopenic purpura and pure red cell aplasia are also sometimes seen.

Demographics of the disease

Demographics of CML

For CML, the median age at presentation is 50–60 years of age, and the disease affects men slightly more often than it does women. The incidence is 1–2 per 100 000 per year.

Demographics of CLL

For CLL, incidence increases with age, with the median age at presentation being 60–70 years of age. Like CML, CLL affects men more than women. The annual incidence of CLL is approximately 10–20 per 100 000 per year.

Natural history and complications of the disease

Natural history and complications of CML

CML has defined phases of disease, although the natural history has been significantly altered by improvements in treatment. Most patients present with chronic phase disease, which is characterized clinically by slowly evolving symptoms and in the laboratory by a

neutrophilia and circulating immature granulocytes called myelocytes (but a relatively small number of circulating primitive cells, or blasts). Without treatment using modern tyrosine kinase inhibitors (TKIs), the risk of progressing to the accelerated or blast phase is 10% per year for the first 2 years but this rises to 30% per year thereafter. This means that a typical duration for the chronic phase before the advent of TKIs was 3–4 years.

The onset of the accelerated phase of CML is characterized by the progression of symptoms and haematological abnormalities, despite escalation of treatment. At the molecular level, there is an accumulation of additional genetic alterations and genomic instability. The accelerated phase proceeds to blast crisis, which is the accumulation of primitive cells in the bone marrow, leading to bone marrow failure. The prognosis for blast crisis remains poor.

Natural history and complications of CLL

CLL has a much less predictable clinical course than CML. Patients who are diagnosed incidentally, at a very early stage, may never progress to the point where they need treatment. However, a proportion will and, despite advances in prognostication, it is not easy to identify those with an indolent course from those with an aggressive course. In those who do progress, treatment is not curative but frequently results in a remission. CLL then becomes a relapsing and remitting illness, although the benefit obtained from treatment tends to become less the higher the number of previous treatment courses used. It is not unusual for patients with CLL to develop extremely high white-cell counts ($>300 \times 10^9/l$). However, leucostasis due to such a high count is extremely uncommon, and treatment is rarely initiated purely due to a high white-cell count.

Other well-known complications of CLL include haematological autoimmune disorders. Autoimmune haemolytic anaemia is a relatively common occurrence during the course of the disease and its incidence is increased by treatment with fludarabine monotherapy. Immune thrombocytopenic purpura is the second most common autoimmune manifestation, followed by pure red cell aplasia, whereby there is immune attack against red cell precursors, resulting in profound anaemia with low reticulocytes. It is also becoming appreciated that the incidence of solid cancers is increased in CLL, although the mechanism is unclear. Finally, infections are common in CLL, mainly due to hypogammaglobulinaemia (although bone marrow failure and drug-related immunosuppression also contribute). The most common organism involved is *Pneumococcus*.

Approach to diagnosing the disease

Diagnosing CML

In diagnosing CML, a clinical history should be taken and the examination and investigations should be performed to exclude other causes of splenomegaly with or without hepatomegaly and to search for solid malignancies, as, in a blood film test, these can sometimes produce a so-called leukaemoid picture which can be similar to that seen in CML. Specific investigations for CML should then be undertaken.

Diagnosing CLL

In diagnosing CLL, a clinical history should be taken and the examination and investigations should be performed to exclude other causes of lymphadenopathy. Specific diagnostic tests should then be performed.

Other diagnoses that should be considered

Other diagnoses that should be considered aside from CML

Other diagnoses that should be considered aside from CML include:

- myelofibrosis (another cause of massive splenomegaly in developed countries)
- a solid tumour (which can produce a 'leukaemoid' blood film appearance)
- essential thrombocythaemia (CML and essential thrombocythaemia can present with isolated thrombocythaemia)

Other diagnoses that should be considered aside from CLL

Other diagnoses that should be considered aside from CLL include:

- a solid tumour with regional lymphadenopathy (e.g. head and neck cancer causing cervical nodes)
- infections (endocarditis, TB, viral infections):
 - note that, in children, a raised lymphocyte count is never indicative of CLL, as children have a higher lymphocyte:neutrophil ratio than adults
 - pertussis is also well known to cause a very elevated lymphocyte count
- other lymphoproliferative disorders can present with a lymphocytosis (e.g. follicular lymphoma, mantle cell lymphoma)

'Gold-standard' diagnostic test

Gold-standard diagnostic test for CML

The gold-standard diagnostic tests for CML are:

- PCR for the BCR–ABL fusion gene on peripheral blood and/or bone marrow aspirate
- fluorescent in situ hybridization (FISH) for t(9;22) on peripheral blood or bone marrow aspirate

Gold-standard diagnostic test for CLL

The gold-standard diagnostic tests for CLL are:

- immunophenotyping of peripheral blood lymphocytes
- bone marrow aspirate with immunophenotyping of lymphocytes

Acceptable diagnostic alternatives to the gold standard

Acceptable diagnostic alternatives to the gold-standard test for CML

An acceptable diagnostic alternative to the gold-standard test for CML is conventional karyotyping to identify the Philadelphia chromosome.

Acceptable diagnostic alternatives to the gold-standard test for CLL

An acceptable diagnostic alternative to the gold-standard test for CML is lymph node excision or core biopsy with immunohistochemistry. This is usually not needed, as blood or bone marrow will usually give the diagnosis. Rarely, only lymph nodes are involved (a condition often called small lymphocytic lymphoma rather than CLL). In these cases, a lymph node biopsy is required.

Other relevant investigations

Other relevant investigations for CML

Other relevant investigations for CML include:

- a full blood count and a blood film:
 - patients will often be anaemic at presentation
 - blast count, basophil count, and platelet count also give an idea as to the prognosis of the disorder
- bone marrow aspirate and cytogenetic evaluation: in addition to establishing the diagnosis, cytogenetic changes in addition to t(9;22) may give prognostic information
- CT chest, abdomen, and/or pelvis **if** there is diagnostic doubt, looking for a solid tumour giving rise to a 'leukaemoid' reaction
- PCR for BCR–ABL: if not already performed to establish the diagnosis, a baseline is needed in order to monitor response to treatment
- biochemistry, including liver function tests: note that the TKIs can cause liver toxicity, so baseline readings are important

Other relevant investigations for CLL

Other relevant investigations for CML include the following:

- a full blood count and a blood film:
 - the classic blood film picture shows numerous mature lymphocytes with smear cells; while this is characteristic, it is not pathognomonic and should not be considered diagnostic

- the film may also show evidence of haemolysis (polychromasia and spherocytes)
- a direct Coombs test, a bilirubin test, a lactate dehydrogenase test, and a reticulocyte count, to look for the presence of coexisting autoimmune haemolysis
- biochemistry, including renal and liver function tests: these measurements are needed to calculate the correct doses of chemotherapy drugs to use and to monitor for side effects
- FISH (or, preferably, mutation analysis) for p53: although not required at diagnosis, it is required before treatment, as p53 deletion or mutation is strongly predictive of resistance to standard chemotherapy agents
- immunophenotyping for CD38 and Zap70: expression of these markers has been associated with a worse prognosis
- analysis of the mutational status of immunoglobulin heavy chain genes: mutated cases have a better prognosis than unmutated ones
- serum beta 2 microglobulin is raised in more aggressive disease
- CT chest, abdomen, and/or pelvis: may be helpful in cases characterized more by lymph node involvement than blood or marrow involvement (e.g. cases of small lymphocytic lymphoma)

Prognosis, and how to estimate it

Prognosis for CML

For CML, various factors at diagnosis indicate a worse prognosis, although these are less important in the era of TKI therapy. The two most commonly used prognostic scores are the Sokal score and the Hasford score. Poor prognostic factors include advancing age, increasing spleen size, raised platelet count, raised basophil count, and raised blast count. However, the most important factor is the response to treatment. Patients who respond to TKIs have an excellent prognosis. Overall, current estimates are of a 90% 5-year survival rate for a newly diagnosed patient with CML treated with TKIs. In those who respond well (defined as achieved a stable cytogenetic remission in which the t(9;22) translocation cannot be detected by FISH on bone marrow samples), the 8-year survival rate is in excess of 95%.

Prognosis for CLL

In CLL, the following factors at diagnosis confer a worse prognosis:

- deletion or mutation of the p53 gene
- an 11p deletion
- a rapid lymphocyte doubling time (less than 12 months)
- CD38 expression
- Zap70 expression
- a raised level of beta-2 microglobulin
- an unmutated immunoglobulin heavy chain gene
- advanced clinical stage (by the Rai or the Binet staging system)

Overall, the average life expectancy of a patient with CLL is in the region of 10–12 years. However, this is highly variable. A Binet stage A patient with mutated immunoglobulin heavy chains has a life expectancy of 25 years, whereas this falls to 8 years when the heavy chains are unmutated. In cases of p53 mutation or deletion, the average life expectancy is only on the order of 3 years.

Treatment and its effectiveness

Treatment for CML

The standard treatment for patients with CML is with TKIs (e.g. imatinib). This is highly effective at inducing haematological remission (normal blood count) and cytogenetic remission (no evidence of t(9;22) by FISH). In some patients, it also produces a molecular remission (no evidence of BCR-ABL on PCR testing). Drug resistance can be present at diagnosis or can evolve. Depending on the mechanism of resistance, a number of novel TKIs (e.g. dasatinib, nilotinib) remain effective in many of these cases. These drugs have transformed the outlook of CML and are generally well tolerated. Before TKIs, the life expectancy of a patient with CML was 3–5 years, unless the patient had an allogeneic bone marrow transplant. With TKIs, the 5-year survival rate is approximately 90%. However, they are not considered curative, as most patients who stop them do relapse, even when they achieved a molecular remission. TKIs also should not be taken in pregnancy; interferon is the drug of choice in this situation. The treatment of blast crisis, however, is poor and consists of high-dose chemotherapy followed by an allogeneic stem cell transplant if the patient is young and fit enough to tolerate this approach.

Treatment for CLL

Asymptomatic CLL is usually not actively treated. However, the development of symptoms or evidence suggesting critical organ involvement does warrant treatment. Treatment is in the form of chemo-immunotherapy. In younger patients with a good performance status, fludarabine and cyclophosphamide combined with rituximab is considered to be the gold-standard treatment, due to clinical trial evidence showing superior survival outcomes. In older patients, drugs such as bendamustine or chlorambucil (again, usually in combination with rituximab) may be more appropriate, due to a more favourable toxicity profile. Treatment of relapsed disease is more difficult, relying mainly on similar chemo-immunotherapy agents. In younger patients with more aggressive disease, an allogeneic stem cell transplant offers a potential cure but at relatively high risk of morbidity and mortality. In p53 mutated or deleted cases, treatment with the anti-CD52 antibody alemtuzumab followed by a stem cell transplant is considered optimal therapy. Novel agents which are being trialled include novel monoclonal antibodies (e.g. ofatumumab) and immunomodulatory drugs such as lenalidomide. Chemo-immunotherapy is not considered curative.

288 Myelodysplasia

Chris Bunch

Introduction

The myelodysplastic syndromes (or myelodysplasias) comprise a spectrum of disorders characterized by dysplastic or ineffective haemopoiesis that leads to variable anaemia, neutropenia, and thrombocytopenia. There is often a degree of red-cell macrocytosis. The majority are clonal stem cell disorders in which the abnormal clone predominates and expands only slowly over a number of years. Myelodysplasias have a tendency to develop ultimately into acute leukaemia in some patients; for this reason, they are sometimes referred to as 'preleukaemias', even though two-thirds of patients will never develop this complication.

Classifications of myelodysplasia have traditionally focused on clinical and pathological features but now take into account other prognostic features, notably cytogenetics (see Box 288.1). Additional risk classifications, including multiple scoring systems, have been used to define prognosis in myelodysplasia and to evaluate its potential for transformation to acute myeloid leukaemia. The International Prognostic Scoring System takes into account specific cytopenias, age, and cytogenetics, in addition to bone marrow morphology. It defines four risk categories, Low, Intermediate-1, Intermediate-2, and High, which indicate both survival and evolution to acute myeloid leukaemia.

General features

Myelodysplasia is mainly a disease of the elderly, and is becoming more common as the population ages. The median age at diagnosis is 70–75, and comorbidities are common and have a significant effect on prognosis. Most cases arise de novo, but myelodysplasia develops occasionally in patients who have been treated with radiation and/or cytotoxic chemotherapy for some other condition. These secondary cases occur mostly 5–10 years after the original therapy and, again, are more frequent in older patients.

The condition usually presents as a mild symptomatic, refractory anaemia or comes to light following a routine blood count. This may be normocytic but typically shows a mild macrocytosis (mean corpuscular volume, 95–110 fl) with frequent red-cell abnormalities on the blood film. There may also be mild-to-moderate thrombocytopenia and/or neutropenia. Platelets and neutrophils may also be morphologically abnormal with giant platelets and neutrophil hypogranularity with reduced nuclear lobulation. Bleeding and infection may occur in severe cases.

The marrow is usually hypercellular and shows abnormal cellular and nuclear maturation with evidence of ineffective haemopoiesis and intra-medullary cell death (i.e. dysplasia). Thus, despite apparent increased cellular activity, output of blood cells is reduced. In around 10% of cases, the marrow is hypocellular; here, there is overlap with aplastic anaemia.

An abnormal karyotype is found in at least one-half of primary cases and 85%–90% of secondary cases and generally has an adverse effect on prognosis. Over 600 different cytogenetic abnormalities have been described, although only a few occur commonly.

Box 288.1 The World Health Organization classification of myelodysplasia (2008)

Refractory cytopenia with unilineage dysplasia (RCUD)
Refractory anemia with ring sideroblasts (RARS)
Refractory cytopenia with multilineage dysplasia (RCMD)
Refractory anemia with excess blasts-1 (RAEB-1) (<5% marrow blasts)
Refractory anemia with excess blasts-2 (RAEB-2) (5–19% marrow blasts)
Myelodysplastic syndrome—unclassified (MDS-U)
MDS associated with isolated del(5q)

Reprinted from Blood, Volume 114, issue 5, Vardiman et al., The 2008 revision of the World Health Organization (WHO) classification of myeloid neoplasms and acute leukemia: rationale and important changes, pp. 937–951. Copyright (2009) World Health Organization

Translocations are rare: the commonest affect Chromosome 8 (gain), Chromosome 5 (deletion or loss), and Chromosome 7 (deletion or loss). There is a tendency for abnormalities to accumulate as the disease progresses, and complex (multiple) abnormalities carry a worse prognosis. Isolated deletion of the long arm of Chromosome 5—del(5q)—is associated with a specific form of refractory anaemia characterized by a high prevalence in elderly females and a relatively good prognosis. It is characterized by a macrocytic anaemia, a normal or high platelet count, a modest leucopenia without excess blasts in the marrow, and a particular megakaryocyte appearance.

The risk of leukaemic transformation is about 30% overall in primary myelodysplasia but much higher in secondary cases. Leukaemia occurs less often and at a later stage in the 'refractory anaemia' subgroup. Acute myeloid leukaemia arising from myelodysplasia responds very poorly to chemotherapy, and cure is realistically only feasible following allogeneic bone marrow transplantation.

Treatment is supportive in the early stages, with blood and platelet transfusion and prompt treatment of infection as required. Erythropoietin may help the anaemia in some patients. The thalidomide analogue lenalidomide has shown a beneficial effect on anaemia in ~80% of patients with del(5q) and in ~50% of other low-risk patients. Cytotoxic therapy is inappropriate (and usually harmful) in most cases unless acute leukaemia develops, and is usually unsuccessful when it does. An exception may be younger patients (less than 65 years) who have a suitable donor, in which case they should be considered for bone marrow transplantation.

289 Lymphoma

Graham Collins and Chris Bunch

Definition of the disease

Lymphoma is a cancerous disorder characterized by a clonal proliferation of lymphocytes. There are two broad categories: Hodgkin lymphoma and non-Hodgkin lymphoma (NHL), with Hodgkin lymphoma defined by the presence of Reed–Sternberg cells on histological examination of affected tissue. Within the NHLs, there are the much more common B-cell lymphomas and the uncommon T-cell lymphomas. Within the B-cell non-Hodgkin lymphomas, there are clinically aggressive (high-grade) forms and much more indolent (low-grade) forms.

Aetiology of the disease

In most cases of lymphoma, no cause can be identified. Less often, one or more of the following factors may be involved:

- infectious agents
- immunosuppression
- inflammatory conditions

Infectious agents

Infectious agents associated with lymphoma include:

- HIV
- EBV
- *Helicobacter pylori*
- other agents

HIV

HIV infection is associated with a much higher incidence of high-grade B-cell lymphomas such as diffuse large B-cell lymphoma, Burkitt's lymphoma, and primary CNS lymphoma. There is also a more moderate association with Hodgkin lymphoma. In some cases, HIV infection predisposes to co-infection with other viruses such as EBV, which are thought to be directly involved in lymphomagenesis.

EBV

EBV infection is associated with 100% of cases of endemic Burkitt lymphoma (a condition predominantly affecting African children) and around 50% of cases of Hodgkin lymphoma in developed countries. It is also linked with other types of lymphoma such as diffuse large B-cell lymphoma in the elderly, and lymphomas arising in the setting of immunosuppression such as HIV infection or following organ transplantation.

Helicobacter pylori

Infection with *Helicobacter pylori* is associated with a low-grade B-cell lymphoma called gastric MALT (mucosa-associated lymphoid tissue) lymphoma. In some cases, eradication of the infection is sufficient to cure the lymphoma.

Other agents

Human T-lymphotropic virus 1 is associated with adult T-cell leukaemia/lymphoma. Hepatitis C has been associated with some cases of splenic marginal zone lymphoma (a low-grade B-cell NHL). *Campylobacter jejuni* has been implicated in immunoproliferative small intestinal disease (otherwise known as alpha-heavy chain disease), and *Chlamydia psittaci* has been linked with ocular adnexal MALT lymphoma (although this is controversial).

Immunosuppression

Lymphoma is associated with the following immunosuppressive conditions:

- HIV infection
- immunosuppression following organ transplantation; this may lead in some cases to clonal outgrowth of EBV-infected B-cells which are no longer inhibited by the host's T-cell response, leading to post-transplant lymphoproliferative disease
- other, rare, immunosuppressive conditions (e.g. common variable immunodeficiency, X-linked lymphoproliferative syndrome, and Wiskott–Aldrich syndrome)

Inflammatory conditions

Other MALT lymphomas are associated with organ-specific autoimmune conditions such as Hashimoto's thyroiditis (which may give rise to thyroid MALT lymphoma) and Sjögren's syndrome (which may give rise to a salivary or lacrimal gland MALT lymphoma).

Typical symptoms of the disease, and less common symptoms

Lymphoma usually presents in one of two main ways:

- lymph node enlargement
- systemic symptoms

Lymph node enlargement

Lymph node enlargement may present either as a lump (if the node is superficial) or with symptoms due to compression of surrounding structures. In these cases, mediastinal nodal enlargement may present with cough, breathlessness, or superior vena cava obstruction; porta hepatis nodal enlargement may present with obstructive jaundice; and pelvic nodal enlargement may present with a deep vein thrombosis or bilateral lower limb oedema.

Systemic symptoms

Common symptoms include fatigue, anorexia, weight loss, fever, and night sweats. Pruritus is also not uncommon, and alcohol-induced pain is a rare but characteristic feature of lymphoid malignancy.

Lymphoma may, however, present in any number of ways, depending mainly on the sites of involvement. For example, involvement of the gastrointestinal tract may lead to gastrointestinal bleeding, CNS involvement may lead to headaches and focal neurological symptoms, and bone involvement may cause a pathological fracture. Less common systemic effects of lymphomas are also well documented, including a paraprotein-induced peripheral neuropathy and a nephrotic syndrome caused by unknown mechanisms.

Demographics of the disease

The incidence of lymphoma is roughly 19 per 100 000 of the population per year, representing the fifth most common form of cancer. Overall, the incidence of lymphoma increases with age. However, Hodgkin lymphoma peaks in the 20–35 age group. Lymphoma in children is uncommon but, when it occurs, it is usually either Hodgkin's lymphoma (especially in adolescents) or high-grade B-cell lymphomas. Overall, lymphoma is 50% more common in men and affects white Americans 50% more than black Americans.

Table 289.1 Natural history and response to treatment of the various broad categories of lymphoma

	Hodgkin lymphoma	Low-grade B-cell non-Hodgkin lymphoma	High-grade B-cell non-Hodgkin lymphoma	Systemic T-cell non-Hodgkin lymphoma
Disease tempo	Usually fairly rapid	Indolent	Rapid	Rapid
Life expectancy with no treatment	Months to years	Often several years	Months	Months
Cure rate with chemotherapy	>75%	<20%	50%–60%	<20%

Certain lymphoma subtypes have a strong geographical association. For example, endemic Burkitt lymphoma is found almost exclusively in equatorial Africa, whereas adult T-cell leukaemia/lymphoma is most common in Japan and the Caribbean basin. These locations are thought to provide exposure to specific etiological factors.

Natural history, and complications of the disease

Table 289.1 illustrates the fact that, although indolent, low-grade B-cell lymphomas are relatively resistant to chemotherapy, the majority of high-grade B-cell NHLs can be cured. A proportion of indolent lymphomas will, however, undergo a large-cell transformation and then behave as aggressive, high-grade lymphomas. Systemic T-cell lymphomas are usually rapidly progressive and generally respond poorly to treatment. Cutaneous T-cell lymphomas (which will not be dealt with further) often have excellent outcomes, however.

Approach to diagnosing the disease

Lymphoma should be suspected in any patient with lymphadenopathy persisting for more than 6 weeks; or with persisting systemic symptoms with no other identifiable cause (including pruritus).

In a patient suspected of having a lymphoma, the following principles of diagnosis should be adhered to:

- CT and/or PET scanning of the chest, abdomen, and pelvis may show up areas of disease that are not detected on clinical examination and may facilitate biopsy; it is also required to stage the disease
- biopsy material should, where possible, be obtained from an affected lymph node or extra-nodal mass; bone marrow biopsy is a much less sensitive technique for both diagnosing and subtyping the disease
- a biopsy should be either an excision of an affected lymph node (most preferable) or a core biopsy; fine-needle aspiration does not provide sufficient material to diagnose, or exclude, lymphoma
- blood tests are helpful in assessing prognostic factors but are rarely helpful in diagnosing lymphoma; in particular, a raised lactate dehydrogenase (LDH) is very non-specific and is in no way diagnostic of an underlying lymphoma

Other diagnoses that should be considered

Lymphoma can mimic many other diseases. In particular, when a patient presents with generalized lymphadenopathy, the following conditions should be considered:

- viral infections (e.g. EBV, CMV, HIV)
- other infections (e.g. toxoplasmosis, tuberculosis, cat scratch disease)
- generalized skin diseases (e.g. eczema, which causes dermatopathic lymphadenopathy)
- autoimmune conditions (e.g. SLE, rheumatoid arthritis, sarcoidosis)
- other malignancy (usually cause is local lymphadenopathy)
- Kikuchi's disease (necrotizing lymphadenitis)

'Gold-standard' diagnostic test

The gold-standard diagnostic test for lymphoma is an excision nodal biopsy or a core biopsy of affected tissue.

Acceptable diagnostic alternatives to the gold standard

There is really no alternative to obtaining good quality biopsy material. Occasionally, the diagnosis can be made on bone marrow trephine only but biopsy of a lymph node or extra-nodal mass is usually preferable first.

Other relevant investigations

Other relevant investigations for lymphoma include:

- a full blood count: to detect bone marrow infiltration; occasionally, lymphoma cells circulate in the blood and can be identified using flow cytometry
- biochemistry: depending on the site of involvement, lymphoma can affect many biochemical parameters
- serum LDH: a raised LDH is a poor prognostic factor
- serum protein electrophoresis: some lymphomas are associated with a paraprotein
- beta-2 microglobulin: raised levels are associated with a worse prognosis
- HIV test: some lymphomas are associated with underlying HIV infection
- CMV, EBV, and toxoplasma serology: to exclude these common infections from the differential
- antinuclear antibodies: to exclude SLE from the differential
- ECG: in preparation for receiving anthracycline-containing chemotherapy regimens
- echocardiography: if the ECG is abnormal or there is a cardiac history (to assess suitability for anthracyclines)
- chest X-ray: to detect mediastinal masses, which are not uncommon in lymphoma
- CT and/or PET of chest/abdomen/pelvis: to stage the disease
- bone marrow trephine: to stage the disease

Prognosis and how to estimate it

In NHL, prognosis is estimated by the International Prognostic Index (IPI). An individual patient scores a point for each of the following:

- age > 60
- Stage III or IV
- LDH above the upper limit of normal
- two or more extra-nodal sites
- ECOG performance status ≥ 2

Table 289.2 outlines how the final score relates to the prognosis of the commonest type of high grade B-cell NHL: diffuse large B-cell lymphoma treated with R-CHOP chemotherapy which is the gold standard chemotherapy regimen for this disease. This is called the Revised-IPI score (R-IPI) since it has been modified from the original IPI score which was published prior to the routine use of rituximab.

Table 289.2 Association of international prognostic scoring system with 5-year survival in patients with diffuse large B-cell lymphoma treated with CHOP chemotherapy

Score	Prognostic group	4 year overall survival when treated with RCHOP (%)
0	very good risk	94% 4y overall survival
1, 2	good risk	79% 4y overall survival
3, 4, 5	poor risk	55% 4y overall survival

Note: The addition of rituximab has significantly improved the 5-year survival rates in each prognostic category.

Modifications of the IPI have been used to stratify prognosis in low-grade B-cell NHLs such as follicular lymphoma and mantle cell lymphoma. In the low-grade conditions, average life expectancy is typically on the order of 12–15 years.

Treatment and its effectiveness

Treatment of Hodgkin lymphoma

Treatment is generally with combination chemotherapy regimens such as ABVD (**a**driamycin® [doxorubicin], **b**leomycin, **v**inblastine, and **d**acarbazine). Important side effects include neuropathy (from the vinblastine) and lung toxicity (from the bleomycin). Fertility is usually preserved. Adjunctive involved field radiotherapy may be used at sites of bulk disease or at extra-nodal sites. Overall long-term survival rates are in excess of 80%. Due to the high survival rates, concern has shifted to the late toxic effects of treatment. In particular, rates of heart disease and second malignancies are raised in survivors of Hodgkin's lymphoma. Efforts are being made to reduce toxicity of treatment while maintaining the excellent disease control.

Relapsed Hodgkin lymphoma is treated where possible with salvage chemotherapy (consisting of different agents from those initially used to minimize the effects of drug resistance). If the disease remains chemo-responsive, the patient usually receives high-dose chemotherapy with autologous stem cell support. This procedure enables high-dose chemotherapy to be given while minimizing the resulting period of myelosuppression. Cure rates in the relapsed setting are on the order of 40%–60%.

Treatment of high-grade B-cell NHL

The standard treatment for the commonest form of high-grade B-cell NHL is R-CHOP chemotherapy (rituximab combined with cyclophosphamide, doxorubicin, vincristine, and prednisolone). CHOP has been in use since the 1980s, and efforts to improve its efficacy have not been successful until the introduction of the anti-CD20 monoclonal antibody rituximab. The addition of rituximab to CHOP

is associated with increased overall survival rates of high-grade B-cell NHL in nearly all patient groups tested. As for Hodgkin lymphoma, involved field radiotherapy is used in some centres to sites of bulky or extra-nodal disease.

Relapsed high-grade B-cell NHL is still considered potentially curable with non-cross-reactive chemotherapy, which is often based on a platinum drug such as cisplatin. In patients who are fit enough, second remissions are then consolidated with high-dose chemotherapy combined with autologous stem cell support. If patients are not deemed fit enough to undergo this procedure, a palliative approach is frequently adopted.

Treatment of low-grade B-cell NHL

Low-grade B-cell NHL is generally considered incurable apart from in a minority of patients who can undergo an allogeneic stem cell transplant. Therefore, the aim of treatment is to keep the patient as healthy as possible for as long as possible. Initiation of treatment is only indicated for symptoms or critical organ impairment such as bone marrow failure. This means that early stage disease is often managed with a 'watch and wait' policy whereby no active treatment is given. This can be psychologically difficult for a patient who has recently been diagnosed with 'cancer'. When treatment is indicated, chemotherapy combined with rituximab is given. The chemotherapy is often in the form of CHOP or related regimens such as CVP (cyclophosphamide, vincristine, and prednisolone). As for high-grade disease, the addition of rituximab has been demonstrated to improve responses and survival.

Subsequent relapses are treated with further rounds of chemotherapy, although subsequent remissions tend to be of reducing duration. Certain interventions may prolong subsequent remissions, such as the use of high-dose chemotherapy with autologous stem cell support, the use of maintenance rituximab infusions, or the use of radioimmunotherapy (which utilizes a monoclonal antibody conjugated to a radioisotope).

T-cell NHL

Systemic T-cell lymphomas are aggressive and are associated with poor treatment outcomes (except anaplastic large-cell lymphoma associated with the expression of anaplastic lymphoma kinase). Treatment is generally with CHOP chemotherapy. Although initial responses are often seen, relapses are frequent and difficult to treat. Experimental approaches are being investigated.

290 Multiple myeloma and related conditions

Graham Collins and Chris Bunch

Definition of the disease

Multiple myeloma is a cancerous disorder of the bone marrow and arises from a clonal proliferation of plasma cells, resulting in end-organ damage (e.g. renal failure, hypercalcaemia, bone disease, and bone marrow failure). When a plasma cell clone is only detected in one site (either bony or soft tissue), it is termed a plasmacytoma. Monoclonal gammopathy of uncertain significance (MGUS) is also a clonal proliferation of plasma cells but, by definition, does not result in end-organ damage. Primary amyloidosis is dealt with in Chapter 181.

Aetiology of the disease

Cumulative exposure to ionizing radiation increases the risk of myeloma. Exposure to certain chemicals, such as dioxin and other pesticides, also increases the risk. However, in most cases, no etiological agent can be identified.

Typical symptoms of the disease, and less common symptoms

Associated symptoms are either due to the local effect of malignant plasma cells or due to the effect of the monoclonal immunoglobulin produced (see Table 290.1)

Demographics of the disease

Incidence

MGUS is relatively common, with a monoclonal paraprotein being present in 3% of those over 70. Myeloma is the second most common haematological malignancy (after non-Hodgkin's lymphoma), with an incidence in the UK of 4–5 cases per 100 000 per year.

Age

Myeloma is a disease of the elderly, with the peak incidence occurring at 65–70 years of age.

Gender difference

Myeloma is nearly twice as common in men as it is in women.

Racial variations

Myeloma is more common in African Americans than in Caucasians.

Natural history and complications of the disease

Although chemo-responsive in the majority of patients, myeloma is generally considered to be incurable. Until recently, the average life expectancy for those with myeloma was 3–4 years. The introduction of new agents which have proven activity in this condition is thought to extend life expectancy, although the follow-up has not been long enough to determine their precise impact. Complications are related to the disease process itself and the effect of treatment. Renal failure is common at presentation but less common in subsequent phases of the disease. Bone disease with or without fractures or hypercalcaemia frequently occurs with disease progression. Other particularly common complications include:

- infections:
 - myeloma is associated with immunoparesis (i.e. panhypogammaglobulinaemia) due to replacement of normal plasma cells by malignant, clonal plasma cells; this results in increased infection risk, especially with pneumonia
 - treatment is also immunosuppressive and can substantially increase risk of infection; for example, long-term, high-dose steroid treatment is associated with *Pneumocystis jiroveci*

Table 290.1 Myeloma symptoms due to the local presence of malignant plasma cells or due to monoclonal immunoglobulins produced by the malignant plasma cells

Symptoms due to the local presence of malignant plasma cells	Symptoms due to monoclonal immunoglobulins produced by malignant plasma cells
Bone disease, causing: <ul style="list-style-type: none"> • generalized osteopenia (which is in itself asymptomatic) • lytic lesions (may be asymptomatic or painful) • pathological fractures; most commonly vertebral (causing back pain) 	Renal failure (most common cause being cast nephropathy due to precipitation of light chains; can also be caused by light chain deposition disease, amyloid deposition, NSAID ingestion due to pain, or sepsis)
Bone marrow failure, causing: <ul style="list-style-type: none"> • anaemia (fatigue, shortness of breath, headaches, palpitations) • leucopenia (infections) • thrombocytopenia (bleeding) 	Amyloid deposition, causing: <ul style="list-style-type: none"> • nephrotic syndrome • heart failure • neuropathy • organomegaly
Hypercalcaemia, causing: <ul style="list-style-type: none"> • polyuria and polydipsia • constipation and abdominal pain • confusion • renal failure 	Less commonly, the monoclonal immunoglobulin may cause an autoimmune condition such as acquired von Willebrand's disease, paraprotein-associated neuropathy, or acquired C1 esterase inhibitor deficiency; these syndromes may be associated with underlying myeloma or monoclonal gammopathy of unknown significance
Immunoparesis increases susceptibility to infections, especially by encapsulated organisms such as pneumococcus	

infection, and alkylating agents frequently used in this disorder cause myelosuppression and possibly neutropenia, increasing the risk of bacterial and fungal infections

- neuropathy:
 - many of the treatments for myeloma can cause neuropathy, especially thalidomide and bortezomib
 - amyloid deposition frequently affects the nerves, causing a peripheral neuropathy, often with autonomic involvement
 - occasionally, the monoclonal immunoglobulin can possess auto-immune activity against nerve components, causing a peripheral neuropathy
- spinal cord compression:
 - due to bone disease and resulting in vertebral fracture
 - symptoms usually include back pain; weakness and paraesthesiae in the legs; and bowel and bladder dysfunction
 - urgent radiotherapy or surgical decompression is indicated
- venous thromboembolism (VTE):
 - any malignancy is associated with an increased risk of VTE; however, an additional increase in risk is observed when myeloma is treated with thalidomide or lenalidomide
 - prophylactic anticoagulation is indicated, with aspirin, heparin, or warfarin
- anaemia:
 - this is often multifactorial
 - the presence of malignant plasma cells in the bone marrow can cause a degree of myelosuppression
 - renal impairment leads to a reduced erythropoietin level, and underlying chronic infection can lead to anaemia of chronic disease

Approach to diagnosing the disease

Myeloma should be considered in the presence of the following:

- pathological fractures (especially vertebral)
- acute renal failure (especially in the context of a high or normal calcium)
- hypercalcaemia
- recurrent infections
- unexplained anaemia, with or without other cytopenias
- the finding of a serum or urine paraprotein

Other diagnoses that should be considered

The differential diagnosis for myeloma is broad and relates to the presenting features:

- bony pains: consider other malignant conditions or musculoskeletal pathologies
- hypercalcaemia: consider other malignant conditions or hyperparathyroidism
- bone marrow failure: consider other infiltrative conditions of the bone marrow, or primary bone marrow disorders
- recurrent infections: consider other causes of acquired immunodeficiency

An important differential of a paraprotein is an alternative lymphoproliferative condition such as a low-grade lymphoma. Although IgG paraproteins can be associated with myeloma or lymphomas, an IgM paraprotein is almost never associated with myeloma.

'Gold-standard' diagnostic test

Bone marrow aspirate and trephine will usually diagnose myeloma, with more than 10% plasma cells considered diagnostic in the appropriate clinical context. However, myeloma can be a patchy disease, so false negatives are not uncommon.

An isolated plasmacytoma can only be accurately diagnosed by biopsy of the affected region.

MGUS can be accurately diagnosed in patients with a small paraprotein in the absence of end-organ damage.

Acceptable diagnostic alternatives to the gold standard

A diagnosis of myeloma is highly suggestive in the presence of a significant paraprotein detected on serum protein or urine electrophoresis; note that 15%–20% of cases are associated with a urine paraprotein in the absence of a serum paraprotein.

Rarely, myeloma is not associated with a paraprotein (so-called non-secretory myeloma). In most of these cases, a monoclonal free light chain can be detected in the serum by using the Freelite assay.

Lytic lesions demonstrated on plain imaging (usually a skeletal survey) or on MRI are suggestive but other malignancies can produce similar findings.

Note that a bone scan is not an appropriate investigation, as lytic lesions usually appear as 'cold' due to the suppression of osteoblast activity by the malignant plasma cells. For similar reasons, levels of alkaline phosphatase in the bone are normal in the presence of lytic lesions, unless a fracture has occurred.

Other relevant investigations

Other relevant investigations for myeloma include:

- a full blood count: to detect bone marrow failure
- urea and electrolytes: to assess for renal impairment
- calcium: to assess for hypercalcaemia
- beta-2 microglobulin: a raised level suggests poor prognosis disease
- serum albumin: a low level suggests poor prognosis disease
- 24-hour urine collection for quantification of Bence Jones proteinuria: a baseline is required to properly assess response to treatment
- free light chain assay can detect light chain only myeloma which is otherwise missed on a serum electrophoresis
- subcutaneous fat biopsy: if amyloid is suspected
- ECG/echocardiogram: to assess for cardiac amyloid if clinically suspected
- bone marrow cytogenetics: may have prognostic significance

Prognosis, and how to estimate it

The International Staging System (ISS) for myeloma was published in 2005 and replaces the complex Durie–Salmon staging system previously in place. The ISS divides patients into three stages at presentation, based on serum albumin and beta-2 microglobulin levels. Patients with a serum albumin level ≥ 35 g/l and a beta-2 microglobulin level < 3.5 mg/l are in the most favourable prognostic group, with a median survival of 62 months, while those with a serum beta-2-microglobulin ≥ 5.5 mg/l are in the least favourable, with a median survival of 29 months.

Cytogenetics is increasingly being used to determine prognostic groups. Monosomy 13 and translocations involving Chromosome 14 are associated with a poor prognosis.

Treatment and its effectiveness

In the presence of established end-organ damage, treatment is indicated. This is usually in the form of combination chemotherapy, which frequently includes:

- a corticosteroid, such as dexamethasone or prednisolone
- an alkylating agent, such as cyclophosphamide or melphalan
- thalidomide
- bortezomib containing regimes (see below)

Thalidomide-containing regimens are associated with an increased risk of VTE, and suitable prophylaxis should be considered (usually in the form of prophylactic- or treatment-dose heparin or adjusted-dose warfarin).

In fit patients, remissions are frequently consolidated with high-dose chemotherapy with autologous stem cell support, which, in the

majority of trials, is associated with an increase in life expectancy by about 1 year. Subsequent treatments include bortezomib (a proteasome inhibitor) and lenalidomide (an immunomodulatory agent). Bortezomib containing regimens are also being used more commonly in the front line setting especially for patients with renal impairment or high risk cytogenetics. Recently, the anti-CD38 antibody daratumumab has found to have significant activity in myeloma and is likely to play a role in future treatment regimens.

Radiotherapy is indicated for localized painful disease or for spinal cord compression. Surgical decompression is also appropriate for some cases of spinal cord compression.

In young patients with a suitable donor, allogeneic stem cell transplant may be considered as a potentially curative strategy.

This procedure is, however, associated with significant morbidity and mortality.

291 Myeloproliferative disorders

Graham Collins and Chris Bunch

Definition of the disease

Myeloproliferative disorders (also called myeloproliferative neoplasms) can be defined as clonal haematopoietic disorders resulting in excess production of one or more blood cell lineage. The four main conditions are:

- primary polycythaemia, which is characterized by excess red-cell production
- essential thrombocythaemia, which is characterized by excess platelet production
- chronic myeloid leukaemia, which is characterized by excess granulocyte production
- myelofibrosis, which is characterized by excess megakaryocyte proliferation which results in a reactive fibroblast proliferation, causing marrow fibrosis and failure

Chronic myeloid leukaemia will not be discussed further in this chapter—see Chapter 287.

Aetiology of the disease

Apart from exposure to radiation, no causative factors for the myeloproliferative disorders being discussed here have been identified. However, much progress into their pathogenesis has been made in recent years. In 2005, several groups reported the finding of a mutation in the gene encoding the signalling protein JAK2 in the majority of cases of primary polycythaemia. Since then, it has also become clear that the same mutation is found in approximately 50% of cases of essential thrombocythaemia and myelofibrosis. JAK2 is normally involved in mediating a proliferative response of red-cell precursors to the binding of erythropoietin to its surface membrane receptor. The single base pair mutation (V617F) produces a constitutively active tyrosine kinase which delivers a proliferative signal to the cell irrespective of erythropoietin binding. Further work on primary polycythaemia has shown that, in almost all of the rare V617F-negative cases, a different activating JAK2 mutation is present within Exon 12 of the gene. Subsequent analysis of other candidate genes in essential thrombocythaemia has identified an activating mutation in the gene encoding the thrombopoietin receptor (MPL) to be present in about 3%–4% of mostly JAK2-negative cases. Most recently, groups have identified mutation in the last exon of the gene encoding Calreticulin as the most common mutation in Jak2 wild type and MPL negative essential thrombocythaemia and myelofibrosis. This makes it the second commonest mutation in these disorders.

Despite the progress made, many unanswered questions remain. It is unclear why an identically mutated JAK2 gene produces primary polycythaemia in some patients but essential thrombocythaemia or myelofibrosis in others. It may be to do with the cell in which the mutation first occurred, the genetic background of the patient, or the extent to which the JAK2 protein becomes activated. There is also convincing data that, in some patients, there is a pre-JAK2 event resulting in a pool of cells which would only go on to produce a myeloproliferative disorder if JAK2 becomes mutated.

Typical symptoms of the disease, and less common symptoms

In recent years, many patients are presenting with no symptoms. Rather, abnormal blood counts have been detected from blood tests taken for an unrelated reason. When symptoms do occur, they can be thought of as:

- symptoms due to a hypercatabolic state (e.g. weight loss, anorexia, night sweats, gout due to hyperuricaemia)

- symptoms due to raised red cells or platelets (e.g. pruritus (typically after a hot bath), erythromelalgia (painful discolouration of the extremities), headaches, visual disturbances, dizziness, venous or arterial thrombosis); in essential thrombocythaemia, bleeding may also occur which is thought to be due to a low level of circulating von Willebrand factor, secondary to adsorption of this factor onto the increased platelet surface area

It is important to be aware that the red cells and/or platelets being produced are not functionally normal. They are often more thrombogenic than their normal counterparts; this explains why a raised platelet count due to a reactive phenomenon almost never predisposes to thrombosis, whereas a raised platelet count due to essential thrombocythaemia certainly does.

Myelofibrosis often presents rather differently from essential thrombocythaemia or primary polycythaemia. Due to marrow fibrosis, patients often suffer symptoms from bone marrow failure, especially anaemia. Breathlessness and fatigue are common. Extra-medullary haematopoiesis causes a very large spleen which can cause symptoms such as early satiety, abdominal distension, and haemorrhoids.

Demographics of the disease

Collectively, myeloproliferative disorders are uncommon. The total incidence is approximately 3–5 in 100 000 per year. Generally, they are regarded as conditions which increase with age, although childhood cases are well recognized.

Primary polycythaemia and myelofibrosis are more common in men; essential thrombocythaemia is more common in women. The most common myeloproliferative disorder is essential thrombocythaemia, with primary polycythaemia being the next commonest, and myelofibrosis being very rare.

Natural history and complications of the disease

Primary polycythaemia, essential thrombocythaemia, and myelofibrosis are biologically related conditions. As such, they can evolve into one another. Approximately 5% of patients with an original diagnosis of essential thrombocythaemia will develop a raised red-cell count that puts them into the diagnostic category of primary polycythaemia. Although, by definition, primary polycythaemia does not formally evolve into essential thrombocythaemia, a substantial proportion of patients with primary polycythaemia will present with or subsequently develop a raised platelet count which needs treating. Myelofibrosis is thought by some as the inevitable outcome of primary polycythaemia or essential thrombocythaemia, given enough time. However, the time to myelofibrosis can be very long, meaning that only approximately 5%–10% of cases will develop clinically significant marrow fibrosis.

The most feared complication of the myeloproliferative disorders, however, is acute myeloid leukaemia. Happily, the incidence of acute myeloid leukaemia in patients with primary polycythaemia and essential thrombocythaemia is low (approximately 1%–3% lifetime risk). However, for myelofibrosis, this rises to around 20%–30%.

Approach to diagnosing the disease

For primary polycythaemia and essential thrombocythaemia, the approach to diagnosis should involve a thorough history and examination to exclude secondary causes of a high haematocrit or platelet count respectively. Specific investigations should then be performed to come up with a definitive diagnosis.

Other diagnoses that should be considered

Secondary causes for a raised haematocrit or a raised platelet count should always be considered.

Secondary causes of a raised haematocrit

Secondary causes of a raised haematocrit include:

- relative erythrocytosis due to plasma volume contraction seen with high alcohol intake, diuretic use, and stressful lifestyle factors
- absolute erythrocytosis due to appropriately raised serum erythropoietin:
 - severe lung disease with associated hypoxia
 - cyanotic congenital heart disease (e.g. tetralogy of Fallot)
 - living at a high altitude
 - sleep apnoea
- absolute erythrocytosis due to inappropriately raised serum erythropoietin:
 - renal disease: renal cell carcinoma, renal cysts, diffuse parenchymal disease, renal artery stenosis, post renal transplant
 - other tumours: Wilms' tumour, lymphoma, cerebellar haemangioblastoma, hepatoma
- absolute erythrocytosis due to other drugs:
 - androgens
- absolute erythrocytosis due to genetic conditions:
 - high-affinity haemoglobins
 - activating erythropoietin receptor mutations
 - Chuvash polycythaemia

Secondary causes of a raised platelet count

Secondary causes of a raised platelet count include:

- infections: especially occult abscess, TB
- inflammatory conditions (e.g. lupus, rheumatoid arthritis)
- underlying malignancy
- iron deficiency

Other primary haematological disorders can also present with a raised platelet count. These include the other myeloproliferative conditions, such as primary polycythaemia, chronic myeloid leukaemia, and myelofibrosis, and certain forms of myelodysplastic conditions.

'Gold-standard' diagnostic test

The finding of an activating JAK2 mutation (V617F or an Exon 12 mutation) in the context of a raised haematocrit (>0.52 in men; >0.48 in women) or raised platelet count ($\geq 450 \times 10^9/l$) is the current gold standard for diagnosis of primary polycythaemia and essential thrombocythaemia respectively. It ET and MF which are negative for Jak2, mutations in the MPL gene and Calreticulin gene can also confirm the diagnosis. For myelofibrosis, the result of a bone marrow biopsy is more crucial in the diagnosis. Findings of megakaryocytic proliferation and/or atypia plus increased marrow fibrosis in conjunction with an activating JAK2 mutation or other clonal marker is diagnostic of myelofibrosis.

Acceptable diagnostic alternatives to the gold standard

Diagnostic criteria for primary polycythaemia and essential thrombocythaemia where the JAK2 mutations is either negative or unavailable are published.

For primary polycythaemia, the first step is to prove that the raised haematocrit is due to an absolute erythrocytosis (as opposed to a relative erythrocytosis). A haematocrit of ≥ 0.60 in a man and ≥ 0.56 in a woman cannot be due to plasma volume depletion and is diagnostic of an absolute erythrocytosis. In patients with raised values less than these levels, a red-cell mass analysis has to be performed which must show a mass of $>25\%$ above predicted. Secondary causes must then be excluded and, if these patients also have a palpable spleen or a cytogenetic abnormality on bone marrow aspirate, then the diagnosis is secure. If neither of these last two conditions is met, other supportive criteria are needed, such as a raised platelet count, a raised neutrophil count, or radiological evidence of splenomegaly.

For JAK2-negative essential thrombocythaemia, which are also negative for MPL and calreticulin mutations, the first step in diagnosis is to exclude as far as possible secondary causes. These include inflammatory, infectious, or malignant conditions, iron deficiency, other myeloproliferative conditions such as primary polycythaemia, chronic myeloid leukaemia, and myelofibrosis and some cases of myelodysplastic conditions.

For myelofibrosis in the absence of a clonal marker such as an activating JAK2 mutation, the diagnosis is supported by the finding of a leucoerythroblastic blood film (in which circulating red- and white-cell precursors are observed), an increased serum lactate dehydrogenase, anaemia, and palpable splenomegaly.

Other relevant investigations

A blood film can be helpful in determining whether a high red-cell count or platelet count is primary or secondary. Features suggest of a myeloproliferative condition include marked variation in platelet size and a basophilia.

In some situations, a bone marrow trephine can provide useful evidence for a primary myeloproliferative condition.

Cytogenetic evaluation can provide evidence for myeloproliferative disorders and is also helpful in excluding other diagnoses such as the myelodysplastic syndrome known as 5q- syndrome.

The serum erythropoietin level can also sometimes be helpful in distinguishing between a primary and a secondary raised haematocrit. Primary polycythaemia is associated with a low erythropoietin level, whereas a high or inappropriately normal level can be associated with secondary causes.

An ultrasound scan of the abdomen can be helpful in detecting radiological enlargement of the spleen (a criterion for JAK2-negative primary polycythaemia diagnosis) and also to exclude renal cell carcinoma as a cause of secondary polycythaemia.

An oxygen saturation estimation and a chest X-ray may aid the diagnosis of a primary lung pathology leading to hypoxia and a raised haematocrit. Echocardiography may identify cyanotic congenital heart disease. A sleep study may be needed to diagnose sleep apnoea.

Exclusion of a secondary cause of thrombocytosis may require abdominal CT scanning in order to detect occult infection or abscess.

Prognosis and how to estimate it

For cases of primary polycythaemia and essential thrombocythaemia at diagnosis, the prognosis is excellent, although thrombotic risk is significantly raised. Life expectancy is roughly equivalent to the normal population. In the rare cases which transform to myelofibrosis or acute myeloid leukaemia, however, the prognosis is much worse. Transformation risk is increased by certain agents such as busulphan and ^{32}P . Hydroxycarbamide may be associated with a small increased risk of acute myeloid leukaemia, although this remains controversial. The platelet-lowering agent anagrelide is associated with a slightly increased risk of myelofibrosis.

In myelofibrosis, the prognosis is highly variable. Lower-risk patients have a median survival of around 12 years, whereas high-risk patients have a median survival of 2–3 years. A worse prognosis is associated with:

- age > 60
- abnormal karyotype of cytogenetic analysis
- presence of constitutional symptoms
- elevated white-cell count
- increased circulating immature precursors
- circulating blast cells

Treatment and its effectiveness

Treatment of primary polycythaemia

Reduction of the haematocrit is achieved by repeated venesections. In cases of primary polycythaemia, the target haematocrit is <0.45 . Although there is little evidence to directly support this target, it reflects the fact that patients with primary polycythaemia

are prothrombotic even when their haematocrit is in the upper end of the normal range. Recurrent venesections can lead to iron deficiency with increasing microcytosis. This, however, stabilizes the haematocrit and results in a reduction in the need for venesections. Iron supplementation should **not** be given, as this would lead to a rapid haematocrit rise, which would possibly be associated with thrombosis.

Aspirin should be given to all primary polycythaemia patients unless there is a contraindication. This practice is supported by randomized clinical trial evidence showing low-dose aspirin was associated with a reduction in thrombosis.

The platelet count should be controlled. Primary polycythaemia is often associated with thrombocytosis, which may need controlling in order to reduce thrombotic risk. This can be achieved using a gentle cytoreductive agent such as hydroxycarbamide.

In the elderly, control of the haematocrit and the platelet count can be achieved by administration of busulphan or ^{32}P . These both increase the long-term risk of acute leukaemia, which is less of a concern in the elderly.

Treatment of essential thrombocythaemia

Not all cases of essential thrombocythaemia require platelet-lowering therapy. In young patients (less than 60 years of age) with a platelet count of $<1000 \times 10^9/\text{l}$ and no history of major thrombosis or bleeding, such therapy is generally not indicated. In patients <60 years of age and with a predisposition to thrombosis or significant cardiovascular risk factors, platelet-lowering therapy may be indicated, as it may also be for patients with severe vasomotor symptoms despite antiplatelet therapy. However, there is little consensus on when to use platelet-lowering therapy in the more borderline cases. A target platelet count of $<400 \times 10^9/\text{l}$ should be used except when toxicity is a major issue. When platelet-lowering therapy is recommended, the following agents can be used:

- hydroxycarbamide
- anagrelide
- interferon alfa
- alkylating agents

Hydroxycarbamide

Hydroxycarbamide is cytoreductive and is generally well tolerated, although it may rarely cause ulceration. A raised mean corpuscular volume almost invariably occurs on this drug and is simply a reflection of its mechanism of action. Concerns have been raised over a slight increased risk of transformation to acute myeloid leukaemia. For this reason, interferon is often used initially in young patients.

Anagrelide

Anagrelide works specifically as an inhibitor of megakaryocyte proliferation and is effective at lowering platelet counts. In a randomized trial of hydroxycarbamide versus anagrelide in essential thrombocythaemia, anagrelide use was associated with a slightly increased risk of major bleeding and marrow fibrosis. However, both drugs were used with aspirin, and anagrelide is known to have an intrinsic antiplatelet effect which may account for the bleeding risk. Based on these results, anagrelide is generally used as a second- or subsequent-line agent. Palpitations are a frequent side effect, so anagrelide should be used cautiously in patients with a cardiac history.

Interferon alfa

Subcutaneous injection of interferon alfa at 3×10^6 to 6×10^6 units three times per week effectively controls platelet counts, splenomegaly, and constitutional symptoms associated with essential thrombocythaemia. However, it is expensive, inconvenient, and associated with sometimes severe side effects such as fatigue and depression. For this reason, use is usually limited to women who wish to have children, as this is considered the only safe agent to be on during pregnancy.

Alkylating agents

Alkylating agents (e.g. busulfan) may be used in the elderly. The use of these agents is associated with an increased risk of transformation to acute leukaemia and they should not be used in younger patients.

Use of antiplatelet agents in patients with essential thrombocythaemia

Antiplatelet agents should be considered in all patients with essential thrombocythaemia who have no contraindications, although no randomized controlled trials exist for the use of this therapy. Results in primary polycythaemia are generally considered to also apply to essential thrombocythaemia. Antiplatelet agents should be used with caution in those with platelet counts $>1500 \times 10^9/\text{l}$, as coexisting acquired von Willebrand's disease may greatly increase the bleeding risk.

292 Terminal care in haematological disease

Chandramouli Nagarajan

Introduction

Care of terminally ill haematology patients presents a unique challenge, due to the complexity of treatment decisions in an era of newly developing therapeutic options, and the speed of change in patients' condition from a potentially curable to a terminal phase. Terminal illness is defined as progressive disease for which curative treatment is neither possible nor appropriate and from which death is inevitable, although this may not be impending and the prognosis can vary from a few days to many months. The focus of this chapter is to try and bring together various palliative treatment options that should be made available to this cohort of patients with terminal disease.

Many forms of haematological cancers are treatable and, indeed, advances in treatment over the last two decades, such as the use of monoclonal antibodies, transfusion support, and stem cell transplantation, have made it possible to achieve cure in many types of leukaemias and lymphomas. The general principle in the treatment of most haematological malignancies is to get the disease into remission (remission induction) and then consolidate this with further treatment (chemotherapy, radiotherapy, or a stem cell transplant), either up front or when the disease relapses. Most cancers indeed go into a period of 'remission' for months to years but may relapse at any time. At this time, the disease will be reassessed (radiologically, repeat biopsies, cytogenetically as appropriate) and a decision on further treatment taken. Many young or fit elderly patients will go through further intensive or even escalated treatments with the aim of achieving a second remission but in others this may not be possible and the management has to be palliative. Some patients may go through such treatments and relapse again to reach a terminal phase either due to disease itself or due to treatment-related complications. It can be difficult to judge when to stop using intensive forms of treatment; clinicians, patients, and their families often find it difficult to acknowledge when remission induction is no longer possible. This is a complex decision that needs a careful reassessment of the patient's age, history, performance status, comorbid states, and tolerability of further available treatment options in the light of any organ dysfunction, balancing the risks of treatment against the benefits of and potential survival from the regime. The decision to change to a palliative approach may be taken too late or not at all, and persistence with aggressive treatment can cause great distress. This change in approach has to be sensitively, openly, and honestly discussed with the patient and family so that their aims and expectations are correctly set.

Management of patients during the last phase of their illness includes control of physical symptoms such as pain, nausea, and so on, as well as holistic attention to the psychosocial, cultural, spiritual, and social needs of the patient, with the aim of easing suffering and enabling dying patients to live and die with dignity, as well as offering support to their families and carers. Although much of the care is provided by palliative-care professionals, it is best delivered in an integrated multidisciplinary manner with close cooperation amongst haematologists, palliative-care doctors, nurses, psycho-oncologists, GPs, pain control teams, occupational therapists, alternative and complementary therapy practitioners, dieticians, and other clinical/primary-care support staff.

Uncontrolled symptoms in a terminally ill patient not only significantly impair the patient's quality of life but are also believed to impact on the family's subsequent resolution of grief. Hence, it is paramount to achieve symptom control by appropriate intervention (pharmacological, psychological, spiritual, etc.) and referral to specialists where symptoms prove difficult to control.

Common symptoms encountered in the terminal phase

Symptom control in terminal illness is dealt with in more detail elsewhere in this book, and the principles in terminal haematological illnesses are the same as in management of terminal care due any other malignancy.

Pain

Pain is a multidimensional symptom frequently feared by terminally ill patients, occurring in up to 75% of patients with advanced cancer. Uncontrollable pain can affect all aspects of a patient's life, impacting upon mood, family relations, social life, sleep, appetite, and so on. It is important to note that pain may not be directly related to tissue pathology, and its perception can be modified by various elements, including psychological factors.

Practically, it is useful to differentiate opioid responsive pain from opioid insensitive pain, such as neuropathic and bone pain. Management should start with simple non-opioid analgesics (e.g. NSAIDs, paracetamol), proceeding to weak opiates (e.g. codeine) and then to strong opiates (e.g. morphine, oxycodone) in accordance with the WHO analgesic ladder (see Chapter 329).

In some, management of pain in terminal illness can be complex and requires specialized assessment (e.g. pain control teams) and this ensures that most up-to-date evidence based treatments are offered. Where the oral route is not possible or dependable, syringe drivers can be used to deliver medications.

Nausea and vomiting

Nausea and vomiting are other common symptoms at the end of life, experienced by up to two-thirds of people dying of cancer. Diagnostic assessment and management are considered in detail elsewhere in this book. In addition to pharmacological measures, practical steps (e.g. well-presented, small portions of favourite foods eaten 'little and often'; cold, carbonated drinks; the avoidance of strong odours) also can help. Careful consideration of the route of anti-emetic (subcutaneous drivers) should be made when oral delivery is unreliable—such as in bowel obstruction or repeated vomiting.

Dyspnoea

The term 'dyspnoea' is defined by the American Thoracic Society as 'a subjective experience of breathing discomfort' (Rose, 1999, p. 3259). It can be a distressing symptom for dying patients. Although management depends on the cause, since further investigations to find a cause may not be appropriate, management sometimes has to be empiric. Patients with progressive haematological diseases may have bone marrow failure and resulting anaemia leading to dyspnoea and tiredness. Reversible causes of anaemia such as haematinic deficiencies must be looked for and treated. The decision to transfuse should be made on an individual basis after discussions with the patient and family, and these discussions should be regularly reviewed. The focus should be to improve symptoms and quality of life, with minimum adverse effects. It must be remembered, however, that, as the disease progresses, the degree of symptomatic improvement is likely to abate, and the increasing frequency of required transfusions may significantly impair any quality of life that the patient may have. Furthermore, transfusion is not without risks, such as circulatory overload and various transfusion reactions, to name but a few. Hence, regular discussions with patient and family must be undertaken not only to assess the response to transfusion but also to identify adverse effects on patient's quality of life.

The decision to discontinue transfusion support for a patient already on a transfusion programme is a difficult one but must be considered as a part of the management of these patients. The parameters that may guide one's decision to do so include:

- lack of symptomatic benefit from the intervention
- inability to keep up replacement with ongoing blood loss
- difficulty obtaining IV access
- difficulty in obtaining appropriate blood products due to antibodies

At each stage in the decision-making, the involvement of the patient and their family is important.

Opiates at much lower doses than are usually needed for analgesia can relieve the distress associated with dyspnoea. Oxygen is not indicated for every breathless patient and needs assessing on an individual basis. Avoidance/minimizing fluids may decrease and serve as treatment of pulmonary congestion and provide comfort. Treatment of other contributory factors like anxiety and pain can also decrease the feeling of dyspnoea. Patients with large pleural effusions should be considered for chest drains with pleurodesis.

Bleeding

Patients with bone marrow failure may have significant thrombocytopenia and, while some patients may be asymptomatic, some may have significant haemorrhagic symptoms. Prophylactic platelet transfusions in those with no bleeding symptoms are not recommended. Those with petechial rashes or minor nose or mouth bleeds can be managed with oral tranexamic acid or topical application using soaked gauze. Where patients have ongoing bleeding, platelet transfusions may be considered, to improve patient comfort and reduce distress. Patients with major haemorrhagic symptoms must be managed sensitively with appropriate sedation and analgesia as required, using dark-coloured blankets to reduce the distressing visual impact this may have on family and carers. Reassurance and explanation to patients and their families are paramount here.

Other symptoms in terminally ill patients

Fever sometimes associated with chills and sweating can occur due to cytokine release. Simple interventions like tepid sponging and using fans for cooling, as well as administering paracetamol, help relieve the distress associated with fever. NSAIDs may be used but are contraindicated in patients with renal impairment or thrombocytopenia.

Declining social and physical function due to debility and cachexia can be a source of significant discomfort to some of these patients. Reversible causes should be identified and treated (e.g. oro-mucosal candidiasis). Nutritional interventions may be indicated if appropriate, but artificial feeding is controversial and there is no evidence that it provides any comfort or clinical benefit. Families of dying patients may request this in the belief that it will provide comfort or may be due to cultural beliefs. On the other hand, cessation of eating and drinking is a normal part of dying and, by educating the families to understand this, their time and attention can be focused into providing other comforts.

Patients can become delirious due to medications, metabolic changes, infections, and so on. If an obvious reversible cause cannot be found, haloperidol at doses of 1.0–2.5 mg IV or subcutaneously can be used. Benzodiazepines are often ineffective and can potentially worsen delirium.

Psychological/emotional symptoms and their management

The recognition and discussions regarding the terminal phase of a patient's illness pose a considerable professional challenge but are

central to enable the healthcare team to provide appropriate psychological support to the patient and family. This aspect of the terminal care is complex in that it is unique to each individual, and time must be allowed for the patient and family to express their feelings, expectations, and fears so that these can be dealt with sensitively. Haematology clinical nurse specialists are often well placed to support patients and their families, having supported them through the active phase of treatment, and often already have a good relationship with patients. Regular, clear communication between the medical team and patient as well as their family is crucial.

Alternative therapies

Complementary therapies such as acupuncture, spiritual healing, herbal medicine, massage, aromatherapy, reflexology, hypnosis, and meditation have all been applied in the palliative-care setting in managing difficult symptoms. The success rate of these therapies is variable but the side-effect profile tends to be low. The last decade has seen an increase in use and provision of complementary therapies, both within the hospital settings and within hospices. Careful consideration of patient's symptoms and referral to appropriate complementary health practitioners must form a part of the terminal care of patients willing to try these therapies.

Where to manage patients in the terminal phase

There are various settings in which patients can be managed in the terminal phase of their disease and it is important to try and establish the patient's preference and work towards this if possible. Although up to 50%–70% of patients with cancer would prefer to be cared for or die at home, a lot fewer are able to achieve this for various reasons. The establishment of domiciliary palliative-care teams which are usually composed of Macmillan nurses has improved the feasibility of this goal.

Finally, hospices with inpatient facilities may be an appropriate place for some patients. Usually, these units are run by medical and nursing staff specializing in palliative care and symptom control, with high nurse-to-patient ratios. They may admit patients for symptom control, respite, or terminal care if the patient and family cannot manage at home.

Working closely with the patient and family, it is possible to explore the various options and achieve the most suitable place for patient care at the end of life.

To summarize, provision of terminal care in the haematological setting is a complex, challenging process encompassing identification of the onset of the terminal phase of the disease, communicating this to the patient and family effectively, making difficult treatment decisions about what treatments to continue and which ones to abandon, managing complex symptoms, and maintaining good communication within the multidisciplinary team to provide the best possible care to each individual. The importance of patient and family involvement in each stage of this process cannot be highlighted enough.

PART 14

Disorders of the immune system

293 Functions of the immune system

Malini Bhole

Introduction

The environment contains a whole range of pathogenic organisms and toxic substances which constantly challenge the health and well-being of human beings through a variety of pathological mechanisms. The immune system in humans has evolved to provide a defence mechanism against these microbial challenges.

The immune system is divided into two main branches, namely innate and adaptive. In addition, there are physical and chemical barriers, including skin, mucous membrane, mucous secretions, saliva, and various enzymes, and these contribute to the first line of defence against pathogens. The innate immune system provides the initial quick response for rapid recognition and elimination of pathogens, as opposed to the adaptive immune system, which has evolved to provide a more definitive and finely tuned response. The common central feature of both of these systems is the ability to distinguish between self and non-self. The recognition of non-self or 'foreign' pathogens and the subsequent immune response is orchestrated by a whole range of cells and soluble (humoral) factors in both innate and adaptive immune systems.

Components of the immune system

Innate immune system

Cells

Cells in the innate immune system include:

- neutrophils/phagocytes
- monocytes/macrophages
- dendritic cells
- mast cells
- eosinophils
- natural killer (NK) cells

Soluble factors

Soluble factors in the innate immune system include:

- complement
- cytokines
- chemokines
- toll-like receptors (TLRs)

Adaptive immune system

Cells

Cells in the adaptive immune system include:

- T-cells
- B-cells
- NK cells

Soluble factors

Soluble factors in the adaptive immune system include:

- receptors
- other surface molecules
- cytokines

Lymphoid organs

The individual components of the immune system function coherently within the structure of distinct anatomical lymphoid organs. Lymphoid organs play an important role in the development of lymphocytes and their subsequent survival. They form the site of initial lymphocyte education, as well as site of initiation of the adaptive immune responses and interaction between the cells of the innate and adaptive immune system. Lymphoid organs are divided into two groups:

- central or primary lymphoid organs, where lymphocytes are generated; these include:
 - bone marrow
 - thymus
- peripheral or secondary lymphoid organs, where adaptive responses are initiated and lymphocytes are maintained; these include:
 - lymph nodes
 - spleen
 - mucosal lymphoid tissues

Once T- and B-lymphocytes mature in the thymus and the bone marrow, respectively, they circulate through the secondary lymphoid organs in a coordinated fashion (see Figure 293.1). This movement is guided by adhesion molecules (e.g. L-selectin) and chemokine receptors which are present on the lymphocyte surface and which act as homing receptors.

Figure 293.1 The recirculation pathways of lymphocytes in a secondary lymphoid organ (in this case, the spleen). The majority of native T-cells entering the spleen from blood will leave the node immediately via efferent lymphatics (in this case, the periarteriolar lymphoid sheaths in the white pulp of the spleen). Naive T-cells that recognize a specific antigen while in the periarteriolar lymphoid sheath differentiate into effector T-cells and re-enter the circulation. B-cell recirculation follows a similar route; when B-cells, which accumulate in the follicles of the white pulp, encounter a specific antigen, they proliferate to form germinal centres; memory B-cells form a surrounding marginal zone. The red pulp of the spleen contains venous sinuses, which contain plasma cells and macrophages.

Function of the immune system: Recognition of 'non-self'

Closely integrated functioning of both innate and adaptive immune systems is required for adequate and timely host defence. Although each system plays a distinct role in host defence, there is a considerable degree of interplay and crosstalk between different components of the innate and adaptive immune system to provide efficient immune responses.

Innate immune system

The innate immune response characteristically lacks immunological memory and, as a consequence, remains unchanged even after repeated encounters with the same pathogen or antigen. Cells of the innate immune system, particularly phagocytic cells, recognize highly conserved, invariant structures that are shared across entire classes of microorganisms. These structures are called pathogen-associated molecular patterns (PAMPs) and are usually essential for the survival or pathogenicity of these organisms. Examples of PAMPs are given in Box 293.1.

PAMPs are small, conserved molecular motifs that are present in microbes. They include structures of cell walls and cell membranes or intracellular components, including nucleic acids (DNA, RNA, CpG).

The receptors that recognize PAMPs are known as pattern recognition receptors (PRRs; Figure 293.2). PRRs are expressed in

many cells, important amongst them being macrophages, dendritic cells, and B-cells. Structurally, PRRs contain several different protein domains, such as leucine-rich repeat domains, calcium-dependent lectin domains, and scavenger-receptor protein domains. Functionally, they are divided into three main classes:

- secreted PRRs:
 - these function mainly as opsonins
 - examples are complement receptors and mannan-binding lectin
- endocytic PRRs:
 - these receptors are present on the surface of macrophages
 - they mediate uptake and delivery of pathogens into lysosomes
 - examples include the macrophage mannose receptor and the macrophage scavenger receptor
- signalling PRRs:
 - these activate signal transduction pathways that induce expression of immune response genes, including pro-inflammatory cytokines
 - examples include toll-like receptors and NOD-like receptors.

In addition, NK cells, which constitute an important component of the innate immune system, recognize their targets via different sets of receptors: Fcγ receptors and killer receptors.

Fcγ receptors

Fcγ receptors are surface receptors that bind the IgG molecule. NK cells recognize target cells that have been opsonized by IgG molecules and destroy them by a process known as antibody-dependent cellular cytotoxicity.

Killer receptors

The second system of receptors that is characteristic to NK cells is composed of the killer-activating receptors and the killer-inhibitory receptors. These receptors recognize a number of different molecules, including major histocompatibility complex (MHC) Class I molecules, which are normally expressed by all nucleated cells. Expression of these surface molecules may be absent or disrupted in virally infected cells or certain malignant cells. These receptors thus play a very important role in immune surveillance and in recognition between 'self' and 'non-self'. Downstream signalling from these receptors instructs NK cells to either 'kill' or 'not kill' the target cells.

Box 293.1 Pathogen-associated molecular patterns

- bacterial lipopolysaccharides
- peptidoglycans
- lipoteichoic acid
- mannans
- heat-shock proteins
- bacterial flagellin
- bacterial DNA
- single-/double-stranded RNA
- CpG repeats

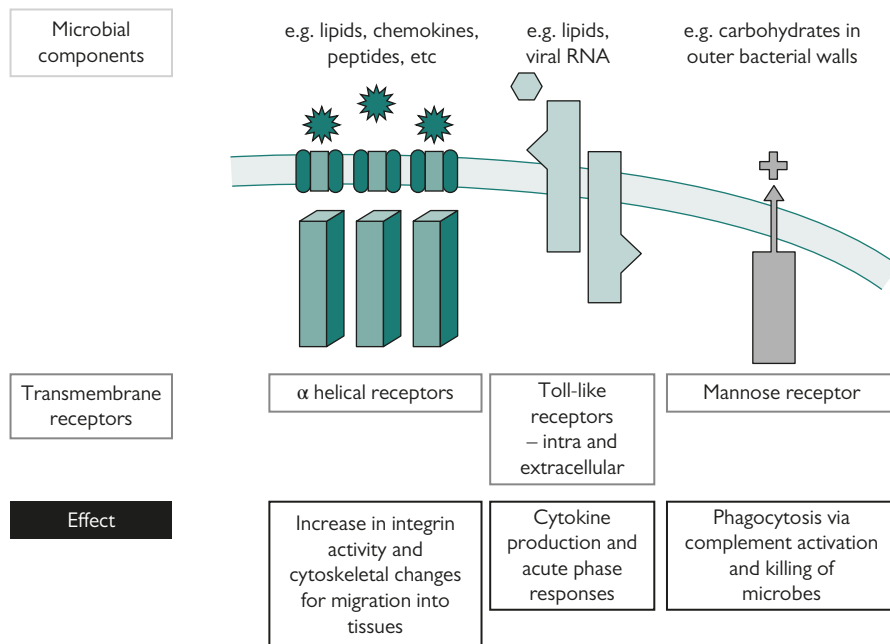

Figure 293.2 Pattern recognition receptors and their functions in mononuclear phagocytic cells.

Adaptive immune system

In contrast to the innate immune system, the adaptive immune response has evolved to provide a refined and specific immune response. The main distinguishing feature is the development of immunological memory, which enhances the subsequent response to the same antigen. The cells of the adaptive immune system, namely T-cells and B-cells, recognize specific antigenic epitopes via cell surface receptors, referred to as the T-cell receptor (TCR) and the B-cell receptor (BCR), respectively.

TCRs are membrane-bound receptors that are present on the surface of T-cells. Most TCR are heterodimers consisting of an alpha chain and a beta chain and recognize protein epitopes from pathogens that are processed and presented in relation to the MHC Class I and II by professional antigen-presenting cells (macrophages, dendritic cells, and B-cells). A small proportion of TCRs are made up of gamma and delta chains and recognize antigens either directly or in relation to MHC-like CD1 molecules; these are not discussed further in this chapter.

MHC molecules are specialized host-cell glycoproteins that bind foreign peptides and transport them to the cell surface for presentation to the host T-cells. They are encoded in a large cluster of genes. There are two classes of MHC molecules, which differ in structure, cellular expression, and function, as detailed in Table 293.1.

BCRs, on the other hand, exist in membrane-bound states on the surface of B-cells, as well as in a soluble state in the peripheral circulation. The soluble BCRs are known as immunoglobulins (Igs) or antibodies and mainly function as opsonins and/or complement activators. They exist as different isotypes with slightly variable individual properties and function, as discussed in 'Functions of the immune system: The role of individual components'.

Both TCRs and BCRs are formed by random recombination of different gene segments, each encoding for different portions of the receptor protein, and this results in the generation of a hugely variable and diverse repertoire of receptors capable of mounting a specific immune response against the large number of pathogenic epitopes that are present in the environment. It is beyond the scope of this chapter to discuss the details of receptor development.

Functions of the immune system: The role of individual components

Neutrophils

Neutrophils are derived from myeloid precursors and are the most numerous in peripheral circulation, forming an important cellular component of the innate immune system. Neutrophils are rapidly recruited to sites of infection and provide the first line of defence. Pathogens are phagocytosed and killed intracellularly via the generation of lysosomal NADPH oxidases and other enzymes in a process known as the respiratory burst. Neutrophils are short-lived cells and die after one round of phagocytosis and form a major component of pus at the site of infection.

Macrophages

Macrophages and newly recruited monocytes, which differentiate into macrophages, also function like neutrophils and destroy microorganisms by phagocytosis and intracellular killing. Once activated, macrophages produce inflammatory mediators, including tumour necrosis factor alpha, prostaglandins, and leukotrienes. Unlike neutrophils, macrophages are long-lived and continue to generate

new lysosomes and enzymes. In addition, macrophages also act as antigen-presenting cells, presenting processed pathogenic protein epitopes to T-lymphocytes in the context of the MHC Class I and Class II molecules and appropriate cytokines, which are required for the induction of adaptive immune responses.

Dendritic cells

Along with neutrophils and macrophages, dendritic cells are a type of phagocytic cell found in the innate immune system. They are distributed all over the body and are strategically located in the skin, mucous membranes, and surfaces that are exposed to the environment. On activation, dendritic cells express increased levels of MHC Class I and Class II molecules, as well as co-stimulatory molecules, and migrate to the local lymph nodes, where they function as antigen-presenting cells.

Eosinophils

The main physiological role of eosinophils is thought to be in the host defence against parasitic infections, predominantly via the release of cationic proteins, reactive oxygen metabolites, inflammatory mediators, and cytokines into the extracellular space. Their role in the delayed phase of the allergic response is being increasingly recognized.

Mast cells and basophils

Mast cells and basophils play a critical role in mounting allergic responses to innocuous environmental agents, and have a lesser role in host defence against pathogens. However, recent reviews suggest that both these cells may have a wider role in shaping the adaptive immune response, particularly with regards to autoimmune disorders. Mast cells and basophils express high affinity receptors for IgE and are coated with specific IgE following initial sensitization with allergens. The subsequent response, on repeat exposure to the allergen, is mediated by cross-linking of the cell-bound IgE molecules, leading to mast cell degranulation, which is a hallmark of allergic reactions.

NK cells

Although derived from a lymphoid lineage, NK cells lack antigen-specific receptors and are considered to be a part of the innate immune system. They circulate in peripheral blood as large lymphocytes with distinctive cytotoxic granules and play an important role in immune surveillance and destruction of virus-infected cells and tumour cells.

Complement system

The complement system is made up of a large number of distinct plasma proteins, which function as proteases and activate each other in a cascade resulting in an inflammatory immune response. Complement proteins act as a bridge between the innate and adaptive immune systems. There are three different activating pathways that initiate the complement cascades (see Figure 293.3); these are known as:

- the classical pathway
- the alternative pathway
- the mannan-binding lectin pathway

All three initiating pathways converge with the formation of C3 convertase, which in turn cleaves C3 to generate large amounts of C3b, the main effector molecule of the complement system. Subsequent effector functions and activation of the terminal

Table 293.1 MHC molecules

Characteristics	MHC Class I	MHC Class II
Structure	Two polypeptide chains; a larger alpha chain and a smaller beta-2 microglobulin chain, which is not encoded in the MHC locus	Non-covalent complex of two equal sized chains; alpha and beta chains, both encoded within the MHC locus
Cellular expression	All nucleated cells	Mainly on dendritic cells, macrophages, and B-cells
Peptide binding	Peptides from cytosolic pathogens, commonly viruses	Peptides from intra-vesicular pathogens, extracellular bacteria, and toxins
Antigen presentation	To CD8 ⁺ T-cells	To CD4 ⁺ T-cells

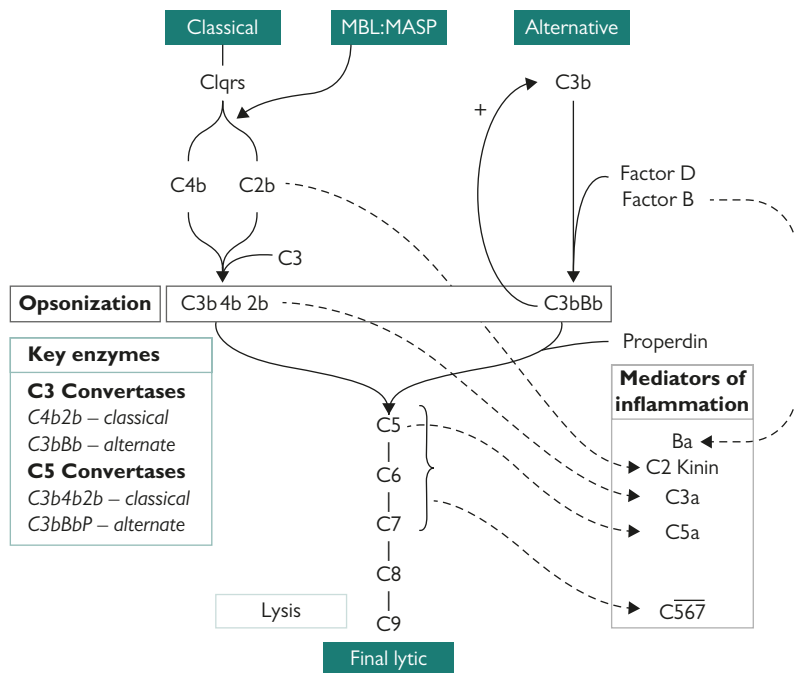

Figure 293.3 Functions of complement pathways; MASP, mannan-binding-lectin-associated serine protease; MBL, mannan-binding lectin. Reproduced with permission from Chapel, Helen, Haeney, Mansel, Misbah, Siraj, Snowden, Neil, *Essentials of Clinical Immunology*, 6th ed, Wiley-Blackwell, Oxford, UK, Copyright © 2014.

components are common to all the pathways. The three main effector functions of the complement system are:

- opsonization of pathogens and subsequent clearance of the immune complexes
- recruitment of inflammatory cells and other mediators via chemoattraction
- direct lysis and killing of pathogens via the formation of a membrane-attack complex

The clinical consequences of complement deficiency are discussed in Chapter 299.

T-cells

T-cells are mainly divided into CD4⁺ T-cells (T helper cells) or CD8⁺ T-cells (cytotoxic T-cells), based on the surface expression of CD4 or CD8 molecules, respectively. CD4⁺ T-cells recognize peptides presented by MHC Class II molecules expressed by antigen-presenting cells. In contrast, cytotoxic T-cells recognize peptides presented by MHC Class I molecules, which are expressed by all nucleated cells. T-cells are responsible for cell-mediated adaptive immune responses, and their main effector functions are:

- direct killing of virally infected cells
- destruction of intracellular pathogens by activation of macrophages
- destruction of extracellular pathogens by activation of B-cells
- epithelial and mucosal immunity

Direct killing of virally infected cells

Direct killing of virally infected cells is mediated by CD8⁺ cytotoxic T-cells, which kill infected cells either via the death receptor-dependent pathway or the perforin/granzyme-dependent pathway.

Destruction of intracellular pathogens by activations of macrophages

Destruction of intracellular pathogens by activation of macrophages is mediated by a subset of CD4⁺ T-cells known as Th1 cells (see Table 293.2). Th1 cells produce large amounts of interferon gamma (IFN γ) and activate macrophages via the IFN γ -interleukin 12 pathway, with resultant destruction of intracellular pathogens.

Destruction of extracellular pathogens via activation of B-cells

Destruction of extracellular pathogens is mediated by T-cell-dependent B-cell activation leading to opsonization and subsequent destruction of extracellular pathogens.

Epithelial and mucosal immunity

Epithelial and mucosal immunity is mediated by a recently described subset of CD4⁺ T-cells, the Th17 cells. These cells can rapidly initiate an inflammatory response which is dominated by neutrophils, and they are thought to play a significant role in maintaining immunity at epithelial and mucosal surfaces.

Table 293.2 Subsets of CD4⁺ T-cells based on cell surface receptors and cytokine profile

Subset	Surface marker*	Cytokine profile	Cellular target and function
Th1 cells	IL-12 receptor	IFN gamma	Activation of macrophages via IFN gamma-IL12 pathway and B-cells to produce opsonizing antibodies (IgG1/IgG3)
Th2 cells	IL-4 receptor	IL-4 IL-13 IL-5	Activation of B-cells to produce immunoglobulins of other classes (IgM, IgA, IgE) Activation of eosinophils and basophils
Th17 cells	IL-23 receptor	IL-17 IL-21 IL-22	Predominantly neutrophils Actively initiate inflammatory response Important role in immunity at epithelial and mucosal surfaces

Abbreviations: IL, interleukin; IFN, interferon; Th, T helper.

*These surface markers are not specific for each subset, but are characteristically co-expressed along with other cell surface markers that define the cell.

B-cells

B-cells produce different classes of antibodies or immunoglobulins (IgG, IgA, IgM, IgD, IgE) and are responsible for the humoral immune response against extracellular pathogens (see Chapter 297). The main effector mechanisms constituting humoral defence against pathogens are:

- neutralization
- opsonization
- complement fixation

Neutralization

In neutralization, antibodies neutralize extracellular pathogens and toxins by binding to them and forming immune complexes, which are subsequently cleared. Neutralization prevents bacterial adherence to target cells and cell entry.

Opsonization

In opsonization, extracellular pathogens are coated by antibody molecules facilitating ingestion by phagocytic cells (with receptors for the Fc portion of immunoglobulin molecules) and subsequent destruction.

Complement fixation

Following opsonization, antibody molecules can also activate the complement system with resultant complement-mediated destruction of the pathogen.

Antigen presentation

In addition to providing humoral defence against extracellular pathogens, B-cells also act as professional antigen-presenting cells and can

present protein epitopes to CD4⁺ T-cells in relation to MHC Class II molecules. This interaction between T-cells and B-cells results in isotype switching and affinity maturation of the B-cell response via processes known as class-switch recombination and somatic hypermutation, respectively.

Conclusion

This chapter provided a brief overview of the function of the immune system. It is clear from this that human host defence is a complex, dynamic process involving a variety of interactions between key cells of the immune system and soluble mediators acting in concert to combat infection.

It is therefore understandable that even minor defects in any arm of the immune system may have far-reaching clinical consequences. It is beyond the scope of this chapter to discuss defects in the immune system and associated diseases. This is covered to a greater extent in Chapters 294–300.

294 Clinical features and diagnosis of immunological disease

Siraj Misbah

Definition of the disease

Immunological disease can be broadly defined as a spectrum of problems ranging from failure of the immune system (primary or secondary immunodeficiency) to the clinical consequences of an overzealous immune system, manifesting clinically as autoimmunity, allergy, or, rarely, as an autoinflammatory syndrome.

Aetiology of the disease

Immunological disease is frequently a reflection of the complex interactions between genetics and environmental factors. Over 150 primary immune deficiency disorders now have clearly defined molecular bases, where environmental influences in the form of infection are responsible for disease manifestations.

For common autoimmune diseases such as SLE and rheumatoid arthritis (RA), observations on increased concordance rates in monozygotic twins have been complemented by genome-wide association studies highlighting significant contributions from a number of genes. Approximately 50% of the risk of developing RA is attributable to genetic factors, with over 30 single nucleotide polymorphisms being associated with disease susceptibility. Some susceptibility loci such as PTPN22 and STAT4 are associated with multiple autoimmune diseases, including SLE and RA. The significant female preponderance of autoimmune diseases underscores the importance of oestrogen on disease susceptibility, although its causal role remains a matter of debate.

For allergy, genome-wide association studies have identified multiple markers located at chromosomal position 17q21 and which are strong and reproducible loci associated with childhood asthma. Allied to genetic predisposition, the role of the environment in skewing immune responses has been the focus of the 'hygiene hypothesis', which states that the lack of immunological priming in childhood by way of infections may divert the immune system away from protective Th1 responses to allergy-prone Th2 responses.

Typical symptoms of the disease

Although there may be overlap in some presenting symptoms, clinical presentation of disease is best considered under the broad headings of immunodeficiency, systemic autoimmune disease, and allergy. In all of these disease categories, disease may be asymptomatic or subclinical until unmasked by a triggering event such as infection.

Immunodeficiency

Patients with immunodeficiency are particularly prone to infections whose characteristics are summarized by the mnemonic SPUR, which stands for severe, persistent, unusual, or recurrent. The pathogens causing these infections range from common ones such as *Streptococcus pneumoniae*, which is responsible for a significant proportion of the infective burden faced by patients with primary and secondary B-cell deficiency, to opportunistic pathogens such as *Pneumocystis jiroveci* in patients with T-cell defects.

In order to deal with the array of pathogens that challenge the immune system, there is a degree of immunological subspecialization that helps deal with various pathogens. This is clinically reflected in the correlation between different types of infections and underlying immunological defects (Figure 294.1).

Just as infections unmask immunodeficiency, iatrogenic disease caused by live vaccines is a strong pointer to immune system failure. Examples of vaccine-induced disease in this context include the

development of BCG vaccine-induced disease in babies with severe combined immune deficiency (SCID), and paralytic poliomyelitis in agammaglobulinaemia.

Paradoxically, some patients with B-cell immune defects are capable of mounting immune responses to self-antigens, leading to autoimmune disease manifesting as immune thrombocytopenia or autoimmune haemolytic anaemia. It is not uncommon to encounter patients who have primary antibody deficiency and present with a combination of recurrent infections and autoimmune disease.

Autoimmune disease

The presenting symptoms of autoimmune disease will depend on the extent of organ involvement. Fatigue is frequently a prominent feature of both organ-specific and systemic autoimmune disease. While in the former, fatigue may be the only symptom, as in Addison's disease and gluten-sensitive enteropathy, in the latter, fatigue may be accompanied by arthralgia, skin rashes, Raynaud's phenomenon, and pleuritic pain, as exemplified by SLE. In patients affected by lupus-overlap disorders such as mixed connective tissue disease, additional symptoms suggestive of inflammatory myositis (proximal muscle weakness), and scleroderma (skin tightening, dysphagia) may be present.

Patients afflicted with small vessel vasculitides of the Wegener's-microscopic polyangiitis spectrum frequently present with sinusitis, epistaxis, haemoptysis, and renal impairment.

Allergy

The symptoms of IgE-mediated allergic disease are influenced by the route of entry of the allergen and driven by the products of mast cell degranulation, in particular the release of histamine, leukotrienes, and platelet-activating factor. Consequently, systemic allergic reactions are characterized by urticaria, bronchospasm, hypotension, and angioedema. The rapid onset of symptoms within 30 minutes of exposure to the offending allergen is a characteristic feature of IgE-mediated allergy.

Demographics

While immunological disease affects all ages, inherited immune deficiencies predominantly present in early infancy or childhood. SCID occurs in approximately 1 in 60 000 births, and is considered an immunological emergency because of the urgency of stem cell transplantation or gene therapy. X-linked agammaglobulinaemia occurs with an incidence of 1 in 200 000, and characteristically presents after 3–6 months of age, once protective maternal IgG (acquired transplantationally) has dissipated. Common variable immunodeficiency (CVID) is estimated to occur with a frequency of 1 in 10 000 to 100 000, and is considered to be the commonest treatable immunodeficiency. A history of parental consanguinity is a common feature of many autosomal recessive immunodeficiency disorders.

For autoimmune disease, a significant female preponderance attests to the importance of female sex hormones on disease pathogenesis. Autoimmune disease affects approximately 5% of the population, with the prevalence of SLE estimated at 40 cases per 100 000 in Northern Europe.

Natural history, and complications of the disease

The natural history of immunological disease is strongly influenced by the time taken to reach a diagnosis and instigate appropriate treatment.

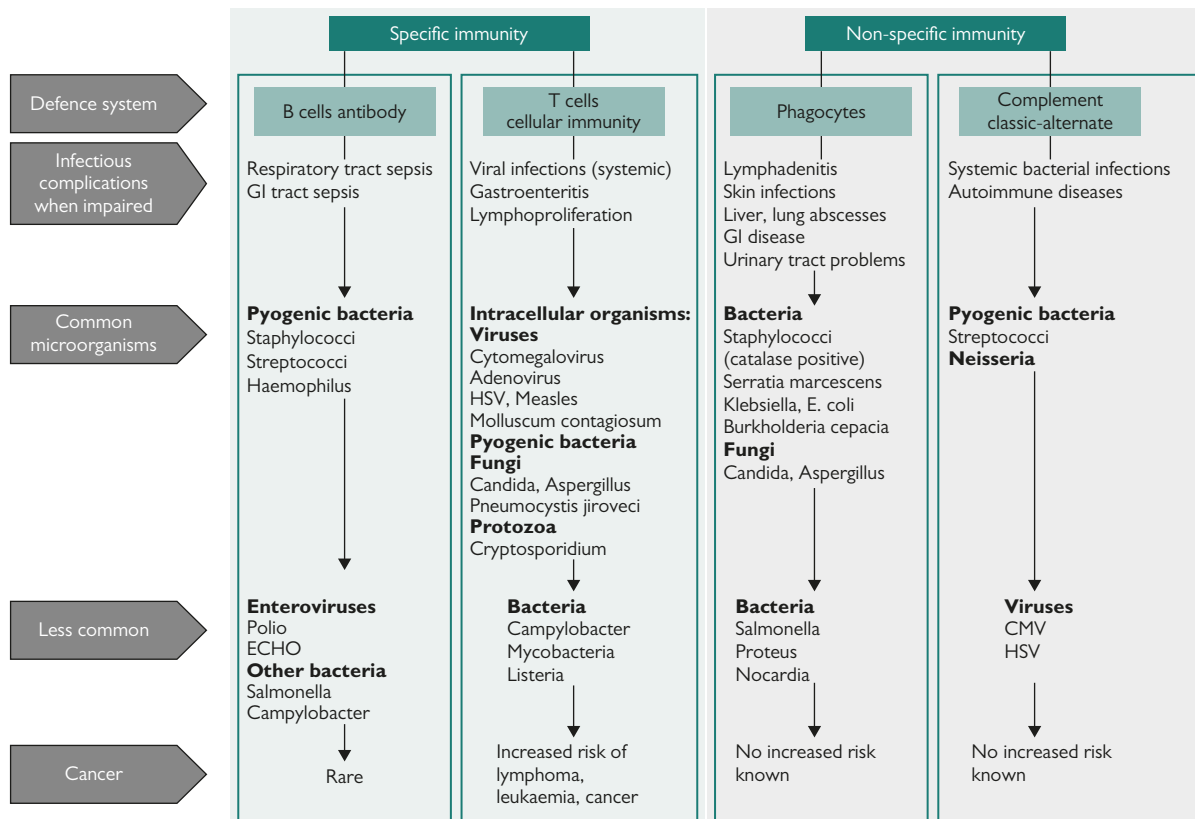

Figure 294.1 Defects in immunity suggested by infections with certain organisms; GI, gastrointestinal; HSV, herpes simplex virus.

Essentials of Clinical Immunology, Sixth edition, Helen Chapel, Maneel Haeny, Siraj Misbah and Neil Snowden. 2014. John Wiley & Sons Ltd.

Immunodeficiency

Failure to treat a baby with SCID or gene therapy results in a high mortality rate (>80%) during infancy. Conversely, successful transplantation from a HLA-matched sibling donor offers an 80% chance of cure, while fully matched unrelated transplant offers a 70% chance.

For adults with CVID, early diagnosis and instigation of adequate immunoglobulin replacement has resulted in substantial improvements in morbidity and mortality, with life expectancy only a decade below that of the normal population.

Autoimmune disease

Early diagnosis and optimal hormone replacement therapy enables most patients with organ-specific autoimmune disease such as Hashimoto's thyroiditis and Addison's disease to enjoy a virtually normal quality of life, with only a minimal reduction in life expectancy. For systemic autoimmune diseases such as SLE, prognosis is determined by the extent of renal involvement, the risk of infection associated with immunosuppressive therapy, and the increased cardiovascular mortality associated with accelerated atherosclerosis. Advances in disease management have led to significant improvements in life expectancy, with a 15-year survival rate of 80% today, in contrast to a 4-year survival rate of 50% in the 1950s.

Allergy

Identification and avoidance, wherever possible, of the offending allergen, prevents a recurrence of acute allergic reactions without any impairment in quality of life. However, occasional fatalities occur in patients with nut allergy and poorly controlled asthma, due to inadvertent ingestion of nuts leading to irreversible bronchospasm.

When to refer patients for an immunological opinion

The need for an immunological opinion or investigations will be self-evident in patients presenting with recurrent infections, symptoms

suggestive of multisystem autoimmune disease, and anaphylaxis, respectively. While immunologists will be the lead physicians in assessing patients with suspected immunodeficiency or allergic disease, patients with systemic autoimmune disease are best served by the relevant organ-based specialist working in conjunction with an immunologist.

The symptoms which merit immunological referral are detailed in 'Typical symptoms of immunological disease' and 'Differential diagnosis'. In addition, it would be worthwhile considering an immunological opinion in cases of immunodeficiency or allergy.

Immunodeficiency and autoimmunity

Failure to mount an appropriate acute phase response, despite invasive bacterial infection, is a pointer to defective innate immunity, as evidenced by patients with mutations in the IRAK4 component of the toll-like receptor pathway. Such patients fail to mount a rise in C-reactive protein levels or the erythrocyte sedimentation rate, despite having pneumococcal septicaemia.

Patients who develop recurrent infections in the setting of autoimmune disease may be thought to have impaired immunity, as a consequence of immunosuppressive therapy. While this is a frequent occurrence, it is equally possible for autoimmune disorders such as immune thrombocytopenia and autoimmune haemolytic anaemia to be the presenting manifestation of primary immunodeficiency disorders (see Chapter 297). The detection of hypogammaglobulinaemia in these patients should prompt immunological referral in such cases.

Allergy

While conventional antihistamines targeting H1 and H2 receptors will be sufficient to control symptoms in the majority of patients with chronic urticaria, a minority will have severe disease requiring high doses of multiple antihistamines coupled with steroids. These patients merit immunological assessment to explore the possibility of autoimmune urticaria or urticarial vasculitis (see 'Differential diagnosis'). Although it is recognized that the majority of patients with uncomplicated allergic problems can be adequately managed in primary care, patients with severe food, drug, or insect-venom allergy

merit specialist investigation and, where appropriate, assessment for immunotherapy.

Approach to diagnosing immunological disease

As in the rest of clinical medicine, the history is crucial in guiding the selection of investigations for the diagnosis of immunological

disease. In most patients, the history alone will suffice to suggest whether a patient should be investigated for allergy, autoimmune disease, or immunodeficiency (see 'Typical symptoms of immunological disease').

Table 294.1 summarizes the key investigations that would be useful in investigating patients with suspected immunological disease.

Disease	Key investigations	Comments
<i>Allergy</i>		
IgE-mediated allergy	Skin tests: prick and intradermal tests or specific IgE antibodies to suspected allergens	Selection of skin tests and allergen-specific IgE should be guided entirely by the clinical history Blanket screens for allergy are wasteful, and frequently lead to inappropriate management
	Total IgE	Marker of allergic diathesis, but a normal total IgE does not exclude type I allergy
	Tryptase	Sensitive marker of mast cell degranulation Useful in the assessment of suspected anaphylaxis and mastocytosis Normal tryptase does not exclude anaphylaxis
<i>Immunodeficiency</i>		
B-cell defects	Total serum immunoglobulins IgG subclasses (in selected cases) Specific antibodies to routine immunizations and common pathogens Circulating lymphocyte subsets	Hypogammaglobulinaemia associated with absent circulating B-cells is suggestive of arrested B-cell development
T-cell defects	Circulating lymphocyte surface markers Lymphocyte transformation (selected cases)	
Combined T- and B-cell defects	As for T- and B-cell defects individually	
Complement	Haemolytic complement activity of classical and alternative pathways (CH50, AP50) Quantification of individual complement components (C3, C4) and others of interest	Assesses integrity of entire complement pathway
Neutrophil defects	Dihydrorhodamine reduction CD11/CD18	Reliable screening test for suspected chronic granulomatous disease For suspected leucocyte adhesion deficiency
Defects in the TLR pathway	Assessment of pro-inflammatory cytokine release	Failure to mount an appropriate acute phase response is an important clue to TLR defects
<i>Systemic autoimmune disease</i>		
SLE	ANA followed by anti-ENA and anti-DNA Complement C3, C4 Anti-cardiolipin Lupus anticoagulant Skin biopsy (selected cases)	Negative ANA at presentation effectively excludes SLE
Scleroderma	ANA Anti-Scl 70 antibody Anticentromere antibody	Anti-Scl 70 and anticentromere antibodies tend to be mutually exclusive
<i>Vasculitides</i>		
WG-MPA spectrum of small vessel vasculitides	ANCA Tissue biopsy	cANCA is associated with antibodies to proteinase-3 pANCA is associated with antibodies to myeloperoxidase The positive predictive value of ANCA for a diagnosis of small vessel vasculitis varies from 50% to 80%, depending on the patient population ANCA is frequently found in non-vasculitic disorders
Mixed cryoglobulinaemia	Cryoglobulins Rheumatoid factor Complement C3, C4	Over 80% of patients with type II cryoglobulinaemia have a low C4 and are positive for rheumatoid factor
Inflammatory myositis	Muscle biopsy Creatinine kinase ANA Anti-Jo-1	Active myositis may be present with a normal creatinine kinase level Anti-Jo-1 (Jo-1 is a transfer RNA synthetase) is a marker of interstitial lung disease associated with dermatomyositis
Autoinflammatory syndromes	Genetic analysis to detect mutations in genes for mevalonate kinase, familial Mediterranean fever, and the tumour necrosis factor receptor	

Abbreviations: ANCA, antineutrophil cytoplasmic antibody; ANA, antinuclear antibody; cANCA, cytoplasmic antineutrophil cytoplasmic antibody; ENA, extractable nuclear antigen antibody; pANCA, perinuclear antineutrophil cytoplasmic antibody; SLE, systemic lupus erythematosus; TLR, Toll-like receptor; WG-MPA, Wegener's granulomatosis-microscopic polyangiitis.

Differential diagnosis

Given the fundamental involvement of immunological mechanisms in disease across the whole of clinical medicine, the possibility of immune-mediated disease needs to be considered in many different clinical scenarios.

Immunodeficiency

The clinical situations in which a diagnosis of various immunodeficiencies should be considered are discussed in the chapters dealing with antibody deficiency (Chapter 297), acquired T-cell deficiency (Chapter 296), combined B- and T-cell deficiencies (Chapter 298), complement deficiency (Chapter 299), and neutrophil defects (Chapter 295).

Autoimmune disease

Systemic autoimmune diseases, such as SLE and small vessel vasculitides, often feature as possible differential diagnoses in the workup of patients presenting with multisystem disease. For example, while joint pains and photosensitivity would be suggestive of SLE, other possible causes should also be considered (see Box 294.1).

If the presenting constellation of problems is widened to arthralgia, joint pains, and renal impairment, the list of differential diagnoses includes SLE, Wegener's granulomatosis, microscopic polyangiitis, mixed cryoglobulinaemia, rheumatoid vasculitis, and Henoch–Schönlein purpura.

Allergy

In the workup of patients presenting with urticaria and angioedema, occurring either singly or in combination, the possibility of allergic

Box 294.1 Causes of joint pains and rash

- SLE
- infections (e.g. parvovirus, rheumatic fever, Lyme disease)
- dermatomyositis
- psoriatic arthritis
- small vessel vasculitides

drivers (food, drugs, venom) should be considered. A significant proportion of patients (up to one-third) will be labelled as having idiopathic disease in the absence of a clear underlying diagnosis, with a small minority (<5%) having autoimmune disease due to IgG antibodies directed against IgE or the IgE receptor. In patients presenting with recurrent isolated angioedema, the possibility of C1 inhibitor deficiency, albeit rare, should be considered.

The differential diagnoses that should be considered in the workup of patients with anaphylaxis has been considered in Chapter 75.

295 Neutrophil abnormalities

Malini Bhole

Definition of the disease

Neutrophils are an important component of the innate immune system, forming the first line of defence against bacterial invasion. Abnormalities in either neutrophil numbers or function lead to immunodeficiency disorders affecting the innate immune system (see Table 295.1) with a predisposition towards developing serious and often life-threatening infections. Alterations in neutrophil numbers and function may also be noted secondary to systemic diseases, where they may act as markers for ongoing disease processes.

Most of the primary neutrophil disorders discussed in this chapter will present in childhood. In adults, acquired neutropenia is the commonest neutrophil abnormality encountered in clinical practice, although rarely, some primary neutrophil defects may present.

Aetiology of the disease

Primary immunodeficiency disorders, due to neutrophil abnormalities, result from genetic mutations affecting the development, maturation, or function of the neutrophils. The inheritance may be X linked, autosomal recessive, or autosomal dominant, as detailed in Table 295.1. Sporadic mutations, although rare, may be seen in certain conditions.

Inherited neutropenias

Neutropaenia is defined as an absolute reduction in the number of circulating neutrophils (absolute neutrophil count (ANC)) to less than $1.5 \times 10^9/l$. In primary phagocytic disorders, this results from a decrease in bone marrow storage pools, either due to decreased total marrow cellularity, arrested maturation at the promyelocyte stage, the myelocyte stage, or both.

Abnormalities of neutrophil function

Abnormalities of neutrophil function may result from genetic disorders that affect the migration of neutrophils, phagocytosis, and intracellular killing.

Acquired neutropenia

The normal ANC in an adult ranges from 1.5 to 8.0 (1500–8000/mm³). Neutropenia, defined as an abnormally low neutrophil count, is divided into mild, moderate, or severe, based on the ANC:

- mild neutropenia (ANC: 1.0–1.5): minimal risk of infection
- moderate neutropenia (ANC: 0.5–1.0) : moderate risk of infection
- severe neutropenia (ANC: <0.5): severe risk of infection

The main causes of acquired neutropenia in an adult are:

- autoimmune neutropenia
- immunosuppressive drugs and chemotherapeutic agents, used in the treatment of autoimmune disease and cancer

Typical symptoms of the disease, and less common symptoms

Patients with neutrophil defects typically manifest in infancy or early childhood, with an increased susceptibility to infections, particularly catalase-positive microorganisms and fungi. In general, these children may present with:

- malaise and lethargy
- skin infections, including cellulitis and skin abscesses
- mucosal infections, such as gingivitis, stomatitis, aphthous ulcers, and periodontitis
- respiratory tract infections, including otitis media and pneumonias
- serious infections, including septicaemia, meningitis, and deep-seated abscesses

Although rare, inherited neutrophil defects such as chronic granulomatous disease (CGD) may manifest as overwhelming aspergillus infection, associated with inhalation of aerosolized mulch or organic material, in mulch pneumonitis.

Table 295.1 Immunodeficiency disorders caused by neutrophil abnormalities

Disease	Mutation/genetic defect	Inheritance
<i>Abnormalities in neutrophil numbers</i>		
Cyclical neutropenia	ELA2	Autosomal dominant, or sporadic
Severe congenital neutropenia/Kostmann syndrome	HAX1 ELA2	Autosomal recessive or autosomal dominant
Schwachman–Diamond syndrome	SBDS	Autosomal recessive, or sporadic
<i>Defects in neutrophil migration</i>		
Leucocyte adhesion defect types 1–3	Type 1 due to mutations in INTG2	Autosomal recessive
Hyper-IgE syndrome	STAT3/TYK2	Autosomal dominant or autosomal recessive
X-linked neutropenia	WAS	X linked
<i>Defects in respiratory burst/ killing</i>		
Chronic granulomatous disease	CYBB NCF NCF2 CYBA	X linked or autosomal recessive
Myeloperoxidase deficiency	MPO	Autosomal recessive
Neutrophil glucose-6-phosphate dehydrogenase deficiency	G6PD	X linked
<i>Defects in neutrophil granules</i>		
Chédiak–Higashi syndrome	LYST	Autosomal recessive

Table 295.2 Clinical features of neutrophil disorders

Disease	Specific clinical manifestation
Cyclical neutropaenia	Periodic/cyclical fever episodes, occurring every 21 days
Schwachman–Diamond syndrome	Pancreatic insufficiency Skeletal abnormalities
Leukocyte adhesion defects	Delayed separation of cord
Hyper-IgE syndromes	Skeletal involvement Distinctive facies
Chronic granulomatous disease	Granuloma formation in both cutaneous and hollow viscera
Myeloperoxidase deficiency	Disseminated candidiasis in patients with diabetes mellitus
Neutrophil glucose-6-phosphate dehydrogenase deficiency	Haemolytic anaemia
Chédiak–Higashi syndrome	Partial ocular and cutaneous albinism Mental retardation Peripheral neuropathy
Specific granule deficiency	Bleeding diathesis

Common organisms include:

- *Staphylococcus aureus*
- *Pseudomonas/Burkholderia aeruginosa*
- *Burkholderia cepacia*
- Gram-negative enteric bacteria
- *Aspergillus* species

In addition to the common clinical features associated with neutrophil abnormalities, there are some clinical features that are typically seen in certain disorders, as detailed in Table 295.2.

Febrile neutropenia as a complication of chemotherapy

Febrile neutropenia is the development of fever, usually associated with other signs of infection, in patients with neutropenia. Febrile neutropenia and neutropenic sepsis is most commonly recognized as a complication of chemotherapy. This is a medical emergency, as the infection may progress within hours and result in shock and death. Rapid and timely recognition with prompt use of appropriate antibiotics are the mainstay of treatment. Appropriate bacterial, viral, and fungal cultures must be requested prior to antibiotic treatment.

Demographics of the disease

Inherited disorders of neutrophil numbers or function are rare, with a variable frequency ranging from 1 to 2 cases per million people for cyclic neutropaenia, to 8.5 per million live births for CGD (UK registry). Most of the inherited neutrophil disorders present in infancy and early childhood.

Natural history, and complications of the disease

The natural history and complications associated with primary neutrophil disorders depends on the underlying genetic mutation.

Cyclical neutropaenia

Patients with cyclical neutropenia develop oropharyngeal and skin infections associated with fever episodes which occur in a regular 21-day cycle.

Severe congenital neutropenia

It is estimated that about 2% of patients with severe congenital neutropenia undergo malignant transformation every year. Patients progress to develop myelodysplasia (MDS) or acute myelogenous leukaemia (AML), and this has been linked to partial or complete loss of Chromosome 7 and abnormalities in Chromosome 21.

Shwachman–Diamond syndrome

Shwachman–Diamond syndrome is associated with exocrine pancreatic insufficiency and metaphyseal dysplasia (25% of cases). Survival to adulthood has been reported in approximately 50% of patients, and up to one-third of these survivors progress to develop AML or MDS. Progression to MDS or AML has been associated with abnormalities in Chromosome 7.

CGD

Patients with the X-linked variety of CGD present in early infancy and tend to have a more severe clinical course. Autosomal recessive forms of CGD may present later in childhood and often have a milder clinical phenotype. Prior to the development of antibiotics, survival beyond childhood was unusual. The introduction of antibiotic and antifungal prophylaxis has increased the survival of patients with CGD to the fourth decade. The overall survival is still low without definitive treatment, and patients succumb to serious fungal infections or obstructive complications due to granuloma formation.

Leukocyte adhesion molecule deficiency

Leukocyte adhesion molecule deficiency may present in the neonatal period, with delayed umbilical cord separation beyond 21 days. The condition is characterized by absence of pus at infected sites, despite a pronounced peripheral blood neutrophilia. Survival beyond 5 years of age is unusual without a bone marrow transplant.

Approach to diagnosing the disease

An important approach to diagnosing neutrophil abnormalities is an accurate clinical history, and a high degree of clinical suspicion. Repeated full blood counts with differential white-cell count may detect a persistent or chronic abnormality in neutrophil numbers. Abnormally high neutrophil counts, especially in the presence of poor wound healing and lack of pus formation, must raise the suspicion of leukocyte adhesion defects. Patients with recurrent superficial or deep abscess must be investigated further for defects in innate immunity, particularly neutrophil functional defects including CGD.

Differential diagnosis

Alterations in neutrophil numbers due to secondary causes such as ongoing infections, inflammation, medications, or malignancy are more common than primary defects and form an important differential diagnosis. Bone marrow examination may be required in selected cases to rule out other causes such as aplastic anaemia, leukaemia, or malignant infiltration. Serum immunoglobulin levels must be checked to exclude other causes for recurrent infections.

The cause of acquired neutropenia in adults is usually relatively easy to diagnose since it predominantly occurs in the setting of autoimmune disease such as systemic lupus erythematosus or in conjunction with immunosuppressive drug therapy or chemotherapy.

‘Gold-standard’ diagnostic test

Detection of a known genetic mutation, associated with the particular neutrophil defect would be the gold-standard test for diagnosis. However, a strong clinical history supported by the appropriate flow cytometric tests is acceptable for a working diagnosis.

Acceptable diagnostic alternatives to the gold standard

Acceptable alternatives to support the diagnosis of a neutrophil defect would depend up on the condition that is clinically suspected; these include:

- cyclical neutropenia: demonstration of a cyclical fall in neutrophil counts every 21 days by maintaining a record of twice weekly neutrophil counts for a period of at least 6 weeks

- severe congenital neutropenia and Shwachman–Diamond syndrome: bone marrow biopsy
- CGD: abnormal dihydrorhodamine assay on flow cytometry, or abnormal nitro-blue tetrazolium test
- leucocyte adhesion defects: deficient CD11/CD18 expression on flow cytometry
- hyper-IgE syndrome: total IgE levels >5000 with clinical features suggestive of the syndrome
- X-linked neutropenia: abnormal expression of WASP protein

Other relevant investigations

Other relevant investigations would depend on the suspected condition. Screening for periodic fever syndromes would be appropriate while investigating cyclical neutropenia and, similarly, assessing pancreatic function would be appropriate for Shwachman–Diamond syndrome. Patients with suspected CGD may need relevant imaging for deep-seated abscesses or fungal infections, or endoscopy to rule out inflammatory bowel disease. Family screening is appropriate in X-linked or autosomal recessive conditions.

Prognosis and how to estimate it

The overall prognosis for neutrophil defects is poor and, for many conditions, survival beyond childhood is rare without definitive treatment. Although the use of recombinant granulocyte-colony stimulating factor (G-CSF) has significantly increased the life expectancy in severe congenital neutropenia, many of these children progress to develop AML or MDS. Similarly, improved antibiotic and antifungal prophylaxis for CGD patients has improved life

expectancy to the fourth decade, but patients still succumb to invasive aspergillus infection or complications due to granuloma formation.

Treatment and its effectiveness

The definitive treatment for many inherited neutrophil defects is bone marrow transplantation. Prophylactic antibiotic and antifungal treatments have been effective therapeutic interventions for both chronic neutropenias and functional neutrophil defects. Prompt identification and treatment of infections is essential for the management of these patients. Regular recombinant G-CSF has been used successfully in the treatment of patients with severe congenital neutropenia and Shwachman–Diamond syndrome.

Neutropenic sepsis post chemotherapy requires aggressive treatment with broad-spectrum antipseudomonal antibiotics, combined with an aminoglycoside. Appropriate bacterial, viral, and fungal cultures must be requested prior to antibiotic treatment.

296 Human immunodeficiency virus infection

Malini Bhole, Mas Chaponda, and Nick Beeching

Introduction

Since its discovery in the 1980s, infection with the human immunodeficiency virus (HIV) has rapidly spread across the world, especially to large parts of the African continent. By the end of 2013, an estimated 35 million people were living with HIV worldwide. In the UK, this figure was close to 108 000 (a prevalence of 2.8 per 1000 population aged 15–59 years (1.9 per 1000 women and 3.7 per 1000 men)).

Significant progress has been made in diagnosis, and current treatments are life-saving. However, there is still no cure and no vaccine. This chapter will predominantly concentrate on the clinical features and management of HIV infection.

Aetiology of the disease

HIV is an RNA virus with reverse transcriptase activity. There are two distinct types: HIV-1 and HIV-2. Both viruses cause similar immune defects and are associated with similar clinical disease. They originated in the chimpanzee and sooty mangabey, respectively, which carry the simian immunodeficiency virus (SIV). It is likely that HIV-1 and HIV-2 infected humans as a result of these primates being hunted for food. Theories linking the introduction of HIV into humans via polio vaccination campaigns in Africa in the 1950s have been disproved. The replicative cycle of HIV is summarized in Figure 296.1.

The virus gains entry into cells as a result of high-affinity binding of the viral envelope protein gp120 with the CD4 molecule on T-cells. In addition to the CD4 molecule, the virus uses chemokine

receptors as cofactors for cellular entry; these are CXCR4, which is expressed on T-cells (T-tropic HIV), and CCR5, which is expressed on macrophages (M-tropic HIV). Binding of gp120 to CD4 molecule and CXCR4/CCR5 allows HIV to adhere to the cell and to effect conformational change in the gp120/gp41 complex to allow membrane fusion and cell entry. Following entry, the reverse transcriptase enzyme allows transcription of double-stranded DNA from viral RNA, which integrates into the host genome. Viral protein elements are transcribed, translated, and assembled within the affected cell. The virus uses the host's lipid cell wall to form the envelope, and progeny virus is formed.

HIV disease classification and progression

Initial infection with HIV via the mucosal or parenteral route results in a high viral load (viraemia) and may be associated with a brief, acute, flu-like illness. This phase of high viral replication soon resolves to a lower 'set point' of viraemia (see Figure 296.2), which varies between patients. This is followed by a variable period of asymptomatic chronic infection, during which there is an uncontrolled proliferation of HIV within the cells of the immune system, particularly CD4⁺ T-cells. HIV infection is characterized by a profound decrease in the number of CD4⁺ T-cells, resulting in immune failure and a predisposition to infections with a wide range of pathogens and malignancies, including Kaposi's sarcoma and non-Hodgkin's lymphoma (see Table 296.1). Most untreated patients with HIV infection eventually progress to develop advanced/symptomatic HIV. The term

'acquired immune deficiency syndrome' (AIDS) was previously used to classify the medical progression or the presence of specific clinical complications. There are now much better measures of diseases progression, and it is more common to refer to advanced/symptomatic HIV disease.

A small minority of HIV-infected patients (<0.5%) remain clinically well without needing antiretroviral therapy after 20 years or more of infection. These patients are known as 'long-term non-progressors'

(LTNPs) or 'elite controllers' and are defined on the basis of remaining healthy with CD4 counts exceeding 500×10^6 cells/l for 10 or more years and having a very low viral load without antiretroviral treatment. The low level of viral replication in the LTNP group has been attributed to a combination of host genetic factors that prevent HIV from gaining entry to host CD4⁺ T-cells, changes in the host immune response, and, very rarely, infection with attenuated or defective virus.

Table 296.1 Principal complications of untreated HIV infection

Infections	Neoplasms	Direct HIV effects
<i>Early/intermediate HIV infection (CD4 >200x10⁶ cells/l)</i>		
Varicella zoster (shingles)	Non-Hodgkin's lymphoma ^a	Persistent generalized lymphadenopathy
Oral hairy leucoplakia	Cervical intraepithelial neoplasia	Atopy; eczema
Oral candidiasis; candidal vaginitis	Anal intraepithelial neoplasia	Recurrent aphthous ulcers (oral and gastrointestinal tract)
Pulmonary tuberculosis ^a		Immune thrombocytopenia
Bacterial pneumonia, especially pneumococcal		Neutropenia
Bacteraemia, especially pneumococcal and salmonella		Neuropathy (mononeuritis multiplex; Guillain-Barré syndrome)
Bacillary angiomatosis		HIV-associated nephropathy (HIVAN)
		Lymphocytic interstitial pneumonitis (LIP)
<i>Late HIV infection (CD4 <200x10⁶ cells/l)</i>		
Pneumocystis pneumonia ^a	Kaposi's sarcoma ^a	HIV enteropathy
Candidal oesophagitis ^a	Primary cerebral lymphoma ^a	Peripheral neuropathy (distal, axonal)
Cerebral toxoplasmosis ^a	Hodgkin's lymphoma	Autonomic neuropathy
Cryptococcal meningitis ^a	Conjunctival carcinoma	Myelopathy
Chronic cryptosporidial diarrhoea ^a	Cervical carcinoma ^a	HIV dementia ^a
Chronic cystoisosporiasis ^a , microsporidiosis	Anal carcinoma	Wasting syndrome ^a
Chronic HSV ^a ulceration		Cardiomyopathy
Extrapulmonary tuberculosis ^a		
Disseminated <i>M. avium</i> complex (MAC) ^a		
CMV (retinitis and disseminated) ^a		
Progressive multifocal leucoencephalopathy ^a		
Recurrent bacterial pneumonia ^a		
Recurrent bacteraemia, especially salmonella ^a		
Disseminated histoplasmosis ^a , and <i>Talaromyces (Penicillium) marneffei</i>		

^a AIDS-defining conditions; incomplete list.

Many of the early/intermediate manifestations also occur in late-stage HIV disease; non-Hodgkin's lymphoma is more common during the later stages.

Immunopathogenesis

The primary immunological effect of HIV infection is the dramatic depletion of CD4⁺ T-cells. Emerging concepts regarding the immune pathogenesis of HIV infection and the development of AIDS suggest that chronic systemic immune activation is an important feature of progressive HIV infection and differentiates it from non-pathogenic SIV infection in primates. Immune activation is seen in both CD4⁺/CD8⁺ T-cells and B-cells, which are polyclonally activated. T-cell proliferation is beneficial in the early stages of the disease, with partial restoration of CD4⁺ T-cell numbers, but sustained rapid turnover of immune cells imposes a strain on the homeostatic mechanism, resulting in a shorter cell half-life and clonal exhaustion. In addition, activated T-cells are targets for the virus itself, and this allows further replication of the virus, and the infection of more immune cells. Cytotoxic CD8⁺ T-cells only partially limit (but do not stop) viral replication, and neutralizing antibodies have little effect on viral replication. Thus, the clinical manifestations of the disease depend on the balance and interplay between host immune activation and viral replication. Clonal exhaustion leads to the progressive depletion of immune cells, as well as their loss of function, resulting in an immunodeficiency syndrome (AIDS).

Risk factors and transmission

HIV can affect both sexes equally and affects people of all ages. The virus is transmitted via blood and body fluids amongst adults. It is also transmitted vertically via maternofetal transfer and through breast milk. Although widespread across the world, endemicity is variable, with the highest rates in parts of Africa and increasing rapidly in Asia. Screening of blood donors for HIV has greatly reduced the chance of HIV transmission through transfusion. There is a small risk to health-care workers exposed to HIV-infected blood through needle stick injury (about 0.3% for a high-risk deep needle stick injury); this figure is probably much lower if the health worker takes post-exposure prophylaxis very soon after the injury.

Staging of disease

As immunodeficiency progresses, there is an increased susceptibility to a variety of fungal, viral, bacterial, and protozoal infections. The absolute CD4 count is a useful way of staging HIV infection. The disease manifestations and susceptibility are inversely proportional to the absolute CD4⁺ T-cell levels, as shown in Figure 296.2. A count of <200 × 10⁶ cells/l indicates advanced immunosuppression (previously referred to as AIDS) and renders a patient susceptible to a wide range of opportunistic infections. The most common invasive pathogens occurring at any stage of infection are *Mycobacterium tuberculosis*, *Streptococcus pneumoniae*, and non-typhi *Salmonellae*. There is early increase in frequency and severity of mucosal and skin infections with pathogens such as herpes simplex, varicella zoster, candida, and dermatophytes, and bacteria such as staphylococci.

Clinical suspicion and triggers for testing

The availability of effective antiretroviral agents has increased the importance of early diagnosis. This requires a high index of clinical suspicion, to recognize early disease during seroconversion, and awareness of high-risk groups and high-risk behaviour patterns predisposing to HIV infections. Early recognition allows for prompt therapeutic interventions, including disease monitoring and treatment, which dramatically improve patient survival and quality of life and reduce infectivity to others. This is not only beneficial for the individual patient, but also has implications for wider public health.

Historically, HIV testing has been the subject of much political debate, with excessive emphasis on the need for protracted 'counselling' of individuals perceived to be at risk due to lifestyle or other factors. However, HIV infection is now recognized to be a treatable infection that all may contract, and all healthcare workers should be capable of offering the test routinely in any healthcare setting. HIV testing in the UK is now recommended for specific groups with identifiable behavioural risks, and for all patients with medical conditions

that are more common or more severe in HIV-positive individuals (see Box 296.1). The presence of any of these should prompt the clinician to suggest that an HIV test be performed. Universal HIV testing is recommended in all antenatal services; genitourinary medicine or sexual health services; abortion services; and drug dependency

Box 296.1 Clinical indicator diseases for adult HIV infection; patients with the following specific indicator conditions should be routinely offered an HIV test

Respiratory

- aspergillosis
- bacterial pneumonia
- pneumocystis pneumonia
- tuberculosis

Gastroenterology

- chronic diarrhoea of unknown cause
- cryptosporidiosis
- hepatitis B infection
- hepatitis C infection
- oesophageal candidiasis
- oral hairy leucoplakia
- persistent oral candidiasis
- proven salmonella, shigella, or campylobacter infection
- weight loss of unknown cause

Neurology

- cerebral toxoplasmosis
- cryptococcal meningitis
- dementia
- Guillain-Barré syndrome
- leucoencephalopathy
- primary CNS lymphoma
- transverse myelitis

Dermatology

- Kaposi's sarcoma
- severe acne
- severe psoriasis
- severe seborrhoeic dermatitis
- varicella zoster especially recurrent or multidermatomal presentations

ENT

- chronic parotitis
- lymphadenopathy of unknown cause
- parotid cysts

Haematology

- unexplained lymphopenia
- unexplained neutropenia
- unexplained thrombocytopenia

Oncology

- anal intraepithelial neoplasia
- Castleman's disease
- Hodgkin's disease
- lung cancer
- non-Hodgkin's lymphoma
- seminoma

Gynaecology

- cervical cancer
- vaginal intraepithelial neoplasia

Ophthalmology

- cytomegalovirus retinitis
- infective retinal diseases, including herpes virus infection
- toxoplasmosis

Other

- any sexually transmitted infection
- mononucleosis-type syndrome
- pyrexia of unknown origin

programmes. In some parts of the UK with a higher prevalence of HIV in the adult population (>2/1000), all patients presenting for hospital admission should be offered testing.

Evidence suggests that requesting HIV testing on a routine or opt-out basis is easier for healthcare workers and acceptable to patients, as it is perceived as non-judgemental. Although risk should be discussed without prejudgement, it is appropriate to offer the test to anyone who might be at risk. Those considered at risk include men who have had sex with men; female sexual contacts of men who have sex with men; persons from an area with high prevalence of HIV; those who have had multiple sexual partners, a history of sexually transmitted infection, or of injecting drug use; those having been raped; those having had blood transfusions, transplants, or other risk-prone procedures in countries without rigorous procedures for HIV screening; and those who may have had an occupational exposure.

Verbal consent for testing should be recorded in the case notes, and specific arrangements should be agreed on how the result will be given to the patient and who may know about the result. For the small number of people who feel challenged by being asked to have an HIV test, local infectious disease or genitourinary medicine specialists (usually nurses/counsellors/health advisers) can assist. Before giving a patient a positive or equivocal result (always in person, never over the telephone), make arrangements for immediate review by a specialist healthcare worker experienced in HIV.

The most widely used tests identify specific anti-HIV antibodies in blood or saliva. This is done by laboratory ELISA testing. The WHO no longer recommends Western blotting for confirmation, suggesting instead that, if it is necessary, the combination of ELISA with a simple or rapid assay is as reliable. Antibodies to HIV typically appear 4–6 weeks after infection, but this may occasionally take as long as 12 weeks. During acute HIV infection, also known as the seroconversion or ‘window’ period, antibody tests may be negative, weakly positive, or discordant. The CD4 cell count should not be used as a surrogate marker for the diagnosis of HIV infection.

Clinical staging depends on the presence or absence of complications of immunosuppression, and simple laboratory parameters, particularly the full blood count and CD4 cell count. Response to treatment is evaluated primarily by the response of the plasma HIV viral load to therapy and secondarily by the rise in CD4 count following treatment.

Principles of treatment

There is currently no cure or successful vaccine for HIV infection. Current treatment for HIV infection consists of highly active antiretroviral therapy (HAART). The only effective prevention is to take appropriate measures to avoid primary infection. Interventions

supporting safer sex and improving knowledge of HIV and transmission risk have had some success.

Over 20 antiretroviral drugs are licensed for clinical use as antiretroviral therapy (ART). The WHO now recommends that most patients should receive ART when HIV is diagnosed, irrespective of the presence or absence of symptoms or the CD4 cell count, as this prevents the immune system from deteriorating to a point where the individual becomes very susceptible to infections. It also greatly reduces the risk of onward transmission of HIV to others. Since its introduction in 1996, HAART has dramatically reduced patient mortality. The preferred options are combinations containing at least two or three different classes of antiretroviral agents, namely nucleoside analogue reverse transcriptase inhibitors, protease inhibitors, and non-nucleoside analogue reverse transcriptase inhibitors. Newer classes of drugs include CCR5 inhibitors, integrase inhibitors, and fusion inhibitors (see Table 296.2).

Treatment with HAART reduces HIV-associated morbidity, mortality, and infectivity to others. Many antiretroviral drugs are safe to use during pregnancy, to prevent mother-to-child transmission. However, the HIV viral load rises on discontinuation of treatment, and resistance to medication develops, so the clinical effectiveness in suppressing HIV viraemia falls dramatically if patient adherence is less than 90%. Much of the clinic follow-up of patients with HIV is aimed at supporting adherence to ART. Adherence is maximized by altering the daily lifestyle around medication times, minimizing the pill burden by using once-daily combinations of as few pills as possible, and tailoring therapy to minimize side effects. This is one of the areas in which the specialist multidisciplinary team have much to offer in the care of people with HIV.

Some antiretroviral drugs have profound effects on metabolism and have many side effects. These include hypersensitivity, hyperlipidaemia, lipodystrophy, renal impairment, renal stones, insulin resistance, peripheral neuropathy, bone marrow suppression, lactic acidosis, and hepatotoxicity.

Post-exposure prophylaxis following accidental occupational or sexual HIV exposure should be universally available and is about 80% effective in reducing transmission. When prescribing post-exposure prophylaxis after occupational exposure, local protocols should be followed. Following an injury, the wound should be washed and encouraged to bleed. The source patient and the healthcare worker should be tested for HIV but, if the test is not immediately available, there should be no delay in giving prophylaxis, which is only effective if initiated within 72 hours, and preferably within 4 hours of the exposure.

Pre-exposure prophylaxis (PrEP) is available in some countries, including the UK, for HIV negative individuals who identify themselves as having a high risk for acquiring HIV infection.

Table 296.2 Principal antiretroviral agents

Nucleoside reverse transcriptase inhibitors	Non-nucleoside reverse transcriptase inhibitors	Protease inhibitors	Entry inhibitors
Zidovudine	Nevirapine	Lopinavir ^a	<i>Fusion inhibitor</i>
Lamivudine	Efavirenz	Ritonavir	Enfuvirtide (T20)
Emtricitabine	Etravirine	Atazanavir ^a	
	Rilpivirine

Immune reconstitution inflammatory syndrome

Immune reconstitution inflammatory syndrome (IRIS) occurs in a proportion of HIV patients (10%–30%) after introduction of ART. This is thought to be due to the restoration of the host immune system to mount an inflammatory response following treatment and may result from a dysregulated balance between the number and function of T-cells, pro-inflammatory cytokines, and T-regulatory cells.

The factors associated with an increased risk of developing IRIS are:

- low CD4 cell count at the start of ART
- good virological response to ART (>2 log drop in plasma HIV viral load within 90 days)
- preexisting antigenic burden of opportunistic infection prior to starting ART
- early initiation of ART after opportunistic infection

The clinical manifestations are varied and are predominantly driven by the type of underlying opportunistic infection prior to starting ART. There is no diagnostic test for IRIS. Early initiation of ART prior to the development of significant immunosuppression and opportunistic infection may reduce the risk of development of IRIS. The suggested approaches for the treatment of IRIS, either as monotherapy or in combination, include:

- use of corticosteroids or NSAIDs
- pathogen-specific treatment (e.g. antituberculous treatment)

Prognosis and how to estimate it

In the absence of HAART, the median time from infection with HIV to progression to advanced symptoms is about 10 years, and

median survival after diagnosis of AIDS is less than 1 year. The range is wide: poor prognostic indicators include low CD4 count at diagnosis, male gender, age >40, and concurrent morbidities. The use of HAART has increased the life expectancy of a newly diagnosed individual by at least two decades, as evidenced by the survival of patients diagnosed in the late 1980s and early 1990s. However, together with increasing survival, there is an increased incidence of complications such as lymphoma, other cancers (e.g. lung, cervix), and non-infectious comorbidities (e.g. renal disease, myocardial disease, and metabolic syndromes). People with diagnosed HIV infection should follow safer sex and safer drug use practices. Delays in diagnosis can increase transmission of HIV and lead to decreased life expectancy, death, and increased morbidity.

297 Antibody deficiencies

Malini Bhole

Definition of the disease

Antibody deficiencies comprise a heterogeneous group of disorders characterized by a failure of antibody production and recurrent infections. Antibody deficiency may be primary or secondary to other medical conditions such as B-cell lymphoid malignancies, drugs, and urinary or gastrointestinal loss of IgG.

Aetiology of the disease

Antibody deficiencies result from inherited or acquired disorders that lead to abnormalities in the development, maturation, and/or function of B-lymphocytes. Impaired functioning of B-cells leads to decreased immunoglobulin production, which manifests clinically as an increased susceptibility to infections. Some of these diseases occur due to single-gene mutations which affect the development or function of B-lymphocytes. Key steps in B-cell development, and known genetic defects responsible for arrested B-cell development, are summarized in Figure 297.1. B-cells are derived from the common lymphoid progenitor and develop within the bone marrow. Mature, naive B-cells leave the bone marrow and circulate within the bloodstream. The final stages of maturation occur within the germinal centre of secondary lymphoid organs (lymph nodes, spleen) on encounter with the specific antigen. This process requires interaction with CD4⁺ T-cells, resulting in class switch recombination and somatic hypermutation, which leads to formation of antigen-specific high-affinity antibodies (immunoglobulins).

The most common group of symptomatic antibody deficiencies, common variable immunodeficiency (CVID) disorders, are, however, likely to be polygenic disorders resulting from yet unidentified environmental triggers in genetically predisposed individuals.

From the point of view of clinical investigation, it is useful to classify antibody deficiency in terms of circulating B-cell numbers and the pattern of reduction of serum immunoglobulins (see Table 297.1). While the absence of B-cells is highly suggestive of an inherited defect interfering with B-cell development, an elevated serum IgM in association with reduced IgG and/or IgA points to a defect in immunoglobulin

class switching, as exemplified by the spectrum of hyperimmunoglobulin M (HIGM) syndromes.

Typical symptoms of the disease, and less common symptoms

Typically, patients with inherited antibody deficiencies are protected for the first 6 months of life because of transplacental transmission of maternal IgG. Many of the single-gene defects and primary defects that result in pan-hypogammaglobulinaemia (severe reduction in all three major immunoglobulin isotypes) present later in infancy or early childhood. However, CVID may not clinically manifest until adolescence or early adulthood.

Recurrent bacterial infections of the respiratory tract are a common feature of all types of antibody deficiency. In addition, up to 40% of patients with CVID develop inflammatory gastrointestinal disease, concomitant lymphoproliferative disorders, autoimmune phenomena, or granulomatous inflammation.

Demographics of the disease

The overall prevalence of clinically significant primary antibody deficiency is estimated to vary from 1: 25 000 to 1: 110 000. The commonest immunodeficiency is selective IgA deficiency with a prevalence of 1:500 to 1:700, but a majority of these patients remain asymptomatic. CVID occurs with an estimated incidence of 1: 25 000 to 1:50 000. HIGM syndromes are estimated to occur in 1:1 000 000 to 1:2 000 000 live births. Other single-gene defects are even rarer, with only few reported cases for some conditions.

Natural history, and complications of the disease

Bronchiectasis is a frequent consequence of recurrent sino-pulmonary infections with encapsulated organisms, commonly, *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus*

Figure 297.1 Diagram showing key stages of B-cell development, and known genetic defects resulting in antibody deficiencies; BLNK, B-cell linker; Btk, Bruton's tyrosine kinase; RAG, recombination activating gene.

Table 297.1 Inherited disorders resulting in antibody deficiency

Disease	Genetic disorder	Inheritance
I. Severe reduction in all Immunoglobulin isotypes with absent B-cells		
1. X-linked agammaglobulinaemia (XLA)	Mutations in <i>BTK</i>	X-linked recessive (XL)
2. Autosomal recessive agammaglobulinaemia	Mutations in μ heavy chain or $\lambda 5$	Autosomal recessive (AR)
3. Ig heavy chain defect	Mutations in $Ig\alpha$ or $Ig\beta$	AR
4. BLNK deficiency	Mutations in <i>BLNK</i>	AR
II. Reduction in at least 2 isotypes with normal or decreased B-cells		
1. Common Variable Immunodeficiency disorders (CVIDs)	Possible polygenic disease. Associated polymorphisms in <i>TACI</i> , <i>BAFFR</i> and <i>Msh5</i> reported	AD/AR, 10% positive family history
2. ICOS deficiency	Mutation in <i>ICOS</i>	AR
3. CD19 deficiency	Mutation in <i>CD19</i>	AR
III. Single isotype deficiencies with normal B cell numbers		
1. Selective IgA deficiency	Unknown	Variable
2. Isolated IgG subclass deficiency	Unknown	Variable
3. IgA with IgG subclass deficiency	Unknown	Variable
IV. Hyperimmunoglobulin M (HIGM) syndromes		
1. CD40L deficiency	Mutations in <i>CD40L</i> (CD154)	XL recessive
2. CD40 deficiency	Mutations in <i>CD40</i>	AR
3. AID deficiency	Mutations in <i>AICDA</i> gene	AR
4. UNG deficiency	Mutations in <i>UNG</i> gene	AR

Abbreviations: AD, autosomal dominant; AR, autosomal recessive.

aureus. Other sites of infection include the skin, the joints, the gastrointestinal tract, and the urinary tract. Chronic fungal or viral infections are rare. However, enteroviral meningoencephalitis has been reported in patients with X-linked agammaglobulinaemia. The current practice of maintaining a higher-trough IgG level has significantly reduced the incidence of this complication. *Pneumocystis jiroveci* (*carinii*), which is an unusual pathogen in pure antibody deficiency, has been reported in patients with HIGM syndromes, in keeping with the combined B- and T-cell defects seen in these patients.

Despite the inability to mount antibody responses against exogenous antigens, some patients with CVID mount paradoxical immune responses to self-antigens, resulting in autoimmune disease.

Other non-infectious complications include polyclonal lymphocytic infiltration, frank lymphoma, enteropathy, and liver abnormalities.

Recent data from CVID patients collected from seven European centres showed that the highest mortality in this cohort was seen in patients with enteropathy or polyclonal lymphoid infiltration.

Approach to diagnosing the disease

A good clinical history, a high degree of suspicion, and awareness of the possibility of a new diagnosis of primary antibody deficiency in any age group are important for the diagnosis of this condition. Antibody deficiencies must be considered in patients with SPUR (severe, persistent, unusual, or recurrent) infections.

First-line investigations are:

- full blood count, including lymphocyte count
- serum immunoglobulin levels
- specific antibodies and vaccine responses to protein and polysaccharide antigens
- serum and urine electrophoresis
- renal and liver function tests, including albumin levels
- quantification of circulating T-cells, B-cells, and natural killer cells
- B-lymphocyte memory panels for naive and switched memory B-cells

Second-line or specialized tests for known single-gene defects include:

- BTK protein expression and mutation analysis for the BTK gene
- CD40L/CD40 expression by flow cytometry, a technique by which the surface and intracellular characteristics of single cells

are analysed via a combination of lasers and fluorochrome-tagged antibodies

- mutation analysis for known genetic defects
- genetic tests for other known single-gene defects and polymorphisms

Screening for complications includes:

- radiology: baseline CT scan, ultrasound scan of abdomen (if clinically indicated)
- pulmonary function tests and gas transfer
- investigation for autoimmune diseases as appropriate

Differential diagnosis

Primary antibody deficiency must be differentiated from antibody deficiency, due to secondary causes such as loss of protein from the gut or urinary tract, chronic infections (HIV, persistent EBV), and disorders where the function of B-lymphocytes may be affected due to a malignant process (myeloma or lymphoma) or as a side effect of medications (including immunosuppressive agents and anticonvulsants). In children with recurrent bacterial infections, it is important to consider other causes of impaired immune function, such as:

- transient hypogammaglobulinaemia of infancy
- leaky severe combined immunodeficiency
- undefined combined immunodeficiency
- cystic fibrosis

'Gold-standard' diagnostic test

The gold standard for diagnosis of primary antibody deficiencies due to single-gene defects is demonstration of the genetic defect. The diagnosis of CVID still remains a diagnosis of exclusion, after ruling out other known causes of antibody deficiencies (see Box 297.1).

Acceptable diagnostic alternatives

The initial working diagnosis of primary antibody deficiency can be established with a good clinical history and supporting evidence from initial blood tests, including serum immunoglobulin levels, specific antibody responses, and lymphocyte surface markers

Flow cytometric analysis for expression of proteins (BTK and CD40L) may be required in selected cases. These results are usually

Box 297.1 Diagnostic criteria to define common variable immunodeficiency disorders

- less than 4 years of age
- serum IgG level less than 4.5 g/l for adults or the 2.5th percentile for age; serum IgA level less than the lower limit of normal for age and/or serum IgM level less than the lower limit of normal for age
- lack of antibody responses to protein antigens from exposure or immunization
- exclusion of all other known causes of failure of antibody production

Chapel H, Cunningham-Rundles C. Update in understanding common variable immunodeficiency disorders (CVIDs) and the management of patients with these conditions. *Br J Haematol* 2009; 145: 709–727

sufficient to institute appropriate management while further investigations are carried out to establish a definitive diagnosis.

Prognosis and how to estimate it

Treatment of patients with antibody deficiency syndromes with replacement immunoglobulin therapy and aggressive antibiotic treatment significantly improves the prognosis, with a reduction in the number of infection episodes and infection-related complications, such as the development or progression of bronchiectasis. This, however, does not alter the natural course of the condition or the development of non-infectious complications.

Although it is impossible to make accurate prognostic judgements for individual patients with primary antibody deficiency, there is sufficient evidence to support the contention that maintenance of adequate trough IgG levels, rapid treatment of infections, and close monitoring for complications such as lymphoproliferative disease have resulted in long-term survival that is only a few years below that of the actuarial curves of the normal population.

Treatment and its effectiveness

The mainstay of treatment for primary antibody deficiency is replacement immunoglobulin therapy, along with judicious use of antibiotics for the treatment of acute infections as well as for prophylaxis in individual patients. Currently, immunoglobulin replacement can be achieved effectively either intravenously or subcutaneously. Both methods have been shown to be safe and efficacious in decreasing the incidence and severity of infections in patients with antibody deficiencies. The recommended starting dose is 0.4–0.6 g/kg per month, titrated in each individual patient to achieve optimal protection against infections.

298 Combined T- and B-cell immunodeficiencies

Siraj Misbah

Definition of the disease

Combined defects in the functioning of T- lymphocytes and B-lymphocytes are predominantly disorders of childhood, and are encompassed by the term severe combined immunodeficiency (SCID). SCID comprises a heterogeneous group of inherited disorders characterized by fundamental defects in T-cell development, accompanied by severe impairment of B-cell function. Although SCID is largely a paediatric problem, prompt diagnosis followed by early haemopoietic stem cell transplantation (HSCT) has resulted in many adult survivors, who are followed up by clinical immunologists.

Aetiology of the disease

Several different molecular defects which lead to SCID have been identified (see Table 298.1). These comprise mutations in genes encoding for purine pathway enzymes, and a range of molecules involved in signal transduction, including tyrosine kinases, cytokine receptors, and key cell surface receptors. Of the different molecular defects responsible for SCID, X-linked SCID (due to mutations in the gene encoding the common gamma chain of cytokine receptors (γ_c) shared by five interleukins (interleukins 2, 4, 7, 9, and 15)) accounts for 40% of all cases of SCID in the US. Deficiency of adenosine deaminase (ADA), a key enzyme in the purine salvage pathway, accounts for approximately 15% of cases. While lymphopenia is characteristic of all forms of SCID, analysis of the exact numbers of circulating T-cells, B-cells, and natural killer (NK) cells provides useful clues as to the underlying genetic defect. For example, ADA deficiency causes severe global lymphopenia (T-cell negative, B-cell negative, NK-cell negative), while γ_c deficiency causes T-cell and NK-cell lymphopenia (T-cell negative, B-cell positive, NK-cell negative).

Apart from SCID, a rare group of patients with the hyperimmunoglobulin M (HIGM) syndrome have combined T-cell and B-cell defects, which are characterized by defective immunoglobulin class switching. Typically, patients have elevated serum IgM levels, accompanied by reduced IgG and IgA, due to a failure to switch from IgM to other classes of immunoglobulin when mounting a secondary immune response against pathogens. The commonest form of the HIGM syndrome affects males, due to transmission in an X-linked recessive manner, and is due to mutations in the gene encoding for the CD40 ligand on T-cells. Defective expression of the CD40 ligand interferes with crosstalk between T-cells and B-cells, leading to impaired antibody production (Figure 298.1).

CD40 deficiency results in a clinical picture identical to CD40 ligand deficiency but is inherited in an autosomal recessive fashion.

Typical symptoms of the disease

Children with SCID typically present in the first few months of life, with recurrent viral and fungal infections on a background of lymphopenia. The latter is an important diagnostic clue which is present in most cases. Awareness of the importance of persistent lymphopenia in the context of a baby with recurrent infections is enabling earlier diagnosis and, consequently, has improved the chances of curative treatment with HSCT or gene therapy.

In keeping with the profound T-cell and B-cell defects associated with SCID, infection with a range of intracellular pathogens (CMV, varicella, adenovirus, respiratory syncytial virus, EBV), fungi (*Pneumocystis jiroveci*, *Candida* sp.), and bacteria (*Pseudomonas* sp., *Streptococcus pneumoniae*) are a prominent part of the clinical picture. Contrary to popular belief, some babies with SCID may show no evidence of growth retardation.

In keeping with the lack of functioning T-cells and B-cells, babies with SCID are unable to reject foreign tissue and are at serious risk of transfusion-associated graft-vs-host disease (TA-GvHD). All babies with suspected or confirmed SCID should, therefore, only receive irradiated blood which has been screened to be CMV negative. Equally, immunization with live vaccines is contraindicated, to avoid the risk of vaccine-induced disease, as evidenced by the development of BCG-induced mycobacterial disease in SCID.

Boys and adults with the X-linked HIGM syndrome present with recurrent bacterial infections, neutropenia, and pneumocystis infection. Defective T-cell function is associated with chronic intestinal and biliary colonization with *Cryptosporidium* spp., leading to enteritis and ascending cholangitis. The lack of lymph node germinal centres due to defective interaction between T-cells and B-cells is a characteristic histological feature.

Demographics of the disease

SCID is rare, with an estimated incidence of 1 in 50 000 to 1 in 100 000 live births. This figure is likely to be higher in those populations with a high degree of consanguineous marriages. Although the disease predominantly presents in infancy, less severe forms of combined T-cell and B-cell deficiency (leaky SCID) may present in adulthood, as seen in ADA deficiency. The preponderance of genes encoding important immunological functions on the X-chromosome leads to a predominance of affected boys.

Table 298.1 Common causes of severe combined immunodeficiency

Site of deficiency	Inheritance	Phenotype	Percentage of cases
Common gamma chain (γ_c) of T cell receptor	X-linked recessive	T-, B+, NK-	~40%
Adenosine deaminase (ADA)	Autosomal recessive	T-, B-, NK-	~15%
Alpha chain of IL-7 receptor	Autosomal recessive	T-, B+, NK+	~10%
Janus kinase3 (Jak3)	Autosomal recessive	T-, B+, NK-	<10%

Abbreviations: B, B-cell; NK, natural killer cell; T, T-cell.

John Wiley & Sons Ltd.

Natural history, and complications of the disease

Until the advent of HSCT, SCID was invariably fatal during infancy. The only exceptions to this dictum were rare cases of spontaneous reversion of gene mutations, as described with SCID associated with γ c deficiency. Lack of awareness of the possibility of SCID in an ill baby may lead to unirradiated blood transfusions with the attendant risk of TA-GvHD. Iatrogenic disease may also result from the use of live vaccines in babies before the diagnosis of SCID has been made; for example, a newborn baby with SCID may receive a BCG vaccine due to a failure to grasp the significance of a family history of previous siblings affected with SCID.

Approach to diagnosis

The combination of recurrent infections and lymphopenia in a baby should prompt serious consideration of SCID as a possible diagnosis. In pursuing this diagnosis, it is essential to obtain evidence of combined T-cell and B-cell dysfunction, as evidenced by the presence of T-cell lymphopenia, impaired lymphocyte proliferation, and hypogammaglobulinaemia. The key investigations required to demonstrate these features are circulating lymphocyte surface marker analysis to quantify numbers of T-cells, B-cells, and NK cells. Simultaneous analysis of key cell surface markers, such as human leukocyte antigen (HLA) Class II proteins, may provide additional clues regarding the precise form of SCID. Measurement of serum immunoglobulins and specific antibodies serve as markers of B-cell function. While the circulating lymphocyte surface marker profile provides useful clues as to the underlying molecular defect, definitive diagnosis requires sequencing of the relevant gene to identify disease-causing mutations.

The diagnosis of HIGM syndrome should be considered in any patient with the characteristic immunoglobulin profile of elevated or normal serum IgM, low serum IgG, and low serum IgA on a background of recurrent bacterial infections or chronic cryptosporidial enteritis. Suspicion of the X-linked HIGM syndrome should be investigated by the demonstration of the absence of CD40 ligand expression on activated T-cells.

Other diagnoses that should be considered

The main alternative diagnosis that should be considered in the setting of recurrent infections and lymphopenia is HIV infection, because of similarities in the clinical presentations of vertically transmitted HIV infection and SCID. Indeed, it is good practice to exclude the

possibility of HIV infection in the workup of any baby with suspected SCID. Very rarely, intestinal lymphangiectasia may be associated with T-cell lymphopenia and a low serum IgG as a direct consequence of loss of IgG and efflux of lymphocytes via aberrant lymphatic channels. These cases are distinguishable from SCID by the characteristic clinical picture and low albumin accompanying an isolated low-IgG and low-T-cell lymphopenia.

Clinically significant drug-induced combined T-cell and B-cell defects may occur in some patients who have received chemotherapy for cancer or immunosuppressive therapy for autoimmune disease. Drugs responsible for such iatrogenic immune defects include corticosteroids, cyclophosphamide, fludarabine, methotrexate, azathioprine, mycophenolate mofetil, and ciclosporin. Interestingly, while ciclosporin interferes with CD40 ligand expression on human T-cells, this is not associated with clinical features suggestive of the HIGM syndrome. Where significant drug-induced immune deficiency associated with T-cell and B-cell defects does develop, they do not usually pose a diagnostic challenge because of the clinical context in which immunodeficiency develops.

'Gold-standard' diagnostic test

The demonstration of arrested T-cell development, by way of T-cell lymphopenia, accompanied by evidence of severe B-cell deficiency in the form of hypogammaglobulinaemia in the context of a baby with recurrent infections, is sufficient to establish a diagnosis of SCID. However, precise molecular diagnosis is essential for purposes of genetic counselling, prenatal diagnosis, assessing prognosis, and, in the future, using gene therapy. The selection of which genes to focus on is heavily influenced by the circulating lymphocyte profile in terms of T-cells, B-cells, and NK cells (see Table 298.1).

Confirmation of suspected X-linked HIGM syndrome requires sequencing of the CD40 ligand gene.

Acceptable diagnostic alternatives to the gold standard

In view of the ease with which serum immunoglobulins and circulating lymphocytes can be measured, there is little need for alternative surrogate tests of T-cell and B-cell function. In a resource-limited setting where access to flow cytometry may be limited, the finding of an absolute lymphopenia would be highly indicative of T-cell lymphopenia, since T-cells constitute approximately 70% of the circulating lymphocyte count. Similarly, the absence of a thymic shadow on a chest X-ray would point to a T-cell defect, but its utility as a diagnostic marker is limited by the occurrence of thymic atrophy in acutely ill babies.

Other relevant investigations

In the assessment of a child with suspected SCID or HIGM syndrome, a thorough microbiological investigation is essential to make a precise diagnosis of infective pathogens and institute appropriate treatment. Imaging of the chest followed by bronchoalveolar lavage, where possible, is important to explore the possibility of pneumocystis infection. A chest X-ray may also yield additional diagnostic clues regarding thymic size and the presence of chondro-osseous dysplasia, which is a feature of ADA deficiency. Measurement of ADA activity should be performed in any baby with profound lymphopenia affecting all classes of lymphocytes (T-cells, B-cells, and NK cells). Once the diagnosis of SCID is confirmed, HLA typing of the patient and family members will be required in a search for a suitable bone marrow donor.

Prognosis and how to estimate it

Speed is of the essence in making a diagnosis of SCID in order to enable prompt and potentially curative HSCT or gene therapy to be performed. The donor source and extent of HLA matching is a strong influence on the outcome of HSCT, with the best results being obtained with a HLA-matched, genotypically identical transplant, where survival rates of 80% at 20 years have been achieved. While HSCT is curative in the majority of patients, a significant minority will

experience long-term problems with persistent chronic TA-GvHD and autoimmune and inflammatory complications.

In CD40 ligand deficiency, 40%–50% of patients treated with immunoglobulin replacement therapy and antibiotics will not survive beyond the fourth decade.

Treatment and its effectiveness

Currently, HSCT from an HLA-matched sibling donor offers an 80% chance of cure, while a fully HLA-matched unrelated donor transplant offers a 70% chance of cure. A minority of patients will fail to achieve adequate B-cell reconstitution, thus requiring long-term immunoglobulin replacement even after HSCT.

For babies with SCID due to a clearly defined single-gene defect, where a suitable HLA-matched donor is unavailable, gene therapy offers great promise, as shown in some children with ADA deficiency or common γ c-chain deficiency, with clear evidence of T-cell, B-cell, and NK-cell reconstitution in the former, and T-cell and NK-cell reconstitution in the latter. Gene therapy does, however, carry with it the risk of insertional mutagenesis, as exemplified by the development of T-cell lymphoproliferative disease in some babies with common γ c-chain SCID, due to integration of the retroviral vector

close to a known T-cell proto-oncogene, LMO2. While this serious adverse event proved to be a temporary setback to gene therapy, the development of new strategies to minimize the risk of insertional mutagenesis and allow better regulation of gene expression has allowed gene therapy trials for SCID to continue.

In CD40 ligand deficiency, while the B-cell defect is managed by regular immunoglobulin infusions, correction of the fundamental defect requires HSCT. Currently, HSCT is curative in approximately 60% of cases. The mortality in the remainder of cases has been due to severe infection, with reactivated cryptosporidial disease being a particular problem.

<i>Waste disposal</i>	
Clearance of immune complexes and apoptotic cells	C1q Covalently bound fragments of C3

of these components in clearing immune complexes and apoptotic debris.

Angioedema

Congenital and acquired C1-inhibitor deficiency results in spontaneous, episodic angioedema but this is not primarily due to dysregulation of the early classical complement pathway. C1-inhibitor is also a major regulator of kallikrein (contact system), plasmin (fibrinolytic pathway), and factor XII. Deficiency of C1-inhibitor leads to inappropriate generation of bradykinin, with resultant increased vascular permeability.

Dysregulation of the alternative pathway

Factors H and I are the main regulators of the alternative pathway, and deficiency of either of them result in an uncontrolled activation of this pathway with consumption of C3. Deficiencies in these factors are associated with an increased susceptibility to develop atypical haemolytic–uraemic syndrome (HUS) in children and adults. The clinical features of atypical HUS are renal failure due to glomerular thrombotic microangiopathy; thrombocytopenia; and microangiopathic haemolytic anaemia. Factor H deficiency is also associated with membranoproliferative glomerulonephritis or dense deposition disease, predominantly in children.

Demographics of the disease

Defects and deficiencies of complement components are rare, but are being increasingly recognized and reported. Inherited complement deficiencies form only a very small proportion of patients with SLE, but over 75% of patients with defects in the C1 complex and C4 have lupus or lupus-like syndromes.

Homozygous C3 deficiency is a rare autosomal recessive disease which is associated with recurrent bacterial infections and defects in adaptive immune responses. Approximately 1 in 10 000 individuals are reported to be deficient in one of the terminal complement components, but geographical and ethnic differences in prevalence and incidence have been noted.

MBL deficiency is considered to be the most common congenital immunodeficiency, with an estimated frequency of between 5% and 10% of the general Caucasian population. Individuals with MBL deficiency, however, remain healthy and are only susceptible to recurrent infections when the deficiency is associated with other immunodeficiencies or occurs prior to the maturation of the adaptive immune system.

Properdin deficiency is the most common defect associated with the alternative pathway and is transmitted as an X-linked recessive condition.

Hereditary angioedema due to C1-inhibitor deficiency is the best-studied inherited defect of complement regulators. The prevalence is

estimated to be 1:10 000 to 1:50 000, and the disease occurs in both sexes. Spontaneous de novo mutations occur in up to 25% of cases.

Defects in the components of the alternative pathway, including in factor H, factor I, factor B, membrane cofactor protein, and CD59 are very rare, with only individual cases or a few families currently reported.

Natural history and complications of the disease

Natural history of infections in complement disorders, and their complications

The most common presentation of patients with complement deficiencies is an increased susceptibility to recurrent infections by encapsulated bacteria, particularly *Neisseria meningitidis* (Table 299.2). Homozygous C3 deficiency is also associated with increased susceptibility to *Streptococcus pneumoniae* and *Haemophilus influenzae* sino-pulmonary infections and meningitis. While the majority of the infections occur in childhood, there is a reduction in frequency and severity of infections as the adaptive immune response matures.

Patients with MBL deficiency are generally asymptomatic. MBL concentrations correlate with gestational age, as reflected by a high prevalence of MBL deficiency in preterm neonates. MBL deficiency is clinically relevant in certain cohorts, including preterm neonates and other immunocompromised patients, including patients on chemotherapy.

Natural history of SLE-like syndrome in complement deficiencies, and its complications

There appears to be a hierarchy for deficiencies of the early components of the classical complement pathway, with respect to the risk of development of SLE or SLE-like disease, with the highest risk being in patients with C1q deficiency and the lowest risk associated with C2 deficiency: 90% of individuals with C1q and C1r/C1s deficiency develop a SLE-like disorder, while the estimated incidence in individuals with C2 deficiency is 10%–20%. Patients with C1-complex or C4 deficiency present early in life, and both sexes may be equally affected. In contrast, the disease in C2-deficient patients is similar to classical SLE but starts later and occurs more frequently in females

Table 299.2 Presentations of complement deficiencies

Deficiency	Clinical phenotype
<i>Complement components</i>	
C1q	SLE-like syndrome
C1r	Infections
C1s	
C2	
C4	
C3	Recurrent pyogenic infections
C2	
C4

Factor B	
<i>Regulatory proteins</i>	
C1 Inhibitor	Hereditary angioedema
Factor H	Atypical haemolytic–uraemic syndrome Membranoproliferative glomerulonephritis
Factor I	Atypical haemolytic–uraemic syndrome Membranoproliferative glomerulonephritis
CD59	Paroxysmal nocturnal haemoglobinuria
Decay accelerating factor	

Note: All of the above disorders may present either in children or in adults.

than in males (7:1). Renal involvement may be seen in about 30% of patients. Individuals with early complement defects, however, do not have an increased risk of development of any other systemic or organ-specific autoimmune disease.

Natural history of angioedema in complement deficiencies, and its complications

There is wide phenotypic variation amongst patients with inherited or acquired C1-inhibitor deficiency even within the same family, ranging from almost asymptomatic disease to frequent episodes of subcutaneous and/or mucosal angioedema and severe abdominal attacks. Patients may develop symptoms at any age, but the disease commonly manifests during adolescence or during periods of stress or trauma. It is potentially life-threatening when associated with laryngeal involvement. Patients with severe, unexplained abdominal episodes may be subject to unwanted exploratory laparotomies prior to diagnosis of the condition, especially in the absence of a family history. Certain medications, including oestrogen-based contraceptive pills and angiotensin-converting-enzyme inhibitors, are associated with an increased frequency of symptoms.

Approach to diagnosing the disease

Assessment of the integrity of the entire pathway should be made by testing for haemolytic complement activity (using the CH50 assay for the classical pathway, and the AP50 assay for the alternative pathway), coupled with quantitative measurement of serum C3 and C4. These initial results will help determine which part of the complement pathway might be defective, and help direct further, more detailed testing. Normal CH50 and AP50 values effectively exclude significant complement deficiency in most patients. In rare cases where the clinical history is compelling, further testing will be required, even with normal CH50 and AP50 values.

In most patients with recurrent angioedema a normal C4 test effectively excludes the diagnosis of C1-inhibitor deficiency. Additional tests of the complement pathway include:

- quantification of individual complement components
- C1-inhibitor quantitative and functional assays
- functional assays of classical and alternative pathway
- molecular analysis for underlying gene mutations

Differential diagnosis

The differential diagnosis includes:

- recurrent infections: primary antibody deficiency
- defects in innate immune system
- other causes for recurrent meningitis
- SLE
- idiopathic angioedema
- allergy
- medications

'Gold-standard' diagnostic test

The gold standard for complement defects is to establish a molecular diagnosis and identify the disease-causing genetic mutation for the condition. Complement deficiencies are rare conditions, and a registry of complement deficiencies has been established recently in Europe with the support of the European Complement Network. The aim of the registry is to collect information regarding complement defects from participating countries in order to define the prevalence, distribution, and disease associations in different populations and ethnic groups.

Acceptable diagnostic alternatives

A working diagnosis of complement defects may be established using the clinical history supported by appropriate functional assays, but definitive testing requires referral to a specialist complement laboratory.

Other relevant investigations

The following additional investigations may be of value in the appropriate clinical context:

- C3 nephritic factor (in cases of marked C3 hypocomplementaemia)
- anti-C1q antibodies (in hypocomplementaemic urticarial vasculitis)
- demonstration of complement and immunoglobulin deposition on renal biopsy (in immune-complex-mediated glomerulonephritis)

Prognosis and how to estimate it

The long-term prognosis with regard to infections is good, with a reduction in severity and frequency of bacterial infections with age, reflecting the maturity of the adaptive immune system. Thirty per cent of patients with early complement defects and SLE-like symptoms develop renal involvement, and the long-term prognosis depends on the extent of renal disease.

The natural history and prognosis of hereditary angioedema due to C1-inhibitor deficiency is unpredictable and varies from patient to patient, even in those with the same genetic mutation.

Treatment

Treatment of recurrent bacterial/neisserial infections

The treatment for recurrent bacterial/neisserial infections is:

- antibiotic treatment/supportive care
- penicillin prophylaxis/immunization

Treatment of SLE-like syndrome

The treatment for SLE-like syndrome is:

- use of corticosteroids and immunosuppressive treatment
- replacement of C1q using fresh frozen plasma in selected cases

Treatment of angioedema

The treatment for angioedema is:

- use of C1-inhibitor concentrate (for acute attacks/short-term prophylaxis)
- use of synthetic androgens/antifibrinolytic agents (for long-term prophylaxis)
- use of a bradykinin receptor antagonist (a new alternative to C1-inhibitor for the treatment of acute attacks)
- use of a kallikrein inhibitor/recombinant human C1-inhibitor (under development)

300 Hypersensitivity diseases

Malini Bhole

Definition of the disease

Hypersensitivity reactions are aberrant immune responses that are provoked by innocuous extrinsic or self-antigens, are mediated by B-cells or T-cells, and may result in tissue or organ damage.

Aetiology of the disease

Coombs and Gell classified hypersensitivity reactions into four types, based on the different immune responses, as shown in Table 300.1.

Pathophysiology of hypersensitivity reactions

Pathophysiology of type I hypersensitivity reactions

Type I hypersensitivity reactions result from IgE-mediated mast cell degranulation, with resultant release of early (preformed) mediators, newly formed mediators, and cytokines, predominantly interleukins 4, 5, 6, and 13. The important mediators include histamine, tryptase, leukotrienes, prostaglandin D₂, and platelet-activating factor. Release of these mediators leads to vasodilatation, bronchial constriction, increased vascular permeability, smooth muscle contraction, increased mucus production, and pruritus.

Pathophysiology of type II hypersensitivity reactions

Type II hypersensitivity reactions are caused by autoantibodies that are directed against cell membrane-bound antigens. The cells may then be destroyed by different mechanisms, including:

- complement-mediated cytotoxicity
- antibody-dependent cell-mediated cytotoxicity
- phagocytosis

Pathophysiology of type III hypersensitivity reactions

In type III hypersensitivity reactions, antibodies react with soluble antigens and form immune complexes, which are deposited on the vascular endothelium or the glomerular membrane. The ensuing complement activation via the classical pathway leads to tissue damage and destruction.

Pathophysiology of type IV hypersensitivity reactions

Type IV hypersensitivity reactions are T-cell-mediated delayed hypersensitivity reactions directed against persistent antigens or foreign bodies. The main effector cells include cytotoxic T-cells and macrophages, which drive chronic inflammation and granuloma formation.

Typical symptoms of the disease, and less common ones

Typical symptoms and clinical manifestations of a hypersensitivity reaction depends on the type of reaction it is, as well as the route of entry of the allergen and/or the site of the antigen-antibody reaction.

Symptoms of type I hypersensitivity reactions

The symptoms of type I hypersensitivity reactions may vary in severity and manifest clinically as anaphylaxis, urticaria (generalized or local), angioedema, allergic rhinitis, or asthma. These reactions can occur in response to:

- inhaled aeroallergens (e.g. pollen, dust, mould, animal dander):
 - allergic rhinitis
 - allergic asthma
- ingestion of medications or food:
 - food allergies
 - drug allergies
- injection (e.g. venom stings):
 - local urticaria and angioedema
 - generalized reactions
 - anaphylaxis
- skin contact (e.g. poison ivy, animal scratches, pollen, latex):
 - urticarial rash
 - dermatitis

Symptoms of type II hypersensitivity reactions

The symptoms of type II hypersensitivity reactions manifest clinically as:

- autoimmune cytopenias
 - autoimmune haemolytic anaemia
 - immune thrombocytopenia

Table 300.1 Types of hypersensitivity reactions

Hypersensitivity reactions	Immune mechanism	Cells/mediators involved	Typical clinical features
Type I, or immediate hypersensitivity	Antigen cross-linking IgE molecules bond to mast cell membrane	Mast cell degranulation and release of mediators like histamine, tryptase, and leukotrienes	Urticarial rash Bronchoconstriction Hypotension
Type II, or antibody-mediated (humoral) cytotoxicity	Antibodies directed against cell or membrane-bound antigens	Complements Neutrophils Macrophages Natural killer cells	Haemolysis Cytopenias
Type III, or immune-complex disease	Antibody binds to soluble antigens with resultant formation of immune complexes	Immune complexes activate complement cascade leading to recruitment of neutrophils and macrophages, and local inflammation at site of deposition	Cutaneous and systemic vasculitis
Type IV, or delayed hypersensitivity	Autoreactive T-cells recognize antigens in relation to self-MHC molecules	Cytotoxic CD8 ⁺ T-cells, macrophages, and cytokines	Contact dermatitis Granuloma formation

Data from Gell PGH, Coombs RRA, *Clinical Aspects of Immunology*. 1st ed. Oxford, England: Blackwell; 1963.

- bullous pemphigoid
- Goodpasture's disease (anti-basement membrane antibody)
- some drug reactions

Symptoms of type III hypersensitivity reactions

The symptoms of type III hypersensitivity reactions manifest clinically as:

- systemic disease, such as:
 - serum sickness (following certain drugs or injection of foreign serum)
 - arthus reaction (a localized immune-complex reaction; e.g. extrinsic allergic alveolitis)
- organ-specific manifestations, such as:
 - glomerulonephritis
 - vasculitis
 - arthritis

Symptoms of type IV hypersensitivity reactions

The symptoms of type IV hypersensitivity reactions manifest clinically as:

- contact dermatitis (in response to an epidermal antigen, e.g. metals, poison ivy, organic chemicals, etc.)
- a tuberculin reaction (in response to an intradermal antigen, e.g. tuberculin administered during a Mantoux test)
- granuloma formation (in response to a persistent antigen)

Demographics of the disease

Hypersensitivity reactions, in general, result from a complex interplay between genetic predisposition and environmental factors. The overall prevalence of allergies, or IgE-mediated type I hypersensitivity reactions, appear to be increasing, especially in relation to food and aeroallergens (see Chapter 75). Atopy is defined as the genetic predisposition to make IgE antibodies in response to allergen exposure, and patients prone to IgE-mediated allergic reactions are said to be atopic.

Natural history and complications of the disease

The natural history and complications vary with the type of hypersensitivity reaction.

Natural history of type I hypersensitivity reactions, and their complications

A type I hypersensitivity reaction typically occurs within 15–30 minutes from the time of exposure to the antigen. A delayed phase

may occur 2–6 hours after exposure. The severity of the reaction is unpredictable and may vary from minor localized reactions to severe, generalized manifestations, including anaphylaxis and death. The factors affecting the natural history and complications of type I hypersensitivity reactions include the nature and amount of the allergen, the site of allergen entry, the duration of the exposure, and the degree of sensitization of the individual patient.

Natural history of type II hypersensitivity reactions, and their complications

The reaction time for a type II hypersensitivity reaction is usually minutes to hours and primarily involves autoantibody- and complement-mediated injury directed against endogenous or exogenous (commonly, drug haptens) membrane-bound antigens. The natural history and complications depend on the site(s) involved in the reaction (e.g. haematopoietic cells; the skin; renal or lung basement membrane).

Natural history of type III hypersensitivity reactions, and their complications

A type III hypersensitivity reaction may manifest several hours after exposure (3–10 hours) and is mediated by soluble immune complexes. The natural history of this type of reaction, and the complications associated with it, depend upon the size of the immune complexes and their site of deposition (joints, blood vessels, kidneys, etc.).

Natural history of type IV hypersensitivity reactions, and their complications

A type IV hypersensitivity reaction is a delayed hypersensitivity reaction, which typically manifests 48–72 hours after exposure. The natural history and course of reaction depends upon the antigen and the site of contact. Granuloma formation is a more chronic manifestation of a type IV reaction to a persistent antigen or foreign body and may present 3–4 weeks after initial exposure. Complications of this reaction are directly related to the site of granuloma formation.

Approach to diagnosing the disease

The initial approach to the diagnosis of hypersensitivity diseases is based on a detailed clinical history and examination for typical clinical manifestations (see Figure 300.1). The important points in the clinical history would include details of the reaction, the nature of the exposure, the route of entry, the time period between exposures, and the clinical manifestations. Obtaining these allows an early differentiation between the four main types of hypersensitivity

Approach to Hypersensitivity diseases

History

- Timing of reaction in relation to exposure to suspect agent
- Type of manifestations
- Duration of reaction
- History of background atopy
- History of previous exposure/reaction

Appropriate immediate management and further investigations and long term treatment according to manifestations

Figure 300.1 Initial approach to hypersensitivity diseases.

Table 300.2 Gold-standard diagnostic tests for hypersensitivity diseases

Type of reaction	Gold-standard test	Risks/difficulties
Type I hypersensitivity	Double-blind, placebo-controlled allergen challenge	Potentially life-threatening, with inherent risk of severe reaction Time consuming
Type II hypersensitivity	Biopsy and direct immunofluorescence of involved tissue The staining pattern is typically smooth and linear , and contains antibodies, complement, and neutrophils	Accessibility of tissue Expertise to interpret findings
Type III hypersensitivity	Biopsy and direct immunofluorescence of involved tissue The staining is granular, and contains primarily deposits of immune complexes and complement	Accessibility of tissue Expertise to interpret findings
Type IV hypersensitivity	Biopsy of involved tissue Typical granulomatous infiltrates containing lymphocytes and macrophages	

reactions; this is then confirmed with further specific investigations (see Table 300.2 and 'Acceptable diagnostic alternatives to the gold standard').

Differential diagnosis

Differential diagnosis for type I hypersensitivity

The differential diagnosis for type I hypersensitivity includes:

- non-IgE-mediated direct mast cell degranulation
- vasovagal symptoms and panic attacks
- systemic mastocytosis
- chronic idiopathic urticaria/angioedema

Differential diagnosis for type II hypersensitivity

The differential diagnosis for type II hypersensitivity includes:

- non-antibody-mediated causes of haemolytic anaemia
- other causes of pulmonary–renal syndrome (e.g. Goodpasture's disease, Wegener's granulomatosis, microscopic polyangiitis)

Differential diagnosis for type III hypersensitivity

The differential diagnosis for type III hypersensitivity includes other causes of glomerulonephritis and vasculitis

'Gold-standard' diagnostic test

'Gold-standard' diagnostic tests for hypersensitivity diseases vary according to the immunological process involved in the pathogenesis. These tests, as detailed in Table 300.2, are not always practical or feasible. Acceptable alternative investigations and tests are therefore used in the diagnosis of these conditions (see 'Acceptable diagnostic alternatives to the gold standard').

Acceptable diagnostic alternatives to the gold standard

Acceptable diagnostic alternatives to the gold-standard test for type I hypersensitivity

Acceptable diagnostic alternatives to the gold-standard test for type I hypersensitivity are:

- serial measurement of serum mast cell tryptase at 1, 6, and 24 hours, to demonstrate immediate mast cell degranulation
- measurement of specific IgE antibodies against the suspected allergen(s)
- newer in vitro tests, including basophil activation tests and component-resolved diagnostics, which are still under investigation
- skin prick tests and intradermal tests with the suspected allergen(s)

Acceptable diagnostic alternatives to the gold-standard test for type II hypersensitivity

Acceptable diagnostic alternatives to the gold-standard test for type II hypersensitivity are:

- detection of circulating antibody against tissues involved (via indirect immunofluorescence, ELISA)
- direct Coomb's test, for autoimmune cytopenias

Acceptable diagnostic alternatives to the gold-standard test for type III hypersensitivity

Acceptable diagnostic alternatives to the gold-standard test for type III hypersensitivity are serum complement levels, to demonstrate hypocomplementaemia.

Acceptable diagnostic alternatives to the gold-standard test for type IV hypersensitivity

Acceptable diagnostic alternatives to the gold-standard test for type IV hypersensitivity are:

- intradermal tests
- patch tests

Other relevant investigations

Other relevant investigations for hypersensitivity diseases are tests to rule out other immunological conditions that form the differential diagnosis of hypersensitivity disease. Depending on the clinical context, the following investigations should be considered:

- screening for C1-inhibitor deficiency (e.g. C3, C4, and C1-inhibitor concentrations)
- tests to exclude systemic mastocytosis (e.g. baseline serum tryptase, bone marrow examination)
- tests to exclude chronic urticaria (e.g. thyroid function tests, auto-immune screening)
- tests to exclude other causes of cytopenia (e.g. bone marrow examination)
- tests to exclude vasculitic syndromes (e.g. tests for antineutrophil cytoplasmic antibodies; renal biopsy)
- tests to exclude granulomatous conditions such as tuberculosis and sarcoidosis

Treatment

Treatment for type I hypersensitivity reactions

Treatment for type I hypersensitivity reactions includes:

- allergen avoidance
- use of antihistamines
- administration of adrenalin for acute severe reactions (see Chapter 75)
- allergen immunotherapy
- desensitization

Treatment for type II/III hypersensitivity reactions

Treatment for type II/III hypersensitivity reactions includes:

- use of anti-inflammatory agents
- use of immunosuppressive agents

Treatment for type IV hypersensitivity reactions

Treatment for type IV hypersensitivity reactions includes:

- avoidance of the trigger, if the trigger can be identified
- treatment of underlying condition
- use of steroids and immunosuppressive agents

301 Immunological support

Siraj Misbah

Introduction

Therapeutic immunoglobulin is produced from plasma pooled from approximately 10 000 to 15 000 blood donors. As a direct consequence, a single unit of immunoglobulin has a vast array of antibody specificities (of the order of 10^{15}) which enable it to fulfil its function of antibody replacement in patients with B-lymphocyte immunodeficiency (primary or secondary hypogammaglobulinaemia). Following on from the use of immunoglobulin in immunodeficiency over the past two decades, high-dose immunoglobulin has emerged as an important form of immunomodulatory therapy for patients with various autoimmune diseases.

Although pooled immunoglobulin is largely composed of IgG, there is a range of other immunologically active molecules, including cytokines (interferon gamma, transforming growth factor beta), anti-cytokine antibodies (anti-interleukin 1 alpha), and soluble cell surface glycoproteins (CD4, CD8), which are also likely to influence the therapeutic efficacy of immunoglobulin as an immunomodulator.

Preparation of therapeutic immunoglobulin

Therapeutic immunoglobulin is produced by fractionating plasma from donors who have undergone a rigorous screen for blood-borne viruses, including HIV1, HIV2, hepatitis B, and hepatitis C. The plasma fractionation process using cold ethanol has been shown to inactivate both HIV and hepatitis B, thus providing an added level of safety preventing transmission of these viruses. Because hepatitis C, an enveloped RNA virus, has proved resistant to ethanol fractionation, additional antiviral steps based on solvent-detergent or low pH treatment were introduced in the mid-1990s, following the last outbreak of hepatitis C transmission by IV immunoglobulin (IVIg). Using PCR to perform random testing of plasma minipools for hepatitis C antigen is an additional safety measure that has helped prevent any further outbreaks of hepatitis C in immunoglobulin recipients.

Concerns regarding the remote possibility of prion transmission by blood products have led the UK's department of health to institute leucodepletion of red-cell transfusions and to ban the use of British plasma for the production of therapeutic immunoglobulin.

Mechanisms of action

The efficacy of immunoglobulin therapy in patients who have a B-cell deficiency and so are unable to produce protective antibodies is easily explained by the replacement of missing antibodies. In contrast, multiple mechanisms of action, often variable by disease, are likely to be operational when high-dose IVIg is used for immunomodulation. These include Fc receptor blockade, induction of inhibitory Fcγ receptors, neutralization of cytokines, and accelerated removal of autoantibodies via the FcRn (Fc receptor of the neonate) receptor, expressed on endothelium and monocytes. Although initially identified as a placental receptor, responsible for transplacental passage of IgG in the third trimester of pregnancy, FcRn plays an important role in regulating IgG half-life by acting as a protective receptor preventing lysosomal degradation of IgG (see Figure 301.1).

Indications for therapeutic immunoglobulin

Until the 1980s, the use of immunoglobulin as a therapeutic agent was confined to replacement therapy in patients with primary or secondary antibody deficiency. Its role as an effective immunomodulator was discovered serendipitously, when IVIg was shown to consistently increase the platelet count in a child with antibody

Figure 301.1 Schematic representation of the role of the endothelial FcRn receptor in IgG homeostasis.

Essentials of Clinical Immunology, Sixth edition, Helen Chapel, Maneel Haeney, Siraj Misbah and Neil Snowden. 2014. John Wiley & Sons Ltd.

deficiency and immune thrombocytopenic purpura. Since then, the use of high-dose IVIg as an immunomodulator has become established as an important therapeutic option in many immune-mediated diseases (see Table 301.1). The key difference in the

Table 301.1 Evidence-based indications for therapeutic immunoglobulin

Condition	Evidence
Immunology	
Primary antibody deficiency	Not subjected to placebo-controlled trials when first used as IMIg in the 1950s IVIg subsequently shown to be as efficacious or superior to IMIg as infection prophylaxis
Neurology	
Guillain-Barré syndrome	Demonstrated in RCTs to be as efficacious as plasmapheresis in patients with paralytic disease
Chronic inflammatory demyelinating polyneuropathy	Demonstrated in RCTs to be as efficacious as plasmapheresis
Multifocal motor neuropathy	Immunoglobulin has been shown to be the treatment of choice (evidence from RCTs)
Myasthenia gravis	Of proven benefit in myasthenic crises (evidence from RCTs)
Paediatrics	
Kawasaki disease	High-dose aspirin combined with IVIg is the treatment of choice (evidence from RCTs)
Haematology	
ITP	IVIg equally efficacious as steroids, in both adult and childhood ITP

Abbreviations: ITP, immune thrombocytopenia; IMIg, intramuscular immunoglobulin; IVIg, intravenous immunoglobulin; RCT, randomized control trial.

use of immunoglobulin for antibody replacement versus its use for immunomodulation relates to the dose. Although the dose of immunoglobulin required for immunomodulation (2 g/kg) is five times higher than that required for antibody replacement (0.4 g/kg), it is important to be aware that these doses have been derived empirically. In practice, many patients receiving maintenance high-dose IVIg for autoimmune diseases derive benefit from 1 g/kg administered at variable infusion intervals (3–6 weeks). The lower doses of immunoglobulin used for antibody replacement can also be administered effectively weekly via the subcutaneous route, which eliminates the peaks and troughs associated with IV bolus doses.

Adverse effects

Based on pathogenesis, immunoglobulin-induced adverse effects are classified into the following categories:

- immediate infusion-related adverse effects
- complications attributable to a sudden increase in serum IgG
- transmission of infective agents

Immediate infusion-related adverse effects

Immediate infusion-related adverse effects can occur with any immunoglobulin preparation, irrespective of the dose. These comprise self-limiting backache, chills, headaches, and flu-like symptoms, and, rarely, anaphylaxis. The latter is associated in some patients with the presence of anti-IgA antibodies complexing with the small amounts of IgA contained in some immunoglobulin preparations.

Complications attributable to a sudden increase in serum IgG

Complications attributable to a sudden increase in serum IgG are largely confined to patients receiving high-dose IVIg for immunomodulatory therapy. Haematological adverse effects include arterial or venous thrombosis in patients with preexisting cardiovascular disease or with disorders associated with increased viscosity and acute haemolysis due to passive transfer of anti-blood group antibodies contained in IVIg. Reversible renal impairment due to osmotic renal tubular vacuolopathy caused by the carbohydrate stabilizer (sucrose) found in some immunoglobulin preparations was a particular problem in some patients with preexisting renal disease. The development of sucrose-free preparations has led to a dramatic decrease in nephrotoxicity. Patients with type II mixed cryoglobulinaemia are at particular risk of immune-complex-mediated renal failure arising from the deposition of complexes composed of the IgM component of cryoglobulin (containing rheumatoid factor activity) when combined with infused IgG. High-dose IVIg may also cause a self-limiting acute aseptic meningitis which has been attributed to the sudden increase in the IgG gradient at the blood–brain barrier, and the consequent perturbation of meningeal endothelium.

Box 301.1 Checklist for safe use of intravenous immunoglobulin

- for elective use, exclude IgA deficiency; if the patient is totally deficient in IgA and has high titres of anti-IgA antibodies, consider IgA-depleted preparation of IVIg
- check liver and renal function prior to infusion
- check hepatitis C PCR/antibody status pre-Rx
- proceed with caution in the elderly and in patients with preexisting cardiovascular disease, hyperviscosity, and thrombophilia
- avoid use of IVIg in mixed cryoglobulinaemia and rapidly progressive renal disease
- beware potential risk of haemolysis
- adhere to manufacturer's recommendations regarding reconstitution and rate of infusion
- record batch number of IVIg preparation

Abbreviations: IVIg, intravenous immunoglobulin; PCR, polymerase chain reaction.

Transmission of infective agents

Given its origins as a plasma product, transmission of blood-borne viruses has always been a concern with IVIg. As previously discussed, the main concern is regarding the risk of transmission of hepatitis C. Although no precise estimates of risk of transmission are available for IVIg, the stringency and rigour of current plasma screening methods renders the risk of hepatitis C transmission with a single unit of blood at approximately 1 in 1 million. The risk with pooled IVIg is therefore likely to be even lower.

Minimizing immunoglobulin-associated adverse effects

Used correctly, pooled immunoglobulin has proven to be an effective therapeutic agent in a wide range of immune-mediated disorders. With its increasing use as an immunomodulator, adverse effects associated with high-dose immunoglobulin are gaining prominence. Close attention to the checklist provided in Box 301.1 will minimize the risk of adverse effects.

302 Immunosuppressive therapy and therapeutic monoclonal antibodies

Siraj Misbah

Definition

The term immunosuppressive therapy encompasses all forms of treatment that dampens function of the recipient's immune system, with a view to controlling severe autoimmune, inflammatory, or allergic disease.

All immunosuppressive agents carry an inherent risk of increasing a patient's susceptibility to infection. Hence, given the trade-off between expected therapeutic benefit and possibility of adverse effects, a careful risk assessment and informed discussion with the patient should precede initiation of treatment.

Classification and mechanisms of action

Despite the structural heterogeneity of current immunosuppressive agents, the predominant targets of these drugs are T-lymphocytes, with multiple downstream effects including containment of T-cell activation, inhibition of cytokine production, restriction of clonal expansion, and varying degrees of suppression of B-cell function. Despite inhibition of B-cell function, many patients are still able to mount clinically useful, albeit somewhat blunted, antibody responses. More pronounced effects on B-cell function, leading to frank hypogammaglobulinaemia, may be seen in up to 5% of patients receiving cyclophosphamide, mycophenolate mofetil, or therapeutic monoclonal antibodies targeted at B-cell surface antigens, as exemplified by rituximab (see 'Therapeutic monoclonal antibodies').

The mechanism of action of commonly used immunosuppressive drugs is summarized in Figure 302.1.

Figure 302.1 Schematic depiction of the main intracellular sites of action of the major groups of immunosuppressive drugs.

Essentials of Clinical Immunology, Sixth edition, Helen Chapel, Maneel Haeny, Siraj Misbah and Neil Snowden. 2014. John Wiley & Sons Ltd.

Therapeutic monoclonal antibodies

Conventional immunosuppressive agents are unselective in their effects, with the potential for harm. This has driven the search for safer agents directed at an antigenic target pivotal to the relevant disease process. Therapeutic biologics (monoclonal antibodies or receptor-fusion proteins), which are based on Kohler and Milstein's Nobel Prize-winning hybridoma technology, are a superb example of true translational science which has revolutionized the treatment of many autoimmune and inflammatory diseases. Presciently, Kohler and Milstein envisaged that hybridoma technology, in which specific antibody-producing B-cells from immunized animals (or humans) are fused with a myeloma cell line conferring immortality, thus producing cell lines capable of secreting monoclonal antibodies, would have medical and industrial use. However, the technology was never patented, leading to the loss of millions of pounds to the British economy.

The recent explosion of therapeutic monoclonal antibodies has been led by rituximab, a chimaeric antibody licensed for the treatment of B-cell lymphoma by virtue of its selective targeting of the CD20 surface glycoprotein on B-lymphocytes. Rituximab exemplifies three important criteria for the development of therapeutic monoclonal antibodies:

- the target antigen should be largely restricted to cells or mediator(s) that are pivotal to disease causation (e.g. malignant cells or cells involved in immunopathogenesis)
- the target antigen should not be internalized by cells
- the target antigen should not be soluble (for cancer therapy)

The use of rituximab in a patient with B-cell lymphoma and concomitant rheumatoid arthritis (RA) led to the serendipitous observation of regression of RA, which in turn has spurred the use of rituximab in a variety of autoimmune diseases associated with B-cell overactivity. Rituximab is currently licensed for the treatment of severe RA that has proven to be unresponsive to monoclonal antibodies or receptor-fusion proteins targeted against tumour necrosis factor (TNF). Table 302.1 lists some therapeutic monoclonal

Table 302.1 Some therapeutic monoclonal antibodies used in the treatment of autoimmune, inflammatory, and neoplastic disorders

Monoclonal antibody	Indications	Molecular target
Adalimumab Infliximab Golimumab	Inflammatory bowel disease Ankylosing spondylitis Psoriatic arthritis Psoriasis Rheumatoid arthritis Juvenile idiopathic arthritis	Tumour necrosis factor alpha
Alemtuzumab	Relapsing-remitting multiple sclerosis	CD52 receptor
Rituximab	Rheumatoid arthritis Non-Hodgkin's lymphoma	CD20 receptor
Trastuzumab	HER2-positive breast cancer HER2-positive gastric cancer	HER2

Abbreviations: HER2, human epidermal growth factor receptor 2.

antibodies licensed for use in the UK in the treatment of autoimmune, inflammatory, and neoplastic disorders.

Although rituximab depletes a wide range of B-cells expressing CD20, it spares fully differentiated plasma cells, thus accounting for the lack of significant hypogammaglobulinaemia in the majority of recipients. However, a minority of patients may develop hypogammaglobulinaemia and recurrent bacterial infections following repeated courses of treatment, thus highlighting the importance of monitoring serum immunoglobulin levels in patients receiving rituximab. Other serious infective challenges posed by rituximab include reactivation of hepatitis B in patients previously infected with hepatitis B, despite their being negative for the hepatitis B surface antigen, and the development of progressive multifocal leucoencephalopathy (PML) due to the JC virus. While pretreatment hepatitis viral screens are able to identify and ensure pre-emptive antiviral treatment for hepatitis B, the onset of PML can be neither predicted nor prevented at present.

While the precise mechanism of rituximab awaits elucidation, it is likely that B-cell depletion by a number of routes (see Figure 302.2), coupled possibly with the potentiation of regulatory T-cells, accounts for the therapeutic success of the antibody in autoimmune diseases.

Figure 302.2 Rituximab-opsonized B-cells are subject to attack and killing via at least three pathways. (A) Binding of rituximab causes activation of the complement cascade, which generates the membrane attack complex that can directly lyse B-cells by complement-mediated cytotoxicity. (B) Complement activation also deposits C3b/iC3b fragments on the B-cell. The Fc portion of rituximab and the deposited C3b/iC3b fragments allow for recognition by both Fc gamma receptors and complement receptors 1 and 3 on macrophages, leading to phagocytosis and antibody-dependent cell-mediated cytotoxicity. (C) Binding of rituximab allows interaction with natural killer cells via Fc gamma RIII and complement receptor 3, leading to antibody-dependent cell-mediated cytotoxicity; ADCC, antibody-dependent cell-mediated cytotoxicity; CR, complement receptor; FcγR, Fc gamma receptor; MAC, membrane attack complex; NK, natural killer.

An example of monoclonal antibodies targeting cytokines to induce disease remission is the use of anti-TNF based therapy, which has dramatically improved the management of RA. In view of the pivotal position of TNF in the pathogenesis of RA, interruption of TNF production induces further downstream suppression of other pro-inflammatory cytokines, such as interleukin 1 and interleukin 6. However, the neutralization of TNF in RA carries with it the risk of reactivating TB, reflecting the key role of TNF in the protective immune response to *Mycobacterium tuberculosis*. In order to minimize this risk, patients are screened for latent TB by interferon-gamma-based assays prior to commencing treatment with anti-TNF blockers. Based on the success of TNF blockade in RA, a range of other autoimmune diseases, including ankylosing spondylitis, psoriatic arthritis, juvenile chronic arthritis, and Crohn's disease, have been shown to benefit from the same therapeutic concept.

Selection of immunosuppressive agents

The selection of immunosuppressive drugs in the initial treatment of autoimmune or inflammatory diseases is predominantly guided by disease severity and the need to induce rapid remission, in addition to being informed by knowledge of disease pathogenesis. In practice, this entails the use of corticosteroids, either in combination with other drugs or, occasionally, singly.

High-dose corticosteroids are frequently used to induce disease remission, followed by maintenance immunosuppressive treatment to prevent disease relapse. An example of the use of steroids alone to control disease would be in a patient with giant cell arteritis and presenting with headache and nasal symptoms, as, in this case, urgent treatment would be critical for preventing loss of vision. In contrast, a patient with Wegener's granulomatosis and presenting with a pulmonary–renal syndrome would require steroids and cyclophosphamide to induce disease remission. Where cyclophosphamide is used for induction therapy in small vessel vasculitis, evidence from randomized controlled trials shows that remission can be maintained by switching to azathioprine at 3 months, thus limiting cyclophosphamide-induced toxicity. This model of treatment is increasingly being adopted when planning immunosuppressive regimens for other autoimmune diseases. Alternatives to the use of azathioprine in maintaining disease remission are mycophenolate mofetil, and methotrexate.

Although a knowledge of the immunopathogenesis of the disease being treated is essential, its influence on the choice of immunosuppressive agent is largely nullified by the broad-ranging immunological actions of conventional agents. In contrast, the choice of therapeutic monoclonal antibody is predominantly guided by the immunopathogenesis of the disease being treated, as clearly exemplified by the use of anti-TNF agents in RA, and rituximab in B-cell-driven autoimmune disease.

Adverse effects, and strategies to minimize them

The brief discussion of adverse effects in the ensuing paragraphs is designed to complement the adverse effects listed in Table 302.2. Anticipating and preventing adverse effects is of paramount importance when using immunosuppressive therapy. All immunosuppressive agents increase susceptibility to infection. Where adverse effects are predictable by virtue of the mechanism of action or metabolism of the drug, steps should be taken to prevent or detect them at the earliest opportunity. For example, assessing a patient's thiopurine methyltransferase (TPMT) status would make it possible to avoid using azathioprine in those patients with a homozygous TPMT deficiency, as bone marrow suppression in these patients would be a virtual certainty. The lack of specificity of most immunosuppressive agents means that regular full blood counts are required to monitor therapy.

Cyclophosphamide therapy carries with it particular risks of inducing haematological (acute myeloid leukaemia) and bladder malignancy (with oral therapy). It is important to monitor the cumulative doses

Class	Examples	Major adverse effects
Glucocorticoids	Prednisolone	Adrenal suppression Glucose intolerance/diabetes Osteoporosis
Alkylating agents	Cyclophosphamide	Marrow suppression Bladder toxicity Gonadal toxicity
Antimetabolites	Methotrexate	Marrow suppression Liver toxicity Pneumonitis
	Azathioprine	Gastrointestinal intolerance Marrow suppression Liver toxicity
Drugs acting on immunophilins	Ciclosporin	Nephrotoxicity Hyperkalaemia Hypomagnesaemia
	Tacrolimus	Neurotoxicity Cardiotoxicity
Interferons	–	Influenza-like symptoms Cardiovascular effects
Mycophenolate	–	Marrow suppression Increased susceptibility to infection
Fingolimod	–	Bradycardia Atrioventricular block QT prolongation

of cyclophosphamide received, to identify those patients at greatest risk of these adverse effects. Susceptibility to infections during cyclophosphamide therapy is minimized by the use of prophylactic co-trimoxazole.

303 Defences against infection

Ajit Lalvani and Katrina Pollock

Innate, cellular, humoral, and combined defences

The immune system is classified into a series of component parts, each specialized to defend the host against infection (see Box 303.1); consideration of the acquired and rare congenital immune deficiencies provides insight into this defence (see Table 303.1). Cells of the innate immune system are distributed throughout the body, in the tissues, and in the circulation, to defend against the first signs of danger, combining the acute inflammatory response with the ability to kill and remove invading pathogens. Monocytes, macrophages, and neutrophils phagocytose and kill exogenous and endogenous targets, using both oxygen-dependent and oxygen-independent mechanisms. Some species such as *Mycobacterium tuberculosis* avoid these mechanisms and can grow intracellularly. The fundamental role of neutrophils is illustrated in chronic granulomatous disease, where a lack of oxidative killing leads to bacterial and fungal infection and excessive inflammation. Neutrophil deficiency increases risk of bacterial sepsis and may be acquired from some medications, or occur in autoimmunity

Box 303.1 Basic immunology

Innate responses

Phagocytosis

- monocytes–macrophages: circulate as monocytes; upon contact with antigen, mature into phagocytic macrophages; includes tissue-specific forms (e.g. Kupffer cells in the liver)
- neutrophils: granulocyte; phagocytosis and killing of bacteria
- eosinophils: granulocyte; phagocytosis and parasitic defences

Immune modulation

- basophils: granulocyte; release preformed immune mediators
- mast cells: differentiate in tissues where they can release preformed immune mediators (e.g. histamine)

Complement

- a cascade of serum proteins which have intrinsic antipathogenic function, and interact with cellular and humoral responses

Antigen presentation

- dendritic cells: professional antigen presentation to instigate the adaptive response, includes a minority circulating population, and a majority tissue-resident population (e.g. Langerhans cells)

Adaptive responses

Cellular

- cytotoxicity:
 - natural killer cells: capable of antibody dependent and independent cell-mediated cytotoxicity
 - cytotoxic CD8⁺ T-cells: recognize antigen bound to MHC Class I molecules, and destroy infected cells
- T-cell help:
 - helper CD4⁺ T-cells: recognize MHC Class II molecules, secrete cytokines and chemokines, and provide help to macrophages, cytotoxic T-cells, and B-cells; several subtypes described

Humoral

- B-cells: mature B-cells produce membrane-bound antibody and, upon activation, divide to form memory cells and antibody-secreting plasma cells

or in haematological malignancies. Inherited complement deficiencies are rare, but infection with *Neisseria meningitidis* occurs in patients unable to form the membrane attack complex, the final step in the complement pathway.

The adaptive immune system creates a structurally specific and prolonged response mediated by lymphocytes to clear infection and generate immunological memory. It is instigated by antigen presentation, often by dendritic cells. T-thymocytes (thymic lymphocytes, or T-cells) are responsible for cellular immunity and comprise an array of subsets which are broadly described as T-helper cells (Th cells), T-cytotoxic cells (T_c cells), and T-regulatory cells. Aplasia of the thymus and failure of T-cell development (DiGeorge syndrome) results in a predisposition to chronic viral and fungal infections. B-lymphocytes (bone marrow cells, or B-cells) are present but, without Th-cell help, antibody production is abnormal. Natural killer (NK) cells kill virally infected and tumour cells; in Chédiak–Higashi syndrome, which is associated with severely depressed NK cell function, patients respond abnormally to EBV infection and have abnormal lymphoproliferation but normal immunoglobulin responses. B-cells create the humoral immune response. They express membrane-bound antibody specific for an antigen, which triggers the generation of antibody-secreting plasma cells. Some antigen–B-cell interactions require help from Th cells for this process to occur. Congenital plasma cell deficiency and hypogammaglobulinaemia (common variable immune deficiency) lead to recurrent infections. Hypogammaglobulinaemia may also be acquired in later life.

Routine testing for immunodeficiency is often not undertaken in the acute phase of an infection, as it is difficult to interpret the results and may be non-contributory. If immunodeficiency is felt to be a strong possibility, then the clinician should liaise closely with the local clinical immunology service, as immunodeficiency is a specialized area. Table 303.2 provides a broad overview of the different types of tests that should be considered for the different forms of immunodeficiency.

Causes of acquired immunodeficiency

HIV infection

The most common acquired immune deficiency is infection with HIV. In 2013, there were 35 million people living with HIV. Since the start of the epidemic, around 78 million people have become infected with HIV, and 39 million people have died of AIDS-related illnesses. The reason for the extreme virulence of HIV is manifest in its evasive multifaceted interaction with the human immune system. Untreated, HIV infection results in severe immune deficiency and infection with pathogens that would be controlled by an immunocompetent host. Cells bearing the CD4 receptor, including Th cells, dendritic cells, and monocytes–macrophages, are susceptible to infection. The destruction of CD4⁺ T-cells is profound during primary infection, after which there is a slow decline over 5–10 years, towards clinical immunodeficiency. Innate and cellular immune processes are affected early in infection; later, there is evidence of a combined immunodeficiency. Infection with HIV-1 conveys early susceptibility to progression of latent TB infection to active disease. Fungal infections (e.g. oral candidiasis) and viral recrudescences (e.g. varicella zoster virus), along with early malignancies such as cervical dysplasia, herald advancing immunosuppression. Late-stage disease is characterized by opportunistic infection that may be fungal (e.g. cryptococcosis), viral (e.g. CMV infection), bacterial (e.g. salmonella septicaemia), and protozoan (e.g. cryptosporidium infection). Treatment with highly active antiretroviral therapy

Table 303.1 Acquired and inherited immune deficiencies				
Immunity	Acquired	Examples of resulting infection	Inherited	Examples of resulting infection
Innate	HIV-1	TB	Chronic granulomatous disease	Susceptibility to bacterial and fungal infection due to lack of oxidative killing, except organisms that generate hydrogen peroxide (e.g. pneumococcus)
	Neutropenia secondary to autoimmune diseases (e.g. SLE) or iatrogenic causes (e.g. chemotherapeutic drugs)	Serious bacterial infections due to extracellular organisms (e.g. <i>Staphylococcus aureus</i> , <i>Escherichia coli</i>), and systemic fungal infection (e.g. <i>Candida</i> spp.)	Chédiak–Higashi syndrome	Recurrent bacterial infections due to failure of phagocytes to kill bacteria
	Steroids	Neutrophil adhesion deficiency Increased infection with <i>Staphylococcus</i> spp. and Gram-negative bacteria		
Cellular	HIV-1	Viral (e.g. CMV, herpes simplex virus 1 and 2, EBV) Bacterial (e.g. non-typhi <i>Salmonella</i> spp., TB) Fungal (e.g. <i>Cryptococcus neoformans</i> , <i>Candida</i> spp.)	DiGeorge syndrome	Defective or absent T-cell responses result in viral and fungal infections and chronic diarrhoea
	Iatrogenic causes Anti-tumour necrosis factor alpha therapy Steroids Other immunosuppressive agents (e.g. ciclosporin, tacrolimus)	Failure of cellular control of latent tuberculosis infection Viral, fungal, or opportunistic infection		
	Protein–calorie malnutrition	Infection with helminths, viruses (e.g. influenza), or protozoa (e.g. malaria)		
	Chronic infections (e.g. TB)			
Humoral	Acquired humoral immune deficiency	Recurrent bacterial infection (e.g. <i>Campylobacter</i> spp., <i>Mycoplasma</i> spp.)	Common variable immunodeficiency	Failure of B-cells to mature into plasma cells causes recurrent bacterial infections
	Hyposplenism	Encapsulated bacteria (e.g. <i>Neisseria meningitidis</i>) Protozoans (e.g. <i>Babesia</i> spp.)		
Combined cellular and humoral	HIV-1	Broad range of infections depending on the severity and underlying disorder, including bacterial, fungal, viral, and protozoan	Severe combined immunodeficiency	Severe recurrent infections, usually as a result of defective T-cell immunity (e.g. fungi and viruses), although defective B-cell immunity is also present
	Chronic morbidities Chronic renal failure Diabetes mellitus	Broad range of infections depending on the severity and underlying disorder, including bacterial, fungal, viral, and protozoan		
	Disorders of consumption Alcohol dependency Micronutrient malnutrition (e.g. zinc deficiency)	Broad range of infections depending on the severity and underlying disorder, including bacterial, fungal, viral, and protozoan		

Table 303.2 Initial investigation of immunodeficiency	
Type of suspected immunodeficiency	Specific investigations
All	Full blood count with differential white-cell count
Antibody deficiency	Immunoglobulin levels, especially IgG, IgA, IgM IgG subclass analysis
B/T-cell deficiency: <ul style="list-style-type: none"> ● number ● B-cell function ● T-cell function 	Quantification of B- and T-cell numbers Antibodies to routine immunizations (e.g. <i>Haemophilus influenzae</i> type b, pneumococcus) Skin tests for delayed-type hypersensitivity, cell response to mitogens
Neutrophil/phagocyte deficiency	Absolute numbers of full blood count (may be neutropenic) Reduction of nitro blue tetrazolium chloride
Complement deficiency	Total serum classic haemolytic complement test/alternative haemolytic complement test

suppresses viral replication, to prevent and partially reverse the immune destruction.

Other acquired immunodeficiencies

Other acquired immunodeficiencies include the cellular immune deficiency of chronic renal failure, which is due to chronic immune activation, reduced immune function, vitamin D deficiency, and lymphopaenia. The latter may be mediated by uraemia, predisposing T-cells and B-cells to apoptosis. Progression of latent TB to active disease is increased in these patients and is exacerbated by advancing age, low body mass index (BMI), and the presence of diabetes mellitus. Uraemia affects the innate immune responses; macrophage cytotoxicity is impaired *in vitro* and neutrophils are less able to kill organisms intracellularly, increasing bacterial sepsis. Patients may also have an underlying hypogammaglobulinaemia, and vaccine responses are impaired.

Diabetes mellitus

Diabetes mellitus predisposes to infection through uncontrolled blood sugar, minor trauma, and immune suppression. The immune dysfunction in diabetes is wide-ranging, including deficiencies in complement, and impaired monocyte phagocytosis and chemotaxis. Glycaemia leads to increased immune activation and basal cytokine levels, but neutrophil, monocytes–macrophage, and T-cell functions are all depressed. Patients commonly experience fungal infections, such as candidiasis, and bacterial infections of the extremities, as well as frequent urinary tract and respiratory infections.

Steroids and other immunosuppressive drugs

Steroids and other immunosuppressive drugs are agents that have broad-reaching immunological effects. Long-term use of steroids such as prednisolone causes neutrophil and cellular immune dysfunction, and hypogammaglobulinaemia may occur, although the functional significance of this is unclear. Bacterial and yeast infections, such as candidiasis, are more common and more severe. Azathioprine causes dose-related bone marrow suppression with neutropenia and a high risk of bacterial sepsis. Mycophenolate, used post organ transplantation, increases susceptibility to opportunistic infections, especially CMV. The calcineurin inhibitors ciclosporin and tacrolimus affect T-cell immunity and may reduce antiviral immunity. Finally, therapy with drugs blocking tumour necrosis factor- α (TNF- α) or its receptor, to reduce the inflammatory process in rheumatoid arthritis, has inadvertently revealed the importance of TNF- α in the control of *Mycobacterium tuberculosis* infection. Where therapy is considered, screening for and treatment of latent TB infection will reduce the risk of progressive disease.

Malnutrition

Malnutrition is a common cause of immunodeficiency worldwide; protein–calorie malnutrition causes thymic damage and a reduction in T-cell memory responses; skin test reactivity is reduced, and there is an increased risk of viral, bacterial, parasitic, and opportunistic infection. Micronutrient deficiencies cause patterns of immune dysfunction: zinc deficiency alters thymic and T-cell functions; copper deficiency is associated with lymphopaenia and a reduced interleukin-2 response; and selenium and vitamin E deficiencies damage antioxidant defences. Vitamin C is necessary for phagocyte function, and its deficiency increases the risk of infections. Nutritional insufficiency, chronic immune activation, and liver dysfunction contribute to the immune deficiency seen in chronic heavy alcohol intake. Long-term alcohol dependents are at much greater risk of post-operative infection; this may be related to downregulation of the pro-inflammatory Th type 1 response. Progression from latent to active disease and death from TB are both associated with alcohol dependence.

Organs and tissues involved in defence against infection

The spleen

Disorders of splenic function greatly affect the immune response. The spleen removes senescent red blood cells and traps antigen for presentation. It is important for phagocytosis and antibody production,

as T-cells are found in the white pulp surrounding the splenic arterioles, and B-cells are found in the marginal zones. Infectious causes of splenic enlargement include malaria, EBV infection, leishmaniasis, TB, and bacterial infections such as *Salmonella typhi*, resulting in hypersplenism, pancytopenia, and, in some cases, a functional immune deficiency. Hyposplenism from surgical removal, trauma, or splenic atrophy in coeliac disease increases the susceptibility to infection with encapsulated bacteria (e.g. *Neisseria meningitidis*). Patients with hyposplenism should be given vaccination for pneumococcus, *Haemophilus influenzae* type b, meningococcus, and influenza. Oral prophylaxis with phenoxymethylpenicillin or erythromycin is recommended.

The skin

Human skin forms a barrier defence that contains a network of immune cells. The outer epidermal layer consists of a tightly knit keratinized layer, which prevents the entry of microorganisms; breakdown secondary to conditions such as eczema or burns greatly increases the risk of localized infection. The keratinocytes express major MHC Class II molecules and can produce cytokines such as interleukin-23 which enhances Th type 1 responses. The second dermal layer includes sebaceous glands that form acidic sebum (pH 3–5) to inhibit microbial growth. Skin-associated dendritic cells (Langerhans cells) are migratory and can move to draining lymph nodes to present antigen. Immune reactions manifesting in skin can form useful diagnostic tools; for example, the delayed-type hypersensitivity (type IV hypersensitivity) reaction has been used for a century in the diagnosis of tuberculosis, and the wheal and flare of atopic urticaria (type I hypersensitivity) is used in the assessment of response to common allergens; these reactions are depressed in conditions associated with cellular immune suppression (e.g. HIV-1 infection, and uraemia). Breaches of the integumental defences, either through instrumentation or via indwelling devices such as IV lines (e.g. Venflons, central lines), are common sources of nosocomial infection. Localized pyogenic collections may occur, or more serious disseminated bacteraemia or fungal infection. To reduce this risk, such devices should only be used where absolutely necessary, should be placed using an aseptic technique, and should be changed regularly as a matter of course or at the first sign of infection.

The gastrointestinal system

Gut-associated lymphoid tissue forms a network throughout the gastrointestinal tract. A large population of CD8⁺ T-cells are found in the small intestine. The lamina propria contains many subtypes of immune cells. Below the lamina propria are Peyer's patches, which are loose aggregation of dendritic cells, T-cells, and germinal follicles. Specialized M cells, which are similar to enterocytes, transport antigens across the Peyer's patches. Primary HIV infection causes preferential and, to some extent, irreversible loss of CD4⁺ cells in the gut mucosa.

Mucous membranes

The mucous membranes lining the conjunctivae, respiratory, genitourinary, and gastrointestinal tracts use secretions to prevent pathogen binding to the epithelium. The secretions contain defensive proteins, including large amounts of IgA antibody, and lysozyme, which cleaves components of bacterial cell walls. Secretory IgA from plasma cells is able to form complexes with large viral and bacterial antigens, which are then removed with the rest of the secretions. Secretions are reduced in volume in cystic fibrosis; in the respiratory tract, this encourages colonization, infection with pathogenic bacteria such as *Pseudomonas aeruginosa*, and inflammation.

Conclusion

Where there are deficiencies in the immune system, either present from birth or acquired through other disease processes or treatment, there is vulnerability to infection which can be often fatal. A basic understanding of the cellular, humoral, integumental, and secretory defences against infection is fundamental both to the recognition of pathological immune deficiency and to the recognition of infectious processes. Congenital defects are rare but their specificity has

provided insight into the immune system's components. Acquired immune deficiencies are common but often overlooked, to the detriment of patient care. Understanding how the immune system defends the body and recognizing when it is likely to be deficient can promote prescient action for the treatment and support of affected patients.

304 Nature and demographics: Epidemiology of infective organisms

Andrew Lever and Sian Coggle

Definition of disease

An infection is an interaction between a host and a parasitic microorganism, with the interaction being deleterious to the host. Its occurrence and outcome are a combination of the nature of the organism, the site at which it is found, and the competence of the host defensive (immune) system. There are around 1500 documented agents that are infectious for man. The majority of the microorganisms in the world do not cause disease in humans. An organism which in one bodily compartment may be a beneficial commensal (such as some gut bacteria) may become a pathogen if it escapes into the blood. Similarly, a benign organism, such as the BCG mycobacterium used as a vaccine, may become a life-threatening infection in a patient with a serious immunodeficiency. Many microorganisms cause disease by accident. *Neisseria meningitidis*, despite its name, is designed to be a throat commensal. Invasion of the blood and subsequently the cerebrospinal fluid is a mistake, and a dead-end niche for the bacterium, as well as being highly lethal to the host.

Infectious agents are incredibly diverse, in their physical nature, in their complexity (from a prion to a helminth), and in the diseases they cause (from the 'common cold' to the haemorrhagic fever caused by Ebola virus).

Demographics of infectious disease

In resource-poor settings, infectious diseases are associated with poverty and overcrowding, and lead to a greater proportion of the morbidity and mortality than in the developed world. As antimicrobial use has increased in the latter, the burden of disease has decreased, but it has also resulted in new problems emerging, such as antibiotic-resistant organisms (e.g. methicillin-resistant *Staphylococcus aureus* (commonly referred to as MRSA), or the depletion of commensals and thus allowing the overgrowth of disease-producing organisms such as *Clostridium difficile*.

The global epidemiology of infectious diseases has changed rapidly over the last few decades. Increased air travel has meant that new epidemics can spread much more rapidly around the world (e.g. SARS) and also that diseases such as malaria, which were traditionally thought of as 'tropical' diseases, now must be included in some differential diagnoses in more temperate countries. New infectious diseases are constantly appearing—approximately one per year for the last 25 years—such as HIV or H1N1 'swine flu', and some old problems are re-emerging (e.g. drug-resistant forms of TB). In addition, climate change is likely to influence epidemiology in the future, as vector habitats and breeding patterns are altered.

Pathogenic organisms

There are four categories of causative organisms recognized for infectious diseases: prions, viruses, bacteria, and eukaryotes.

Prions

Prions consist of only a single protein. They contain no nucleic acid, and disease arises as a consequence of their inducing the homologous host protein to physically mutate into a prion protein. Diseases caused by prions have been recognized for many years, but their biological nature was established only recently, and their properties are still being fully elucidated.

Viruses

Viruses contain either RNA or DNA as their genetic material, and have to utilize host cell machinery to replicate; they are obligate intracellular parasites. They range in size from 20 nm to 300 nm. They cause disease either by direct cytopathicity or as a consequence of the damage caused by the immune system in trying to clear them. Viral infections can be diagnosed in a variety of ways, including through the use of PCR or serological tests.

Bacteria

Bacteria have a genome encoded by DNA. They have a cell membrane, and most are able to replicate independently of their host. They are generally larger than viruses. Bacteria can cause disease by direct damage to tissue, through the secretion of exotoxins, or by endotoxin-mediated hyperactivation of the immune system. They can generally be diagnosed by culture, although some require special media or may be extremely difficult to grow. In some cases, serology is an alternative and, when appropriate, the toxins can be used in diagnosis. Generic PCR methods, such as 16S ribosomal PCR, are becoming more widely used.

Eukaryotes

Eukaryotes infecting man are the most complex of the causative organisms and are extremely diverse, from unicellular amoebae, to fungi, or multicellular helminths. They all have function-specific organelles. Diagnostics for this category are equivalently diverse, ranging from microscopic examination of a 'hot' stool specimen for amoebae to macroscopic identification of a tapeworm, as well as including serology.

Modes of transmission

There are many possible modes of transmission of infectious agents. Commensal organisms can, under certain circumstances, cause infection in their hosts (e.g. coliform bacteria from the gut leading to a urinary tract infection). Other organisms only cause an infection when they are transmitted to a new and susceptible host, by one of the methods detailed in this section.

Environmental reservoir

Organisms may have a reservoir in the soil (e.g. *Clostridium tetani*), where they are able to exist independently of a human host. Some parasites, such as *Strongyloides stercoralis*, have a stage of their life cycle which involves soil-living larvae, although the adult worms require a vertebrate host. Organisms with an environmental reservoir are rarely capable of direct person-to-person spread.

Animal reservoir

Zoonotic infections are transmitted from another vertebrate host to a human, in a number of different ways (e.g. via eating an infected foodstuff (*Salmonella enteritidis*) or through inoculation of saliva into a bite (rabies)). Examples of zoonoses can be found from all forms of causative organisms, and they can often be transmitted onwards from person to person.

Vector-mediated transmission

Arthropod vectors can transmit disease from animal to person, or person to person. Usually part of the life cycle of the pathogen

occurs inside the vector, and a specific arthropod is required for each organism (e.g. *Plasmodium falciparum* inside the gut lining of the female *Anopheles* mosquito). Vector-borne diseases are generally a problem in tropical climates, but this has the potential to change if the correct vector is present (e.g. the Chikungunya outbreak in Italy in 2007, transmitted by the *Aedes albopictus* mosquito).

Direct person-to-person transmission

Direct person-to-person transmission encompasses several modes of transmission. Airborne spread of droplets or droplet nuclei is a common method of transmission of respiratory tract infections (e.g. influenza). Direct contact with skin infections or infestations may lead to transmission (e.g. scabies). All sexually transmitted infections rely on direct contact during sexual intercourse. Blood-to-blood contact can occur (e.g. during delivery, or as a result of sharing needles) and transmit agents such as HIV and the hepatitis B and C viruses.

Indirect person-to-person transmission

Sometimes organisms can survive for a period of time outside their host, and this means they can be transmitted via an intermediate surface (e.g. via a fomite or a stethoscope). Examples include typhoid or cholera.

Epidemiology

Epidemiology is the study of the aetiology, distribution, and control of a disease in a defined population. By knowing the epidemiology of infectious organisms, it is possible to refine a differential diagnosis, and limit the number of investigations needed. Certain specific definitions pertain:

- **incidence:** the number of new cases of a specific disease in a designated population over a defined time period, usually expressed as a proportion of the total study population
- **prevalence:** the total number of cases in a designated population at a specific point in time, expressed as a proportion of the total study population
- **endemic infection:** one which remains at a relatively constant rate, with respect to both incidence and prevalence, in a population over a prolonged period of time
- **epidemic infection:** occurs when there is a significant increase from the expected incidence of a disease over a defined time period
- **pandemic:** a worldwide epidemic
- **incubation period:** the time from a patient becoming infected with a specific disease, to the development of clinical symptoms
- **latent or pre-infectious period:** the time from a patient becoming infected with a specific disease, to them becoming infectious to others; this is often slightly shorter than the incubation period, and can have important implications for contact tracing
- **secondary attack rate:** a measure of the transmissibility or infectiousness of a disease; it is the risk of developing a secondary case amongst all those exposed to a primary case; thus, if four people were exposed to an infection, and two of them developed the disease, the secondary attack rate would be 2/4, or 50%
- **case reproductive number:** the average number of secondary cases that are caused by a single case of the infection; for example, a single patient with measles will infect, on average, 12 other susceptible people (note: in an endemic infectious disease, the net reproductive number needs to be greater than 1 for the rates to be maintained, so the aim of many disease control programmes is to decrease the reproductive number to less than 1)
- **herd immunity:** this occurs if there are sufficient people immune to a specific disease in a population so that the infection rates are very low and thus those who are susceptible are indirectly protected from infection; this phenomenon is part of the rationale behind mass vaccination programmes

Diagnostic approach to a patient with a possible infection

Infections can affect any system of the body and may be multisystemic. They can therefore present in a huge variety of ways. Not all infections lead to a fever, and not all fever is a result of infection. It is important to remember other causes, such as neoplasia or autoimmune disease, in the differential diagnosis. If infection is suspected, it is essential to consider where the patient may have acquired the disease, and also the patient themselves. Community-acquired infections from outside the hospital environment may be due to a diverse group of organisms. Nosocomial (hospital-acquired) infections result from a patient's admission. Between 5% and 10% of all hospital patients will acquire a nosocomial infection. Factors which increase this probability include a prolonged admission, intensive care treatment, and the use of prosthetic devices (e.g. intravascular catheters). The main types of nosocomial infection are lower respiratory tract infections, urinary tract infections, wound infections, and intravascular catheter-site infections. The heavy use of antimicrobial therapy in hospitals imposes a selection pressure towards resistant organisms, which must be considered in the treatment of nosocomial infections.

A patient with a compromised immune system will be susceptible to a wider range of infections, including unusual pathogens such as fungi or mycobacteria. A patient may have a weakened immune system as a result of a concurrent illness (e.g. HIV infection or leukaemia), due to treatment they are receiving (e.g. chemotherapy), or because of their age or nutritional status. It is important to recognize this, as the differential diagnosis will be different from that of an immunocompetent patient, and they may have more than one infectious disease simultaneously. Specific immune defects predispose to specific infections (e.g. hypogammaglobulinaemia and mycoplasma/ureaplasma infection).

The keys to the diagnosis of an infection, as in all of medicine, are a detailed history and a thorough clinical examination. Specific investigations for certain infectious diseases will be detailed elsewhere. Some key points to note are detailed in this section.

History

Within the detailed history, knowledge of likely epidemiological risk factors should trigger specific lines of inquiry:

- a full travel history: this is vital, as exposure to some pathogens (e.g. *Plasmodium falciparum*) will only occur if a patient has visited the appropriate geographical area
 - details about dates of travel, the conditions in which the patient stayed, as well as their activities and dietary habits while away
 - a vaccination history and appropriate prophylaxis use
- any exposure to animals, both domestic and wild, for zoonotic infections
- occupational history: this may reveal important exposures
- hobbies (e.g. canoeing may lead to exposure to water-borne pathogens)
- a full sexual history: this is important not only in the case of suspected sexually transmitted infections but also to help assess the patient's risk for HIV and any associated immune suppression
- previous or current IV drug use: this is associated not only with the acquisition of blood-borne viruses, but also with an increase in some bacterial or fungal diseases, due to the skin penetration; tattoos, piercings, and blood transfusions should also be noted if there is a possibility of blood-borne virus infection
- recent food history and source water: this may be relevant in certain cases
- close contact with children under 5 years old: this can increase the risk of certain viral infections

Clinical examination

A thorough general examination is required, particularly including assessment for lymphadenopathy, and ear, nose, and throat examination. Many infections cause a rash, so careful observation of the skin is necessary. If a sexually transmitted disease is being considered, a full genital examination should be performed.

A full set of observations should be obtained to help assess the severity of any possible infection; in addition, check for signs of septic shock.

Basic investigations

Basic investigations will vary, depending on the clinical picture, but the vast majority of patients with a suspected infection should have the following investigations:

- blood tests (see Table 304.1):
 - a full blood count, including a differential white-cell count
 - a coagulation screen
 - renal and liver function tests
 - C-reactive protein level, and erythrocyte sedimentation rate
- microscopy and culture:
 - all febrile patients should have a blood culture, and urine dipstick and culture where appropriate

Table 304.1 Interpretations of common blood test results in the context of infection

Result of investigation	Causes to consider
Anaemia	Malaria Helminth infection Overwhelming sepsis
Neutrophilia	Bacterial infection
Neutropaenia	Overwhelming sepsis Viral infection
Lymphocytosis	Viral infection
Lymphopaenia	Viral infection, particular consideration to HIV
Atypical lymphocytes	Infectious mononucleosis
Eosinophilia	Helminths
Thrombocytosis	Abscess
Thrombocytopenia	Overwhelming sepsis Malaria HIV
Deranged coagulation	Overwhelming sepsis Hepatitis
Markedly elevated transaminases	Viral hepatitis
Raised C-reactive protein level and erythrocyte sedimentation rate	Non-specific sign of infection or inflammation.

- where clinically indicated, sputum samples should be cultured and, if TB is on the differential, the sputum should be examined and stained for acid-fast bacilli
- in patients with diarrhoea, faecal samples should also be taken for routine culture and examination for ova, cysts, and parasites if there is an appropriate history
- any other clinically indicated specimens, such as CSF or wound swabs, should be sent for microbiological examination
- radiology: depending on the clinical presentation, X-ray, ultrasonography, CT, MRI, PET CT, or radionuclide scanning should be used to help localize infection
- echocardiography, if bacterial endocarditis is suspected
- culture of samples from aspiration/biopsy of infected sites is often the critical diagnostic procedure

Treatment and prognosis

Most infections never come to medical attention, and are cleared by the immune system. If, however, treatment is needed, there are therapeutics for most bacterial and fungal infections. Fewer treatments are available for eukaryotic and viral pathogens (in some cases, none), with a few exceptions. The outcome of infection with HIV, for example, has been revolutionized from certain death 30 years ago to there now being over 25 therapeutics, in 6 drug classes, available, and a normal life expectancy if drug adherence is good. For other infections, particularly rare ones in the developing world, the picture is very different, and economic circumstances define access to many drugs. The competence of the host immune system is critical. Pathogens with the capacity to persist in human hosts often can mutate to become resistant to drugs and can evade the immune system. There has been far too slow acceptance of the fact that, for most, if not all, of these diseases, combination therapy is the only way to ensure successful treatment.

305 Diagnosis in suspected infective disease: The history and examination

Ajit Lalvani, Katrina Pollock, and Manish Pareek

Introduction

Physicians assessing a patient with a suspected infective disease should bear in mind that the clinical presentation primarily results from the interaction between organism(s) and host, although this can be modulated by the environment. Therefore, while the critical elements of the diagnostic process for an infective disease follow the same basic tenets as for any clinical assessment—in other words, history, examination, and supportive investigations—this should be tailored when assessing patients who are presenting with an infectious disease, so that appropriate antimicrobial and supportive therapy can be commenced.

History

Obtaining a coherent history from the patient with a suspected infective disease requires a holistic outlook whereby the clinician should aim to collate information about the following aspects:

- the patient's background
- potential exposures to infectious organisms
- details about the illness

Patient's background

A full understanding of the patient's background can help to quickly narrow down the list of potential diagnoses.

Age

One of the most important questions to ask is the patient's age. Risk of infection, the likely causative organism, and the clinical pattern of disease change according to the subject's age.

Age modulates immunity against infection, with individuals at the extremes of life more prone to infection. Neonates (particularly when maternal antibodies have waned) and young children have immature immune systems, while the elderly are immunocompromised, either due to immunity waning over time or, more usually, due to coexisting medical conditions (such as diabetes mellitus) or medications (such as steroid therapy).

The types of organisms causing clinical disease also changes with age. Broadly speaking, children and young adults present with viral infections (such as infection with respiratory syncytial virus, CMV, and EBV), whereas more elderly patients are prone to bacterial infections—especially urinary tract and lower respiratory tract infections. However, this does not mean that children and young adults do not develop bacterial sepsis; the difference simply is that the spectrum of causative bacteria changes. This is highlighted if one considers the case of which organisms cause bacterial meningitis (see Table 305.1).

Clinical presentation of disease may also differ according to age. While children and young adults with established infection would usually be expected to present with a high-grade fever ($>38^{\circ}\text{C}$), elderly patients can often present non-specifically without fever or, in some cases, with hypothermia. This is likely to be due, at least in part, to the host immune response—where a vigorous response results in marked symptomatology.

Preexisting medical conditions

Preexisting conditions can increase the chance of a patient developing an infection, and it is important to enquire about this in the

Table 305.1 Common organisms causing bacterial meningitis in different age groups

Age group	Common organisms
Neonates	Group B streptococci <i>Escherichia coli</i> (carrying K1 antigen) <i>Listeria monocytogenes</i>
Young children	<i>Neisseria meningitidis</i> <i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i>
Adults	<i>Streptococcus pneumoniae</i> <i>Neisseria meningitidis</i> <i>Haemophilus influenzae</i>
Older adults	<i>Streptococcus pneumoniae</i> <i>Neisseria meningitidis</i> <i>Listeria monocytogenes</i> (if >50 years of age) Aerobic Gram-negative bacilli

history. It is useful to consider these conditions under two main headings:

- conditions which affect host immunity
- conditions which allow infection to become established

Underlying immunocompromise can be caused by a medical condition (such as diabetes mellitus or HIV infection) or due to the medication an individual is receiving (such as chemotherapy for neoplasia, or azathioprine for inflammatory bowel disease). The immunocompromised host can be difficult to manage clinically, but making the correct diagnosis is critical as they are more prone to acquiring infections, developing disseminated disease/complications, and becoming infected with a wider range of pathogens.

HIV deserves special mention. As HIV infection becomes more advanced and cellular immunity is affected, individuals become more prone to atypical infections, which are unlikely in those with an intact immune system. Therefore, it is important to enquire about an individual's HIV status (if known) or to test for it, as it will affect the clinical decision-making process. For example, if an individual has fever and headache, a potential diagnosis is bacterial or viral meningitis if the individual is not HIV-positive whereas, for HIV-infected individuals, the differential diagnosis would also include tuberculous meningitis, cryptococcal meningitis, and CNS toxoplasmosis. This clearly will affect the investigations that are undertaken, as well as the empiric therapy that will need to be commenced.

Aside from the host's immune function, it is also important to enquire about other risk factors that render increased host susceptibility to infection. This encompasses individuals with prosthetic devices (such as heart valves, joint replacements, and semi-permanent central venous catheters), which can become foci of infection; those with chronic suppurative lung infection (such as cystic fibrosis, where thick sputum becomes infected); and individuals with anatomical abnormalities, such as strictures within the renal tract (where the slow flow of urine results in the tract becoming infected).

Sociodemographic factors

Certain infections are also more common in those who were born in developing-world nations but have since migrated to the developed

world. It is useful to ask the patient where they were born, where they grew up, when they migrated, and how long they have been living in the receiving country. The pattern of disease seen in immigrants is likely to be very different from that seen in the locally born population. Much of this can be attributed to the different type and quantity of exposure to pathogens during childhood and young adulthood (as most migrants will leave their country of origin as young adults). As a consequence, it is clear that a number of infections are more common in immigrants, including latent TB infection, active TB, hepatitis B/C, and gastrointestinal helminths. An additional point to note is that immigrants are also more likely to continue returning to developing countries to visit friends and relations, which puts them at risk of travel-associated infections such as malaria, dengue, and typhoid fever (see 'Travel history').

Exposure to infectious agents

The clinician should make a point of asking about all aspects of the patient's life, even if some of the questions may be considered intimate, to understand the nature and risk of potential exposure to infectious pathogens. Specific areas to enquire about include travel history; recent operations or antibiotic therapy; lifestyle choices (including occupation); and a family history of infectious diseases.

Travel history

International air travel to all parts of the world has increased hugely and become much more affordable to the general public. As a consequence, enquiring about recent travel is undoubtedly important in an individual presenting with a suspected infective disease. Physicians should ask very detailed questions about the dates of travel, the specific countries (and areas) visited, the type of stay (e.g. a business visit to a 5-star hotel is very different from backpacking), and personal behaviour (such as avoiding local street foods, drinking bottled water, and avoiding mosquitoes). It is also important to establish whether the patient took pre-travel medical advice with respect to travel vaccinations and malaria prophylaxis (as well as whether they were compliant during and after the trip with the medication).

Recent medical procedures/antibiotics

Conventional history taking often overlooks previous contact the patient has had with medical professionals. However, this should be specifically asked if infection is present. For example, if the patient has had recent dental work or a colonoscopy of the bowel and presents with fever and a murmur, infective endocarditis should be included in the differential diagnosis. Similarly, in a patient presenting with diarrhoea, it is important to specifically ask about any recent courses of antibiotics (enquire about the name and duration) as *Clostridium difficile* is a possibility.

Lifestyle factors

Understanding the personal behaviour of the patient is also important. This includes a number of areas, but specific enquires should include blood-borne virus risk (through recreational drug use as an IV drug user, as this increases the risk of hepatitis B/C and HIV infection) and sexual history (if appropriate from the clinical presentation).

Occupation is also important. Certain occupations have an increased risk of exposure to specific pathogens, and clinicians should make sure this is established during the history. For example, healthcare workers will be at a higher risk of occupational exposure to blood-borne viruses (such as hepatitis B/C and HIV) and respiratory infections (such as influenza and tuberculosis), while individuals who work in drains/sewers are at an increased risk of acquiring leptospirosis.

Family history/contact with pathogens

Infectious diseases are, by definition, communicable, and can occur from a single infectious source. In this respect, family structure is relevant, as infections can spread rapidly from member to member, but also because they may all be linked, epidemiologically, to a source of infection (e.g. food poisoning from a restaurant meal). It is important to directly enquire about other family members who are unwell or have already been diagnosed with an infection (e.g. pulmonary TB or a diarrhoeal illness). In this way, the admitting physician can narrow down the differential diagnosis, and instigate therapy more rapidly while also limiting the spread of the infection.

Features of the presenting illness

With a fuller understanding of the patient's background and potential source(s) of exposure, the clinician must go on to establish the symptoms and signs of the presenting illness, so that appropriate investigations can be ordered.

Chronology of illness

On encountering the patient, the clinician should first attempt to delineate illness onset, including its date and nature (abrupt vs indolent). A further important point to establish is when the exposure/infection has occurred in relation to the onset of the symptoms, as this provides an indication of the incubation period (see Table 305.2).

The next step is to try and understand the course of the illness over time. One of the fascinating things about the clinical features of infectious diseases is how they evolve. While some illnesses usually result in rapid deterioration after initial presentation (e.g. meningococcal meningitis), others, such as TB, usually progress more slowly and symptoms may wax and wane. This must be established early in the history, as it will give important clues as to the etiological infectious agent.

A complicating factor is that the course of the illness can be modulated by previous antimicrobial/antipyretic therapy, and it is important to directly enquire about this from the patient.

Symptoms

Detailed questions about the symptoms are critical to the history-taking process. Physicians should ensure that they take time to get a clear understanding of the main symptoms, and the order in which they have appeared. Clinical features of infectious disease can be categorized as systemic or localized/organ specific.

An ongoing difficulty with diagnosing infectious diseases is that systemic symptoms, which are non-specific and non-contributory, often

Table 305.2 Common infectious diseases, their causative organisms, and the lengths of their incubation periods

Type of organism	Disease	Causative organism	Incubation period
Virus	HIV	HIV	2–4 weeks for acute seroconversion illness; many years until advanced HIV/AIDS
	Influenza	Influenza virus	1–5 days
	Dengue fever	Dengue flavivirus	3–14 days
	Dengue haemorrhagic fever		
	Measles	Measles virus (paramyxovirus)	6–19 days
	Mumps	Mumps virus (paramyxovirus)	15–24 days
	Rubella	Rubella virus (togavirus)	14–21 days
	Chicken pox	Varicella zoster virus	10–21 days
Bacteria	Diphtheria	<i>Corynebacterium diphtheriae</i>	2–5 days
	Tetanus	<i>Clostridium tetani</i>	3–21 days
	Typhoid	<i>Salmonella typhi</i>	7–14 days
Protozoa	Malaria (falciparum)	<i>Plasmodium falciparum</i>	1–4 weeks

predominate. As a consequence, they are not that useful at distinguishing different types of infection or, indeed, alternative differential diagnoses. Common systemic symptoms include fever, malaise, lethargy, anorexia/weight loss, and myalgia.

Fever is almost always present in patients who have an underlying infection. Although the definition of fever varies, a temperature above 38°C is generally considered to be abnormal. If the patient does complain of fever, it is useful to try and establish if it is constant or whether the temperature spikes at a certain time of the day. It is also important to determine if there are any associated symptoms with the fever—such as rigors. Rigors are episodes of severe, uncontrollable shivering, and characteristically occur in biliary sepsis, pyelonephritis, malaria, and visceral abscesses. They are less common in viral infections.

Other systemic symptoms, such as anorexia/weight loss, malaise, and lethargy, are fairly common in most infections and are indication of the underlying inflammatory response. Myalgia is also seen in a number of infections, although its severity will vary. While it may be relatively mild in influenza, it may be very severe in dengue, malaria, or leptospirosis.

Localized, site-specific symptoms (such as dysuria and cough) are important to elucidate, as they usually help to identify the specific organ system involved (see Table 305.3 for common localizing syndromes). Armed with this information, the clinician can focus the clinical examination and ensure that site-specific samples are obtained which will increase the chance of identifying the infecting organism. However, it must be understood that some symptoms which appear to be localizing may, in fact, not be. For example, in the returning traveller with fever and diarrhoea, it is tempting to consider this to be simply due to gastroenteritis, even though malaria presents in this way and will be rapidly fatal if not diagnosed and treated appropriately.

After completion of the history, the next step for the physician is to use the information that has been gathered, to underpin a thorough examination of the patient.

Examination

A thorough physical examination is essential in the assessment of suspected infective disease; the physiological state of the patient is gauged, and clinical signs are elicited that, with the constellation of symptoms, build the initial differential diagnosis. This is the major opportunity to comprehensively characterize the patient's condition and enables the clinician to tailor the subsequent investigation plan to be relevant, directive, and brief.

Examination of the patient with suspected active disease should focus on the following areas:

- general appearance
- the lymph system
- the skin
- cardiovascular status
- the respiratory system
- the abdomen
- the eyes, and neurological assessment
- the ears, the nose, and the throat

Findings of particular significance in the examination of the immunocompromised patient are summarized in Box 305.1.

General appearance

The severely unwell patient should be quickly recognized by assessment of pallor or erythema, sweating, ambulatory ability, cognitive functional status, and conscious level (see Box 305.2). Body temperature should be recorded.

The lymph system

The pattern and nature of lymphadenopathy is a useful tool in the diagnosis of infectious disease (see Table 305.4), and examination can identify nodes suitable for biopsy. Examination of the tonsils and the submandibular, preauricular, cervical, clavicular, axillary, epitrochlear, and inguinal lymph nodes for palpable lymphadenopathy should be coupled with inspection of the skin for visible causes such as a

Table 305.3 Localizing symptoms, and the differential diagnoses associated with each one

Organ system	Clinical symptoms	Differential diagnosis
Cardiac	Chest pain	Infective endocarditis TB
Respiratory	Dyspnoea Cough Haemoptysis	Pneumonia Pleural effusion TB Malaria Influenza Respiratory syncytial virus Parainfluenza
Gastrointestinal	Diarrhoea Abdominal pain Jaundice	Viral gastroenteritis Malaria <i>Clostridium difficile</i> Bacterial diarrhoea (<i>Escherichia coli</i> , <i>Salmonella</i> sp., <i>Shigella</i> sp.) Typhoid Giardia Amoebic dysentery TB Hepatitis (A/B/C/E) Infectious mononucleosis (EBV) CMV Leptospirosis Pyogenic liver abscess
Neurological	Headache Meningism Confusion	Meningitis (bacterial, viral, tuberculous, fungal) Encephalitis (viral) Malaria Leptospirosis Dengue Any infection can cause confusion, as part of the sepsis syndrome
Genitourinary	Dysuria Haematuria Discharge Ulceration	Urinary tract infection (bacterial) TB Malaria Schistosomiasis Sexually transmitted infection
Dermatological	Rash	Wide range of conditions Specific type of rash will allude to underlying cause

cellulitis or an infective lesion (e.g. for *Bartonella henselae*). If lymphadenopathy is found, the major differential diagnosis for infection is neoplasia. Generalized lymphadenopathy due to infection is less common than localized eruptions and should immediately alert the physician to the possibility of the persistent generalized lymphadenopathy of HIV infection. Other common causes of generalized lymphadenopathy include infectious mononucleosis; disseminated bacterial infection, such as brucellosis; and rare fungal infections, such as histoplasmosis.

The skin

Infection often manifests in the skin, and descriptive classification detailing the distribution, colour, form, and location (including in the mouth, the nails, and the genitalia) of the infection can aid in the identification of the infectious disease (see Table 305.5).

Pyogenic collections are relatively common, ranging from folliculitis of hair follicles to larger abscesses; lesions are pustular, painful, and erythematous. Spreading forms of bacterial infection of the skin due to *Streptococcal* spp. and *Staphylococcal* spp. include cellulitis, which is common in diabetic patients; erysipelas; and bacterial fasciitis. The latter is a surgical emergency, recognizable by extreme tenderness, failure to respond to IV antibiotics, tissue

Box 305.1 Examination of the immunocompromised patient

HIV infection causes the most common acquired immunodeficiency worldwide. Elucidating the signs of immunocompromise can aid this often subtle diagnosis. As part of a full examination, the following areas should be focused on:

- the general appearance
- the mouth
- the lymph system
- the respiratory system
- the genitalia
- the nervous system

General appearance

There is evidence of wasting and cachexia in advanced disease. Infections are present in unusual distributions (e.g. facial *Molluscum contagiosum*).

The skin

Exacerbation of underlying skin conditions (e.g. psoriasis) is common. Other associated conditions include eosinophilic pustular folliculitis; skin manifestations of opportunistic fungal and mycobacterial infection; seborrheic dermatitis; and Kaposi's sarcoma. Seroconversion gives rise to a maculopapular rash.

The mouth

A thorough examination of the mouth is essential; signs of candidiasis, oral hairy leukoplakia, gingivitis, aphthous ulcers, and Kaposi's sarcoma should be sought.

The lymph system

Lymphadenopathy may occur at any stage of infection due to HIV (persistent generalized lymphadenopathy: enlarged lymph nodes in two or more extra-inguinal sites, for more than 3 months). Kaposi's sarcoma, TB, and lymphoma are also common causes. With more advanced disease, opportunistic and unusual infections, including atypical mycobacterial disease, bacillary angiomatosis, systemic fungal infection, and toxoplasmosis, are possible causes.

The respiratory system

Acute bronchitis and chronic sinusitis are common at all stages of disease. Pulmonary infection is one of the most common complications of HIV infection, either bacterial or due to *Pneumocystis jirovecii* (pneumocystis pneumonia; often referred to as PCP). Mycobacteria and fungi (e.g. *Cryptococcus* sp.) can cause florid pulmonary signs.

The genitalia

Manifestations of dermatological conditions may be found in the genitalia. Genital and rectal lesions due to HSV-1 and HSV-2 are common, as well as lesions of Kaposi's sarcoma, intra-epithelial neoplasia, and condylomata acuminata.

The nervous system

Central and peripheral neurological manifestations of HIV warrant careful examination and investigation, even if signs are subtle. The altered inflammatory response can reduce the signs of florid infection, and mild signs of headache or meningism may belie life-threatening pathology. Fundoscopy may reveal signs of CMV retinitis in late disease.

fluctuance, and warmth. Some rashes, such as shingles, which is dermatomal vesicular rash caused by recrudescence of varicella zoster virus (VZV) infection, are diagnostic; other skin manifestations (e.g. erythema multiforme) have many etiologies. Rashes that appear generalized at first may have a pattern of involvement that can hint at the underlying cause, such as scabies or dermatophyte infection. Lastly, infections such as syphilis mimic other conditions and change throughout the natural history of the disease; primary syphilis may appear as a painless, highly infectious ulcer at the site of inoculation, while secondary syphilis manifests as a generalized

Box 305.2 Recognition of the patient in septic shock

Sepsis is the physiological response to a major insult that is usually infective in origin. Septic shock is severe sepsis plus hypotension not reversed with fluid resuscitation. Recognition of the early stages of sepsis, before irretrievable organ damage has occurred, is crucial to patient survival. The examination should focus on:

- temperature
- general appearance and the skin
- the CNS
- the cardiovascular system
- the respiratory system
- the abdomen

Temperature

Look for fever (temperature $>38.3^{\circ}\text{C}$) or hypothermia (temperature $<36.0^{\circ}\text{C}$)

General appearance and the skin

Look for tissue perfusion, which is assessed from the capillary refill time, and the presence of mottling and cool peripheries. Rashes may represent a response to infection (e.g. the purpura of disseminated intravascular coagulation), haematogenous seeding of organisms (e.g. meningococcal or staphylococcal sepsis), or the source of infection (e.g. cellulitis).

The CNS

Altered mental status is common; evidence of alcohol or illicit drug use frequently confuses this picture and should not be assumed as the primary cause. Signs of meningitis should be carefully sought.

The cardiovascular system

Tachycardia (heart rate $>90/\text{min}$ or more than two standard deviations above the normal value for age) is common, and the pulse may be hyperdynamic. Assess for the presence of arterial hypotension (systolic blood pressure <90 mm Hg, mean arterial pressure <70 mm Hg, or systolic blood pressure decreased by >40 mm Hg in adults or more than two standard deviations below the normal value for age), and a postural drop in blood pressure.

The respiratory system

Tachypnoea is common; signs of respiratory compromise may be the respiratory response of normal lungs to lactic acidosis or incipient acute respiratory distress syndrome, secondary to sepsis as well as indicating a pulmonary focus of infection.

The abdomen

Ileus with absent bowel sounds may occur and there may be signs of underlying infection (e.g. diverticular abscess, subphrenic abscess, *Clostridium difficile*). Hyperglycaemia in the absence of diabetes is indicative of sepsis. Acute oliguria with urine output <0.5 ml/kg per hour for at least 2 hours despite adequate fluid replacement indicates renal dysfunction.

maculopapular rash or wart-like condylomata lata, and tertiary syphilis as skin gummata.

Cardiovascular status

Assessment of the circulatory status can indicate shock, abnormal fluid balance, or a hyperdynamic state as evidenced by skin temperature, capillary refill time, pulse rate, pulse character, jugular venous pressure, and blood pressure. Examination of the mouth and the conjunctivae for signs of anaemia should be undertaken, as anaemia of chronic disease (e.g. in TB), iron-deficiency anaemia (e.g. from intestinal parasites), or anaemia due to haemolysis (e.g. in *Treponema pallidum* infection, malaria, or haemophagocytosis secondary to certain viral infections) or bone marrow failure (e.g. in parvovirus B19 infection or following marrow replacement (e.g. due to disseminated fungal infection)) may be present.

Cardiac auscultation may indicate a murmur, due to infective endocarditis or viral myocarditis. Endocarditis is an important cause of

Distribution	Classification	Examples of aetiology
Localized	Viral	Acute self-limiting viral infection (e.g. adenovirus; cervical/axillary)
	Bacterial	Staphylococci and streptococci Acute bacterial lymphadenitis TB (e.g. cold abscess) <i>Bartonella henselae</i> (cervical/axillary) Lymphogranuloma venereum (inguinal) Tularaemia
	Protozoan	<i>Toxoplasma gondii</i> (occipital/cervical)
	Inflammatory	Reactive hyperplasia (e.g. rheumatoid arthritis)
	Neoplastic	Metastatic tumour (e.g. melanoma) Virchow's node Early stages of Hodgkin's and non-Hodgkin's lymphomas
	Generalized	Viral
	Bacterial	Brucellosis TB
	Fungi	Histoplasmosis Coccidioidomycosis
	Inflammatory	Dermatopathic (e.g. eczema) Sarcoidosis Medications
	Neoplastic	Late stages of Hodgkin's and non-Hodgkin's lymphomas

cardiovascular infection and should not be missed. Features include fever, evidence of valvular surgery, evidence of injecting drug use, splenomegaly, and vascular, embolic, or immunological signs, such as Osler's nodes in the extremities, and Roth spots on fundoscopy.

Lastly, assessment of pitting peripheral oedema may indicate poor physiological status, due to infection. Non-pitting oedema may be related to infectious lymphatic obstruction, which is sometimes florid in lymphatic filariasis (due to *Wuchereria bancrofti* infection).

The respiratory system

The respiratory examination may reveal a source of infection, or the physiological response to infection in the normal lung. The presence of chronic lung pathology such as bronchiectasis will alter the pattern and extent of disease. Measurements of pulse oximetry and respiratory rate are essential assessments of respiratory function. However, the respiratory rate is often raised in the presence of infection or pain and is not a specific sign of lung pathology (see Box 305.2). Unequal chest expansion can indicate unilateral compromise of one lung due to infection. The apices should be examined, as infection with mycobacteria or fungi can occur in this region. Pulmonary infections are common in the developed world, and classic signs of fever, hypoxia, and consolidation (bronchial breathing, reduced air entry) may be coupled with gastrointestinal symptoms and changes in mental status. Pleuritic chest pain may indicate an effusion, and the overlying area should be percussed for dullness and carefully auscultated. Common causes of pneumonia in the UK include *Streptococcus pneumoniae*, *Mycoplasma pneumoniae*, and *Haemophilus influenzae*, although causative viruses (e.g. influenza virus, VZV) and organisms associated with immunocompromise (e.g. *Pneumocystis jirovecii*), should not be overlooked. The simple CURB-65 prediction rule (confusion; urea >7 mmol/l; respiratory rate ≥30/minute; low systolic (<90 mm Hg) or diastolic (≤60 mm Hg) blood pressure; age ≥65 years) is a useful tool for assessing the severity of pneumonia within the context of the full clinical picture.

The abdomen

General inspection may have revealed signs of abdominal involvement in the infectious process; frank jaundice is obvious, but mild discolouration requires closer inspection of the mouth and conjunctivae. Infectious intra-hepatic causes to consider are viral hepatitis, infectious mononucleosis, and leptospirosis. Post-hepatic obstruction may be infective in origin or complicate non-infectious causes such as gallstones.

Examination of the mouth should look for anaemia, candida, and gingivitis, tonsillar infection, and palatal purpura. The source of infection may be found on general palpation and per rectal examination, including intestinal infections (e.g. with *Salmonella typhi*) or complications of diverticular disease, such as diverticulosis. Fever and lower abdominal tenderness are generally present in pyelonephritis, and one or both renal angles may be tender. Acute pelvic inflammation due to a sexually transmitted infection may be distinguished by cervical excitation tenderness (pain on movement of the cervix) with or without adnexal tenderness. Percussion and palpation of abdominal organs for enlargement or tenderness may reveal organomegaly, which has a large differential diagnosis (see Table 305.6). Finally, a genital exam may be required for assessment of inguinal lymphadenopathy, local tissue involvement, and signs of sexually transmitted infection. Serious soft tissue infections of the inguinal, genital, or perianal region (e.g. Fournier's gangrene) should not be missed for want of proper examination.

The eyes, and neurological assessment

Examination of the eyes, including of the visual fields, the pupils, and eye movements, aids the localization of CNS or cavernous sinus infection. Infection of the conjunctiva is common and may have a viral (erythematous, non-pyogenic) or bacterial (erythematous, pyogenic) origin. Clues for infectious diseases can be found by careful fundoscopy and should be performed on all patients; retinal haemorrhages with a white centre (Roth spots), initially described in infective endocarditis, are found in association with other conditions, including diabetes and haematological malignancies. TB can infect the eyes or give rise to several forms of inflammation, including anterior uveitis, which is a valuable indication in those without typical tuberculous symptoms.

A thorough neurological examination should identify level of consciousness, cognitive function, and foci of infection, centrally and peripherally. Any patient with a headache should be examined for signs of meningism, including neck stiffness, photophobia, and Kernig's sign. Encephalitis can be difficult to distinguish clinically, and examination of cognitive function can be key. Florid meningitis may be bacterial in origin, with *Haemophilus influenzae* type b, *Streptococcus pneumoniae*, and *Neisseria meningitidis* being the principal causes worldwide. Clinical suspicion following history and examination is sufficient to initiate antibiotic treatment, which should not be delayed for the results of investigations. Viral meningitides are generally more indolent, but can be indistinguishable, especially where bacterial meningitis has been partially treated. Tuberculous meningitis, while rare in low-incidence countries such as the UK, has an extremely high mortality, and early intervention is essential.

The ears, the nose, and the throat

Examination of the ears, the nose, and the throat completes the examination of the patient with suspected infectious disease. Visualization of a bulging erythematous tympanic membrane can localize a previously elusive febrile infection. Vesicles of varicella zoster infecting the geniculate ganglion may be seen in association with facial paralysis (indicating Ramsay-Hunt syndrome). Viral and bacterial tonsillitis are common and usually easily visualized. Occasionally, a bacterial abscess known as a quinsy may form.

Conclusions

Diagnosing a patient with suspected infective disease can be challenging—particularly as it is not a protocol-driven specialty. As a consequence, the encounter with the patient must be undertaken in a systematic manner so that crucial elements of the history and examination can be gleaned. This directs immediate management and informs the requesting of appropriate investigations.

306 Investigation in infection

Ajit Lalvani and Manish Pareek

Introduction

Making a diagnosis in a patient with a suspected infection is dependent on obtaining a comprehensive history complemented by a thorough examination; these crucial elements narrow down the potential causative agent(s) and the organ systems affected, thereby guiding the clinician in undertaking appropriate investigations.

Investigating a patient with a suspected infectious disease necessitates understanding the multitude of tests that are available to clinicians and being able to interpret and integrate the results.

Investigations in infection can be subclassified into three distinct areas:

- baseline investigations: these are undertaken in all patients and provide an indication of the impact of infection on the host
- specific investigations: these are undertaken to identify the causative organism(s)
- additional investigations: these add weight to the diagnosis of infection and can provide further information about the host/causative organism

Baseline investigations

Admitting clinicians suspecting infection in a patient should undertake simple baseline investigations which provide an initial assessment of the host response to infection—in terms of organ systems affected, disease severity, and its chronicity. These usually consist of urine tests, blood tests, and simple radiology.

Urine and blood tests

Routine urine dipstick and blood investigations, including haematology and biochemistry, are often undertaken in the acute phase.

Table 306.1 outlines the blood tests which should be undertaken as a baseline, as well the commonly seen abnormalities where a patient has an underlying infection.

Radiology

In the acute stage, chest radiographs are useful in patients presenting with respiratory symptoms or as part of a workup in those cases where the source of a fever cannot be localized. The specific abnormalities that are seen include bronchopneumonia, lobar pneumonia, cavitation, or a pleural effusion.

Tests aimed at identifying the infectious agent or categories of infectious agents

Simple baseline investigations only provide an indication of the underlying pathological process. Making the correct diagnosis depends on identifying the causative organism(s) either within the host or tissues/fluids (e.g. sputum). These site-specific specimens can be tested for protein, white cells, red blood cells, and pH (e.g. in pleural fluid, a low pH suggests an empyema). These results can tell us two things:

- whether an infection is present
- if so, what type of infection is present (e.g. if lymphocytes predominate, then TB is more likely, whereas a predominance of neutrophils would suggest a bacterial aetiology)

Determining these allows the clinician to commence antimicrobial therapy while awaiting more specific diagnostic tests which identify the organism directly or indirectly.

Methods of direct identification

Direct identification of the causative organism stems from obtaining samples from sites of disease, as indicated by the history and

Table 306.1 Commonly seen abnormalities on baseline blood investigations in patients with underlying infection

Type of test	Specific investigations	Commonly seen abnormalities in infection
Urine	Urine dipstick	Usually, presence of blood, protein, nitrites, and leucocytes If urinary tract infection suggested, the sample should be sent for culture
Full blood count	Haemoglobin	Anaemia; may be seen both in acute infection and chronic disease
	White-cell count	Raised white-cell count common Neutrophilia present in bacterial infections Lymphocytosis or lymphopaenia present in viral infections In certain infections, neutropenia (e.g. malaria and tuberculosis) or lymphopenia (tuberculosis, HIV infection) may be present Eosinophilia present in parasitic infections
	Platelets	Thrombocytosis Thrombocytopenia (may be seen in infection with or without the presence of disseminated intravascular coagulation)
	Blood film	Leucoerythroblastic blood film in severe sepsis
Biochemistry	Urea and electrolytes	May be non-specifically increased, especially if renal tract infection present
	Liver function tests	May indicate hepatitis if the liver is directly affected May be non-specifically raised when sepsis is at a site other than the liver Albumin level decreases as part of the acute phase response*
	C-reactive protein	Usually raised in bacterial infection Can be used to monitor the response to antimicrobials

*The acute phase response is often seen in infection and results in the following specific abnormalities: an **increase** in the erythrocyte sedimentation rate and in the levels of C-reactive protein, globulins, and ferritin, with a **decrease** in albumin and transferrin.

examination. When obtaining samples, clinicians should closely liaise with the laboratory to ensure that specimens are correctly taken in the appropriate media, handled appropriately, and delivered in a timely manner so that they can be appropriately processed by the microbiologists.

Amongst direct methods of identification, common modalities include microscopy, culture, antigen detection tests, and nucleic acid amplification-based modalities.

Microscopy

Microscopy on sterile, site-specific host samples is a common method of identifying bacteria and protozoa (but not viruses). These specimens can be examined directly as wet mounts or after they have been stained.

Wet mounts are used in stool examination for gastrointestinal parasites or their ova (e.g. in giardia), or in microscopy of blood (e.g. peripheral smears for malaria parasites and whole blood to look for microfilaria which cause lymphatic filariasis).

The performance of microscopy can be enhanced with the use of specific stains. One commonly used stain is Gram's stain, which identifies, and differentiates, bacteria according to their cell walls: Gram-positive bacteria have a peptidoglycan cell wall and stain purple; Gram-negative bacteria have a thin cell wall and stain pink. Table 306.2 highlights other important stains used in microscopy.

Microscopy is useful as it rapidly indicates the causative pathogen before definitive culture results can be obtained, thus allowing targeted antimicrobial therapy to be prescribed.

Culture

Culture complements microscopy. Specimens are plated on growth media and allowed to multiply, with results generally available in 24–48 hours. When interpreting culture results, clinicians should consider the following key questions:

- Where was the sample taken from? Was the site sterile (e.g. in the case of CSF) or non-sterile (e.g. skin/sputum)?
- Does the result reflect contamination? (This is important for specimens such as skin swabs (where coagulase-negative staphylococci reside as commensals)).
- Has the patient received antibiotics prior to the specimen being sent for culture? (This can result in false-negative culture results.)

Culture is the gold-standard test for infection, as it has superior sensitivity to microscopy alone. Specific advantages include the ability to identify the organism, and the ability to perform drug susceptibility testing. However, drawbacks of culture include the fact that some organisms are slow-growing and difficult to culture (e.g. *Mycobacterium tuberculosis*) and, thus, alternative diagnostic modalities are required. Culture is rarely used for viruses, as it has been superseded by antibody-based and nucleic acid amplification tests.

Table 306.2 Different stains used in microscopy when investigating a patient with an infection

Name of stain	Specimen	Common organisms identified by stain
Gram	Blood CSF	Most bacteria, classified as Gram positive (purple) or Gram negative (pink)
Ziehl–Nielsen	Sputum Pleural fluid Lymph node aspirates Pus	Mycobacteria species
Giemsa	Blood Marrow aspirates	Malaria Trypanosomes
Wright's stain	Blood	Malaria
India ink	CSF	<i>Cryptococcus neoformans</i>
Silver stain	Sputum	<i>Pneumocystis jiroveci</i>

Table 306.3 Different antigen detection tests currently in use

Name of organism	Specimen
<i>Cryptococcus neoformans</i>	Blood CSF
<i>Streptococcus pneumoniae</i>	Urine CSF
<i>Legionella pneumophila</i>	Urine
<i>Clostridium difficile</i>	Stool (for toxin)
Influenza A/B	Nasopharyngeal swab/aspirate
<i>Plasmodium falciparum</i> (malaria)	Blood

Antigen detection tests

Antigen detection tests detect the antigen/pathogen itself or the toxin it is producing (e.g. *Clostridium difficile* toxin) and can be undertaken on various specimens, including blood, CSF, urine, and stool, to identify a range of different organisms (Table 306.3).

Several types of antigen detection tests are available, of which latex agglutination and enzyme immunoassays are commonly used. Latex agglutination tests use antibodies to test for the presence of antigen in the clinical specimen (e.g. a cryptococcal antigen test). With enzyme immunoassays, the specimen containing the antigen is mixed with a specific antibody which is linked to an enzyme which produces a detectable signal, such as colour. These tests are relatively cheap and fast with moderate/high sensitivity.

Nucleic acid amplification tests

Recently, traditional methods of identifying organisms are being supplemented by molecular techniques. Nucleic acid amplification tests, of which PCR is the commonest method, are increasingly being used to detect the presence of pathogen DNA/RNA in clinical specimens.

PCR is based on the amplification of pathogen DNA/RNA and is particularly useful for those organisms which are difficult or, in some cases, impossible to culture, such as viruses (e.g. hepatitis C, HIV) and certain bacteria (e.g. chlamydia). PCR can be qualitative or quantitative (e.g. used for determining the HIV viral load or the hepatitis C viral load) and so can be used for staging disease and monitoring response to treatment. While PCR has a very high sensitivity and specificity, it is unable to differentiate between live and dead organisms and is sensitive to contamination.

Methods of indirect identification

While direct identification of the causative organism is preferable, this is often difficult or may take a long time. Consequently, indirect methods that identify pathogen-specific immune responses are used.

Serological diagnosis

Serological tests derive from the normal antibody response to infection in an immunocompetent individual. Following infection with an organism, there is often some delay before antibody production commences. When it does, IgM antibody is initially produced; however, IgM production will eventually wane over time and be replaced by IgG production. It is the antibodies, directed against specific organisms, which are measured by serologically based methods.

The presence of IgM suggests a recent/current infection, while IgG positivity represents a past/already established infection. Having an understanding of this is critical for the physician, although complications in interpretation can arise, as the biology and natural history of infection vary for different pathogens. Antibody results should be interpreted carefully, and, in difficult situations, discussion with a virologist/microbiologist in difficult situations.

An additional method for determining whether the infection is recent is to collect two samples—one at the beginning of the illness (an acute sample) and another 10–14 days later (a convalescent sample)—which can be tested together. A greater than fourfold rise in the antibody titre indicates that disease is present (e.g. mumps and legionella).

Common serological techniques include ELISAs, complement fixation, and agglutination. These are widely used in virological diagnosis (e.g. for infection with HIV or with hepatitis A/B/C) and also to determine whether an individual is immune to certain pathogens (e.g. rubella virus, in pregnant women).

T-cell-based diagnosis: Interferon gamma release assays

Significant advances made over the last decade have resulted in the development of interferon gamma release assays to diagnose latent TB infection. These blood tests, which measure in vitro interferon gamma levels, have been shown to be more specific and sensitive than the tuberculin skin test. In addition, recent longitudinal studies have demonstrated, as with the tuberculin skin test, that a positive result from an interferon gamma release assay predicts the future development of active TB.

Additional investigations to undertake in the patient suspected to have an infection

Aside from the generic initial tests, the investigations described in 'Baseline investigations' aim to identify the infectious organism. However, diagnosing an infectious disease often requires additional tests which, in combination with the clinical findings and other tests, add weight to the diagnosis, provide further information about the host/causative organism, and rule out alternative differential diagnoses.

Blood tests

One of the difficulties with infectious diseases is that the symptoms are often non-specific (e.g. fever) and, hence, the differential diagnosis is wide. Therefore, it is important to rule out alternative diagnoses. Clearly, which blood tests to undertake will depend on the clinical syndrome, but important tests to consider include an autoimmune screen; tests for immunoglobulins; a liver autoantibody screen (if the patient presents with hepatitis); and an ESR.

However, further blood tests may also be the logical sequelae of a diagnosis previously made. For example, once HIV infection is diagnosed, the clinician should ascertain how advanced the HIV infection is by undertaking a CD4 cell count and determining the HIV viral load. Similarly, blood tests may be necessary to monitor the patient's response to treatment; for example, in patients who are diagnosed with *Plasmodium falciparum* malaria, the percentage parasitaemia should be monitored to ensure that the antimalarial treatment is having the desired effect.

Radiology

Detailed radiological examinations have revolutionized the diagnosis of infectious disease and are often undertaken soon after the patient presents to medical care. Usually, the history and examination findings will guide the clinician to the specific area which should be imaged, although more extensive scanning may sometimes be required (such as when investigating a fever of unknown origin).

Cross-sectional imaging is very important, as it can delineate the pathological process, such as with ring-enhancing lesions in a CT/MRI scan. Moreover, imaging can identify the specific focus of infection (if sampling is required), as well as the response to treatment (e.g. it can

be used to look at the change in size of mediastinal lymph nodes in a patient being treated for tuberculosis).

Histology

In some cases, if the initial microscopy results are negative, clinicians will have to wait for several weeks before the culture results are known. In this case, it is recommended that the same sites of disease samples (pus, pleural/peritoneal fluid, CSF, bone marrow) which were sent for culture are also sent, in large volumes, for cytological/histological analysis. The advantage of this is that certain organisms result in such characteristic histological findings that, if these are seen, even while formal culture results are awaited, they may provide enough evidence to commence therapy. TB exemplifies this most clearly; if histology shows caseating granulomas with epithelioid macrophages and multinucleate giant cells, the clinician should strongly consider commencing antituberculous treatment, as any delays may result in clinical deterioration of the patient.

Tests of immune function

In some situations, it is useful to consider if an underlying disorder of immune function has affected the subject's ability to fight infection and resulted in their presentation with the infectious disease.

Immunodeficiency can be primary (usually inherited) or secondary (usually due to external disease/medications). Primary immunodeficiency mainly affects children and is suggested by the history and examination findings. The actual spectrum of disease depends on which element of the immunological system is not functioning appropriately and can include, amongst others, antibody deficiency, T-cell deficiencies, B-cell deficiencies, and complement deficiency (see Chapter 303).

Conclusion

Undertaking investigations in a patient with a suspected infectious disease should complement the history and examination findings. There are several aims of investigation in infection, including identifying the causative organism, elucidating the host response to infection, identifying any underlying susceptibility to infection, and, finally, ruling out non-infectious causes which may present with similarly non-specific features.

As a huge range of tests are available to the physician, it is advisable to liaise closely with the microbiology/virology laboratory so that the correct test is used in the correct situation. However, it must be borne in mind that clinical suspicion remains critical—particularly as all diagnostic tests can suffer from false-negative results. Therefore, even negative test results should not dissuade the clinician, as the diagnostic process is an ongoing one; tests may often need to be repeated over the course of the patient's illness to confirm the diagnosis or, indeed, observe a response to treatment.

307 Treatment of infection

Ian Bowler and Matthew Scarborough

Treatment and its effectiveness

Background

The healthy human body is colonized by a complex mix of microorganisms which numerically outnumber human cells by a factor of 10. These resident flora, located primarily in the gut, respiratory tract, and skin, rarely invade to cause disease unless host surfaces are damaged, for example by viral infection, trauma, or surgery. They play an important role in protecting the host from infection by preventing the establishment of more virulent organisms which might initiate disease. This is called colonization resistance. The distinction between colonization and infection is vital to the interpretation of microbiological investigations.

Infection

Infection can be regarded as a struggle between the host and the infecting organism, which may be a bacterium, virus, protozoan, or fungus. The likelihood that an infection will occur will depend on the number of organisms, their virulence, and the quality of the host defences. Organisms causing the greatest burden of disease in the UK are respiratory viruses, such as rhinovirus, respiratory syncytial virus (RSV), and influenza. Their virulence enables them to initiate disease in healthy hosts. Once mucosae have been damaged by these agents, commensal bacteria may invade. There are strong temporal links between peak influenza activity and the incidence of pneumococcal pneumonia and meningococcal meningitis in the winter in temperate climates. 'Treatment' involves shifting the balance in favour of the host. This might involve:

- supporting the host (e.g. providing oral rehydration solution to patients with gastroenteritis)
- removing the pathogen (e.g. drainage of abscess, excision of osteomyelitic bone, starting antimicrobial therapy)
- modulation of the host immune response (e.g. administration of steroids in TB and pneumococcal meningitis)

The approach to the potentially infected patient

The history and the physical examination are used to formulate a differential diagnosis that is tested using laboratory and radiological investigations. This process includes:

- an assessment of host competence; for instance, the degree of organ dysfunction, which helps to predict:
 - the level of support required (i.e. whether the patient can be managed as an outpatient or requires inpatient care or admission to an ICU)
 - how quickly and comprehensively interventions should be carried out
 - the likely course and outcome of the illness
- an assessment of the presenting features, the pattern of the illness, and which systems are affected; this helps predict the nature of the pathogen and therefore guides initial therapy
- an understanding of the epidemiological context: local travel, sexual history, animal contact, and local epidemiology of infection, including antibiotic resistance patterns (i.e. US vs UK for community-acquired MRSA)
- an awareness of local treatment guidelines based on local epidemiological data; this will ensure that patients are managed according to best practice

- an assessment of infectivity of the patient so that care can be given in a way which minimizes the risk of transmission to other patients and to staff:
 - negative-pressure ventilation rooms can be used to manage patients with open pulmonary TB and chicken pox
- patients with infection caused by varicella zoster virus should be nursed by staff who are immune to the virus, in order to help prevent transmission

Discussion of interventions

Patients with infection may require a variety of interventions to improve their chance of a good outcome in their struggle with the infecting organism; these include:

- supporting the host
- removing or reducing the dose of the pathogen
- immunomodulation

Supporting the host

Patients with a sepsis syndrome characterized by fever and hypotension will benefit from fluid repletion and temperature control by fanning or the use of antipyretics such as paracetamol. Oral rehydration is usually used in the outpatient setting. For more severely affected patients, IV fluids may be required. In those with persisting hypotension, the use of a pressor agent such as noradrenaline may be appropriate. Additional support such as ventilation and haemofiltration may also be necessary.

Removing or reducing the dose of the pathogen

Source control

There are a wide variety of interventions aimed at physically removing the invading pathogen. Examples of 'source control' include:

- laparotomy, for the repair of a perforated viscus, drainage of collections, or diversion of the faecal stream (Hartman's procedure)
- relieving obstruction (e.g. placement of urinary bladder catheter in the setting of acute obstruction due to prostatic enlargement; insertion of a nephrostomy into the renal pelvis when there is obstruction due to a renal stone; sphincterotomy of the duodenal ampulla to release a biliary stone)
- removing non-viable tissue (e.g. in the setting of necrotizing fasciitis or osteomyelitis)
- removing intravascular lines and other foreign bodies that may harbour biofilms on their surface, as biofilms render bacteria insusceptible to antibiotic therapy

These therapeutic interventions have the benefit of providing clinical material for confirmation of diagnosis by histology, culture, or molecular probes via PCR.

Appropriate antimicrobials

Treatment strategy and choice of antimicrobials

The choice of antimicrobial agent depends on the organism, the host, and the pharmacokinetics of the drug.

The identity and the antimicrobial sensitivities of the organism are usually determined by culture or molecular techniques. These diagnostic tests are not rapid; so, in most settings, antimicrobial therapy will be given on an empirical basis before the nature of the infecting agent is known. The spectrum of cover required will depend in part on the severity of illness, with a broader spectrum being appropriate

for the sickest patients. It is important that the initiation of treatment is not delayed while awaiting results of laboratory tests, as there is evidence that early intervention improves outcome in life-threatening infections such as meningitis and pneumonia, and in neutropenic sepsis.

Once the infecting agent has been characterized, the spectrum of antibacterial therapy can be narrowed, thus avoiding side effects, reducing cost, and limiting disturbance to the normal flora. In this way, the risk of *Clostridium difficile* infection, which occurs when the gut flora is disturbed, can be minimized.

Diseases mediated by bacterial toxins are best treated with antimicrobials that are able to inhibit toxin formation. Clindamycin is chosen for this reason in cases of necrotizing fasciitis caused by organisms such *Streptococcus pyogenes* or *Clostridium* spp.

Most antimicrobials are either excreted via the kidneys or metabolized in the liver. The dose will therefore depend on the glomerular filtration rate or liver function of the host. Further determinants of dosage include tissue distribution of the drug (e.g. vancomycin does not cross the blood brain barrier well) and the concentration of drug required to inhibit the target pathogen(s); the latter is known as the minimum inhibitory concentration (MIC).

The dosing interval will depend on the pharmacokinetics and mode of action of the drug. Some antimicrobials, such as aminoglycosides, display concentration-dependent killing and so are best used in large, once-daily doses. Others, like the penicillins and cephalosporins, display time-dependent killing, where the aim of dosing is to keep the drug concentration above the MIC for as long as possible. The ratio of the MIC to the area under the curve of drug serum concentration plotted against time has been found to be predictive of outcome in animal models of infection and in observational studies in humans.

Antimicrobial choice may be affected by a history of allergy. The most common allergic response is a skin reaction to penicillin; in patients who have this reaction, a cephalosporin can usually be given safely. In a patient giving a history of type 1 allergy to penicillin with collapse or bronchospasm, nearly all beta-lactam antibiotics should be avoided.

Route of antimicrobials

Antimicrobials are usually given by the IV route in severely ill patients or if oral absorption is unreliable. As soon as the patient is well enough, IV therapy can be switched to oral therapy. The oral route is preferred, as it is more convenient and cheaper and it does not expose the patient to the risks associated with IV cannulation, such as phlebitis and infection.

Duration of antimicrobial therapy

There are many determinants for duration of therapy but there is increasing evidence that many infections respond to shorter courses of antibiotics than originally thought. This has been most extensively studied in urinary tract infections. In female patients with cystitis (urinary frequency, and dysuria without fever or loin pain), 3 days of oral therapy is effective. In female patients with pyelonephritis, 7 days of therapy with a quinolone is as effective as 2 weeks of therapy with co-trimoxazole. In children, males, and pregnant females, treatment courses shorter than 14 days have not been shown to be effective but, in practice, treatment may be shortened to 10 days. Asymptomatic bacteriuria in pregnancy is usually treated for 7 days, although there is little evidence base for this.

Patients who have mild-to-moderate community-acquired pneumonia and require admission to hospital can be treated for 3 days. Hospital-acquired pneumonia, including in the ITU, is usually treated for 5–7 days, although the evidence base for this is poor.

The optimal duration of therapy for endocarditis depends on the infecting pathogen and the presence of a prosthetic valve. For native valve disease caused by 'viridans' streptococci with an MIC <0.01 mg/l to penicillin, 2 weeks of therapy with penicillin and a synergistic aminoglycoside (e.g. gentamicin) is effective. For prosthetic valve endocarditis caused by the same organism, 6 weeks of therapy is usually required. In bacterial meningitis, studies show that 7 days of therapy is effective for the treatment of uncomplicated meningococcal meningitis, but 10 days of therapy is recommended for pneumococcal meningitis.

In most other settings, the duration of antibiotics is decided empirically depending on the patient's response. For instance, treatment of skin and soft tissue infection may vary from 5 to 21 days, depending on the structures involved and the response to therapy.

Where organisms have a persisting phenotype and are not easily killed by antimicrobials, therapy may need to be prolonged. The treatment for pulmonary TB is usually extended to 6 months. In settings where the organism cannot be eliminated, the aim of therapy is suppression; examples of scenarios where this approach is used include the treatment of HIV infection, and the suppression of metal-ware-related infection in orthopaedic practice, when the metalwork cannot be removed.

Immunomodulation

In some infection scenarios, the host's immune response to the pathogen is overactive and causes tissue damage. The aim of therapy in this instance is to modify the immune response in order to avoid this damage while allowing sufficient response to eliminate the pathogen. Steroids are potent immunomodulators. In patients with acute bacterial meningitis and in chronic meningitis due to *Mycobacterium tuberculosis*, steroid therapy reduces mortality and reduces the risk of complications amongst survivors. Some patients who present with advanced HIV 1 become unwell when their immune system begins to recover with antiretroviral therapy. This immune reconstitution inflammatory syndrome is often directed against *Mycobacterium tuberculosis* and usually responds well to steroid therapy.

In other settings, the immune response is poor but can be boosted to help overcome the pathogen. Patients receiving cadaveric renal transplant require potent immunosuppressive therapy to prevent rejection of the graft. This may allow latent viruses to escape immune control and cause end-organ damage. CMV may cause colitis, hepatitis, and pneumonitis in this way. Treatment is with antivirals to limit viral replication, as well as a reduction in immunosuppressive therapy to allow the immune response to re-establish control.

Some diseases are caused by toxins produced by the infecting pathogen. These toxins are antigenic, and treatment can be given with antibodies raised in animals or human volunteers. Both tetanus and botulism are treated in this way. The role of normal human immunoglobulin for the treatment of necrotizing fasciitis due to *Streptococcus pyogenes* is controversial, as only one small randomized study has been done. Recently, monoclonal antibodies to the *Clostridium difficile* toxin have been shown to be effective in reducing the risk of relapse in patients with recurrent *Clostridium difficile* disease.

Monitoring effectiveness of interventions

Monitoring of patients' progress is important to assess whether therapy is effective. This is done by monitoring vital signs such as blood pressure, pulse rate, fluid balance, and degree of hydration. Pulse oximetry and blood pH monitoring can be used to assess tissue oxygenation and perfusion. The function of the kidneys and the liver is monitored, in case these require support. Regular monitoring of the white blood cell count and serum C reactive protein can be used to assess response to therapy. In chronic viral infections such as HIV and hepatitis B or C, measurement of viral load in the blood can be helpful in assessing response to therapy.

Approach to the patient not responding to treatment

In patients who are responding poorly to therapy, the initial diagnosis should be reviewed. There should be a renewed search for uncontrolled foci of infection, such as drainable collections or infected prosthetic material such as intravascular lines which could be removed. It is more common for patients to fail therapy for these reasons than because of inappropriate empirical antimicrobials or because of the emergence of antimicrobial resistance during therapy. However, a prior history of colonization or infection with an antibiotic-resistant organism such as MRSA or *Pseudomonas aeruginosa* should be sought in order to ensure that empiric antibiotic cover is appropriate. Persisting fever despite several days of appropriate therapy should

prompt consideration of either thromboembolic disease or an allergic response to the antimicrobial therapy.

Wider impact of antimicrobial therapy

All diseases and their therapies carry with them risks of complications and side effects. Infection and antimicrobials hold two additional threats: transmission of infection, and the development of drug resistances. The disciplines of infection control and antibiotic stewardship are directed at countering these concerns, and both have increasing public and political sensitivity.

Minimizing the spread of antibiotic resistance in hospitals and community

Antimicrobials save millions of lives and have contributed significantly to the gains in life expectancy seen since their introduction in the 1940s. However, these advances are now seriously threatened by the emergence of drug resistance.

Antimicrobial resistance emerges as a result of the selective pressure of exposure through the use and abuse of antimicrobials in hospitals and the community, and also in the animal industry as growth promoters.

There are many examples of evolution of antimicrobial resistance. For *Staphylococcus aureus*, penicillin resistance emerged 4 years after its introduction in the 1940s. As a result, methicillin (closely related to flucloxacillin) was developed but, in the 1960s, methicillin resistance was detected. Currently, MRSA accounts for approximately 50% of the bloodstream isolates in the UK. Vancomycin is now the mainstay of therapy for MRSA but, in the 1990s, vancomycin resistance emerged. In 2002, a strain of MRSA with complete resistance (MIC >16 mg/l) to vancomycin was isolated from a patient in the US. There is now increasing concern over the emergence of *Staphylococcus aureus* strains resistant to all glycopeptides antibiotics.

Gram-negative organisms similarly have evolved resistance mechanisms as a result of exposure to antimicrobials. In 2010 there were reports of imported cases of organisms expressing an enzyme, the New Delhi metallo-beta-lactamase NDM1, to the UK and USA. These organisms are resistant to treatment with carbapenem antibiotics. There is a worrying void in the development of new drug classes to combat resistant Gram-negative infections, and current trends suggest that, over the next decade or so, organisms will emerge which will have no effective therapy.

Similar stories of emergent resistance are seen in many other microorganisms including TB—so-called XDR TB—malaria and HIV. All are thought to be driven by exposure to antimicrobial therapies. Prudent and appropriate use of antimicrobials is a key component in managing such resistance.

Antimicrobial stewardship

A critical factor in the evolution of resistance is the total consumption of antimicrobials. Currently, it is thought that up to 30% of prescriptions for antibiotics are inappropriate or unnecessary. Where it is required, antibiotic therapy should be optimized to provide the best chance of cure while minimizing cost, risks of toxicity, and the selection of resistance. In most infections, this is best achieved by using the narrowest spectrum of antibiotic at the lowest dose and for the shortest duration necessary to effect a cure. Antimicrobial stewardship programmes incorporate several strategies to improve prescribing patterns, including:

- public and prescriber education (e.g. campaigns explaining that most sore throats are viral in origin and will therefore not respond to antibiotics)
- the formulation and promotion of appropriate antibiotic guidelines, governed by local epidemiology and resistance patterns
- formulary restriction or prior approval by an infection specialist: mechanisms whereby access to certain antimicrobial classes is carefully controlled in order to prevent inappropriate prescribing and preserve efficacy

- computer-assisted prescribing: software programmes that ensure that the prescription is appropriate for the indication

Antimicrobial stewardship should be supported by a robust surveillance system to identify trends and emerging threats.

Infection prevention and control procedures

Infection prevention and control programmes can minimize the spread of antibiotic-resistant bacteria from patient to patient. It is estimated that, at any one time, 10% of all hospital inpatients suffer from a nosocomial or healthcare-associated infection. Infection control is the discipline concerned with reducing nosocomial infection rates through prevention (education, cleaning, hand hygiene, vaccination, isolation), surveillance (MRSA screening, root cause analyses, contact tracing), and management. Common nosocomial infections include intravascular-device-related bacteraemia, urinary and respiratory tract infections, and surgical-site infections. Nosocomial infection rates have recently become the target of considerable scrutiny by the public and the media and are now used as an important metric against which quality of care is measured.

Many interventions known to be effective in reducing the risk of nosocomial infection are well recognized but poorly deployed. The importance of hand hygiene was established in the mid-19th century by Semmelweis and Holmes but has been notoriously difficult to implement. Similarly, it has been difficult to convince the medical profession of the considerable risks associated with intravascular devices and urinary catheters.

Central and peripheral IV cannulae cause almost 50% of all hospital-acquired bloodstream infections, half of which are due to *Staphylococcus aureus*. The attributable mortality is thought to be between 12% and 25%, and the cost of a single episode has been estimated to be over £6000. The risks associated with cannulae are best managed by ensuring that staff are appropriately trained in their insertion and aftercare.

Urinary tract infections account for a fifth of all hospital-acquired infections, and 60% are related to catheter insertions. Urinary catheters become colonized by bacteria at a rate of 4% per day, and the odds of a septic death in a catheterized patient as compared to a matched non-catheterized patient is about 30:1. Appropriate use and improved care of urinary catheters is likely to limit the associated risks.

In addition to providing appropriate training for clinical staff, infection control teams play an important role in limiting transmission of infections within the hospital. They frequently advise, for example, on the isolation and management of patients with *Clostridium difficile* diarrhoea; MRSA colonization or infection: shingles; TB; hepatitis viruses; and RSV. Through a series of audit programmes, they advance good clinical practice in relation to hand hygiene, hospital cleaning, and surgical-site infections. Infection control teams also serve to protect staff through the promotion of universal precautions and the safe disposal of sharps.

In recognition of the importance of infection prevention and control, the UK government has mandated the implementation of a new code of practice in all healthcare institutions (The Health and Social Care Act 2008 Code of Practice on the prevention and control of infections and related guidance). The code states that 'effective control and prevention of healthcare related infection must be embedded into everyday practice and applied consistently by everyone'. All staff are therefore bound by law to engage with local infection prevention and control policies.

308 Viral infection

Graham Cooke and Richard Lessells

Definition of the disease

Viral infection includes any clinical illness caused by a pathogenic virus. This chapter deals primarily with acute viral infections in immunocompetent individuals.

Aetiology of the disease

Acute viral infections are amongst the most common illnesses of humans, and numerous viruses can cause disease in humans. Specific syndromes can be identified that have certain viruses as potential causative agents (Table 308.1).

Table 308.1 Common syndromes associated with viral infection and the causative agents

Syndrome	Symptoms	Virus
Respiratory viral infection	Sore throat Rhinorrhoea Cough Wheeze Otagia Headache	Influenza Parainfluenza Respiratory syncytial virus Adenovirus Rhinovirus Coronavirus
Gastroenteritis	Diarrhoea Vomiting	Norovirus Rotavirus Adenovirus
Infectious mononucleosis	Sore throat Fatigue/malaise Lymph node enlargement	Epstein-Barr virus Cytomegalovirus HIV: acute infection
Oral–genital ulceration	Oral ulceration Anogenital ulceration	Herpes simplex virus 1 and 2
Exanthema	Skin rash	Varicella zoster virus Human herpesvirus 6 Measles virus Rubella virus Enterovirus Poxviruses Parvovirus B19 Dengue virus
Encephalitis	Headache Confusion Seizures	Herpes simplex virus 1 Varicella zoster virus Enterovirus
Acute hepatitis	Jaundice Abdominal pain Anorexia Nausea/vomiting	Hepatitis A virus Hepatitis B virus Hepatitis C virus Hepatitis E virus Cytomegalovirus Epstein-Barr virus
Viral haemorrhagic fever	Headache Dizziness Myalgia Petechial rash Oedema Shock	Dengue virus Arenavirus (e.g. Lassa virus) Bunyavirus (e.g. Ebola virus, Marburg virus) Filovirus (e.g. Crimean–Congo haemorrhagic fever virus)

Typical symptoms of the disease

Symptoms of viral infections will usually include fever, with more specific symptoms dependent on the site of infection and causative agent (symptoms listed in Table 308.1).

Demographics of the disease

Viral infections can affect individuals of any age, gender, and ethnicity. The host–pathogen response determines different outcomes for specific viral infections. After infection with some viruses (e.g. measles virus, rubella virus) protective immunity develops, there is no latency or chronic carriage, and reinfection is prevented. Other viruses (e.g. herpes simplex virus (HSV), varicella zoster virus (VZV)) enter latency (when viral replication ceases but the virus lies dormant within cells), and reactivation of the virus can cause symptoms at a later stage—a good example of this is VZV, which, after initial infection (chickenpox), enters latency in the trigeminal and dorsal root ganglia and can reactivate many years later to cause herpes zoster disease (shingles). Another group of viruses, in the presence of inadequate immune response, can cause chronic infection (e.g. hepatitis B and C viruses).

Natural history and complications of the disease

Respiratory viral infections

Respiratory viral infections in immunocompetent adults are usually mild, self-limiting, and without complication. In the elderly and other high-risk groups (e.g. those with chronic heart disease or chronic lung disease), respiratory viral infections can cause more significant morbidity, either through the development of pneumonia or through secondary bacterial infection. In recent years, there have been notable outbreaks of respiratory viral infections associated with more severe morbidity and mortality (e.g. infections with SARS coronavirus or influenza H1N1).

Infectious mononucleosis

Mild forms of infectious mononucleosis can resolve within a few days but most cases resolve over 2–3 weeks. Serious complications are rare but include splenic rupture, haemolytic anaemia, thrombocytopenia, and Guillain–Barré syndrome.

Oral–genital ulceration

Primary infection with HSV is asymptomatic in approximately 50% of cases. Primary HSV-1 infection can manifest with orolabial vesicles and ulceration, often accompanied by fever, pharyngitis, and cervical lymphadenopathy. Primary HSV-2 infection can manifest with vesicles and ulceration of genitalia or perineum, often accompanied by fever and inguinal lymphadenopathy.

Both HSV-1 and HSV-2 enter latency in sensory nerves, and reactivation causes recurrent orolabial lesions ('cold sores') or anogenital lesions. Severe complications of HSV infection are rare but include neurological infections (see 'Encephalitis').

Exanthema

Primary infection with VZV causes varicella (chickenpox), which, in children, is usually a self-limiting illness. In adults (particularly, pregnant females), there is a higher risk of severe disease and complications such as pneumonia and encephalitis. VZV reactivation causes

herpes zoster (shingles), which manifests as a vesicular rash in a single dermatome. Complications of herpes zoster include herpes zoster ophthalmicus (zoster affecting the ophthalmic branch of the trigeminal nerve, causing conjunctivitis, keratitis, or uveitis) and post-herpetic neuralgia.

Encephalitis

Acute encephalitis is a serious and potentially fatal consequence of viral infection and can be caused by primary infection or reactivation of HSV-1, HSV-2, or VZV. It needs to be distinguished from meningitis, which can be commonly caused by the same viruses and many others (e.g. enteroviruses), but which generally has a benign course.

Mortality from untreated herpes encephalitis is approximately 70% and, even with appropriate treatment, fewer than 50% recover with no neurological sequelae. Varicella zoster encephalitis is less well understood but is thought to have a more benign course.

Acute hepatitis

The natural history of acute viral hepatitis varies quite considerably between individuals. The hepatitis viruses differ in their propensity to cause liver failure or chronic infection. The majority of hepatitis A virus infections are self-limiting: the case fatality rate is <0.1%, and chronic infection does not occur. Hepatitis B virus infection causes fulminant liver failure in approximately 1% of cases. The rate of chronic carriage of hepatitis B depends on the age at infection: if infected in adulthood, the rate of chronic infection is 5%–10%. Acute hepatitis C virus infection is often asymptomatic. Acute infection rarely causes liver failure, but 70%–80% of those infected develop chronic infection. Hepatitis E can cause fulminant liver failure, particularly in pregnant women, with consequent high mortality rates, but does not cause chronic infection (except in rare cases of immunosuppression).

Viral haemorrhagic fever

Tropical viral infections can be imported into the UK by persons travelling in areas endemic for certain viruses. Viral haemorrhagic fever is a syndrome with a number of causative viral agents. These imported infections are extremely rare in the UK, but retain importance due to the high mortality and the potential for onward spread of the virus. Since 1971, there have been 12 confirmed cases of Lassa fever in the UK (all from West Africa) and one case of Crimean–Congo haemorrhagic fever. During the West African outbreak of Ebola virus (2013–2016), there were three cases of imported Ebola virus disease in the UK, all in health care workers directly involved in the response to the epidemic. Dengue virus infection is more common and can be acquired in sub-Saharan Africa, South America, and Asia. Classical dengue has an incubation period of 3–14 days, is characterized by fever, headache, myalgia, and rash, and is usually self-limiting. Dengue haemorrhagic fever is characterized by more severe haemorrhagic manifestations and circulatory failure (due to vascular leak).

Approach to diagnosing the disease

The principles in diagnosing acute viral infections are, first, recognize the syndrome, then identify key features that might suggest a specific diagnosis, and, finally, consider laboratory investigations to elucidate the specific causative agent. Many of the syndromes are not clearly identifiable as viral infections at initial presentation so the differential diagnosis will often include bacterial infections, other infections (fungal, parasitic), and other conditions (e.g. malignant disease or autoimmune disease). As with any infection, a detailed history is paramount. A travel history in particular might identify a risk for rare but potentially serious infections. Febrile illness in a patient with history of recent overseas travel should always prompt specialist advice, to guide investigation and management.

For many self-limiting viral infections (e.g. respiratory viral infections), there will be no need for specific laboratory diagnosis, as treatment will be largely supportive. Similarly, viral infections with unique features (e.g. herpes zoster) rarely require laboratory confirmation, and treatment can be given based on clinical features alone.

Table 308.2 Important differential diagnoses for common viral syndromes

Syndrome	Differential diagnosis
Respiratory viral infection	Bacterial upper/lower respiratory tract infection
Gastroenteritis	Bacterial gastroenteritis Inflammatory bowel disease
Infectious mononucleosis	Bacterial/viral upper respiratory tract infection Acute toxoplasmosis Haematological malignancy (e.g. lymphoma)
Oral–genital ulceration	Aphthous ulcers Behçet's disease Inflammatory bowel disease Syphilis Chancroid
Exanthema	Meningococcal sepsis Staphylococcal or streptococcal sepsis Scarlet fever (Group A Streptococcus) Rickettsial infection Drug hypersensitivity Kawasaki disease
Encephalitis	Bacterial meningitis TB meningoencephalitis Brain abscess HIV-related opportunistic infections Cerebral vasculitis
Acute hepatitis	Cholecystitis/cholangitis Liver abscess Drug-induced hepatitis Leptospirosis Autoimmune hepatitis
Viral haemorrhagic fever	Malaria Leptospirosis Enteric fever (typhoid, paratyphoid) Rickettsial infection

Other diagnoses that should be considered

Certain viral infections have such a classical presentation (e.g. herpes zoster) that there are usually no other potential diagnoses. The majority of presentations of viral infection, however, are not specific to viral diseases, and the differential diagnosis may be broad. Table 308.2 summarizes some key diagnoses to consider for each of the syndromes previously described.

The differentiation between viral and bacterial causes of upper and lower respiratory tract infection is extremely difficult based on history and physical examination alone. Even the use of inflammatory markers in peripheral blood (white blood cell count, C-reactive protein) does not reliably discriminate between a viral and bacterial aetiology.

'Gold-standard' diagnostic test

Laboratory diagnosis of viral infections encompasses two main forms of diagnosis:

- direct detection of virus in blood or tissue (via PCR)
- detection of virus-specific antibodies in blood (serology); usually requires paired acute and convalescent samples (the latter taken 10–14 days later)

Other diagnostic methods that might be used include virus detection by immunofluorescence or electron microscopy, and viral culture. PCR has surpassed serology as the gold-standard tests for many infections, as it can confirm diagnosis earlier in the illness and it eliminates confusion in interpreting serology results. Testing for resistance to antiviral therapy is not commonplace in the treatment of acute viral infection but is likely to play a greater role in the future as the

Table 308.3 'Gold-standard' diagnostic tests for common viral infections

Syndrome	Recommended samples	Diagnostic tests
Respiratory viral infection	Nasopharyngeal aspirate Nose/throat swabs Bronchoalveolar lavage Tracheal aspirate	Influenza (PCR) Parainfluenza (PCR) Respiratory syncytial virus (PCR) Adenovirus (PCR) Rhinovirus (PCR) Coronavirus (PCR)
Gastroenteritis	Stool (only in outbreaks and in young children or immunocompromised)	Norovirus (PCR) Rotavirus (PCR) Adenovirus (PCR)
Infectious mononucleosis	Serum	Epstein-Barr virus (serology)* Cytomegalovirus (serology) HIV (fourth-generation ELISA)
Oral–genital ulceration	Aspirate/swab from lesion	Herpes simplex virus 1 (PCR) Herpes simplex virus 2 (PCR)
Exanthema	Aspirate/swab from lesion Serum Throat swab	Varicella zoster virus (PCR or immunofluorescence) Human herpesvirus 6 (serology) Measles virus (PCR on throat swab) Rubella virus (serology) Enterovirus (serology) Poxviruses (clinical diagnosis or biopsy) Parvovirus B19 (serology and PCR)
Encephalitis	CSF	Herpes simplex virus 1 and 2 (PCR) Varicella zoster virus (PCR) Enterovirus (PCR)
Acute hepatitis	Serum	Hepatitis A virus (serology) Hepatitis B virus (serology and PCR) Hepatitis C virus (serology and PCR) Hepatitis E virus (serology) Cytomegalovirus (serology and PCR) Epstein-Barr virus (serology and PCR)
Viral haemorrhagic fever	Serum	Specialist investigations (reference laboratory) [†]

*Monospot (or heterophile antibody test) commonly used but should not be considered gold standard for specific diagnosis.

[†]In the UK, Public Health England should be contacted in any suspected case of viral haemorrhagic fever prior to any laboratory tests, as there are special requirements for specimen handling, transport, and so on.

impact of viral mutations on treatment response is better understood (e.g. in the management of influenza)

The gold-standard diagnostic tests for common viral infections are given in Table 308.3.

Acceptable diagnostic alternatives to the gold standard

In most cases, it is also possible to use serology for diagnosis of viral infection. The main drawback of serology is that it often requires a comparison of acute and convalescent sera and, hence, diagnosis is delayed. It can, however, be useful to confirm diagnoses retrospectively and is especially useful in epidemiological investigations.

Other relevant investigations

Other forms of investigation will be warranted for certain syndromes, to assist with the diagnosis or to search for other causes of the presentation. Investigations may include other microbiological tests (e.g. bacterial culture), imaging procedures (e.g. X-ray, CT, MRI), and histopathology. Some examples of other investigations that might be considered for the presentations described are as follows:

- for respiratory infections: sputum culture (bacterial), chest X-ray
- for gastroenteritis: stool culture, stool microscopy, *Clostridium difficile* toxin testing, sigmoidoscopy
- for infectious mononucleosis: throat swab (bacterial), full blood count

- for oral–genital ulceration: syphilis serology, biopsy
- for exanthema: blood cultures, anti-streptolysin titre, rickettsial serology, skin biopsy
- for encephalitis: MRI brain, EEG, CSF bacterial culture, TB culture, cryptococcal antigen test
- for acute hepatitis: abdominal ultrasound, blood cultures, *Leptospira* serology, autoantibodies (antinuclear antibody, anti-smooth muscle antibody, anti-liver–kidney microsomal antibody, anti-mitochondrial antibody)

Prognosis and how to estimate it

The prognosis for the majority of viral infections in immunocompetent individuals is extremely good, even in the absence of specific therapy. However, certain viral infections and their complications (e.g. herpes simplex encephalitis) are associated with high mortality and thus require rapid identification and rapid initiation of specific treatment.

Treatment and its effectiveness

There are few specific antiviral therapies (aside from antiretroviral therapy for HIV infection) available to treat viral infections. The available therapies and their licensed indications are illustrated in Table 308.4. Certain agents may be used outside of their licensed indications (e.g. IV ribavirin for viral respiratory infections and for viral haemorrhagic fever).

Otherwise, for most viral infections, treatment is supportive and symptomatic. Adjunctive treatment might include analgesics and antipyretics.

Table 308.4 Commonly used antiviral therapies and their main indications			
Medication	Indication	Dose	Duration
Aciclovir	Herpes simplex (treatment)	200 mg five times per day	10 days (primary) 5 days (recurrence)
	Varicella or herpes zoster	800 mg five times per day	7 days
	Herpes simplex encephalitis	10 mg/kg three times per day, IV	14–21 days
Valaciclovir	Herpes simplex (treatment)	500 mg twice daily	10 days (primary) 5 days (recurrence)
	Herpes zoster	1 g three times per day	7 days
Ganciclovir	CMV disease in immunocompromised patients	5 mg/kg twice daily, IV	14–21 days
Valganciclovir	CMV retinitis	900 mg twice daily	21 days
Oseltamivir	Influenza	75 mg twice daily	5 days
Zanamivir	Influenza	10 mg twice daily, inhaled	5 days
Amantadine	Influenza	100 mg once daily	5 days

309 Sepsis

Graham Cooke and Jaime Vera

Definition of the disease

Sepsis is a clinical syndrome resulting from infection that is characterized by activation of the immune and coagulation systems. The pathogenesis of sepsis is complex and may differ according to the host's immunological and physiological statuses prior to infection.

Symptoms of the disease

Sepsis syndrome can be associated with a range of signs and symptoms that differ from patient to patient (see Box 309.1). There are general symptoms indicative of systemic inflammation (e.g. sweating, confusion, lethargy, fatigue, myalgia) that should alert the clinician to the development of sepsis syndrome. In addition, there can be localizing symptoms, such as pain, vomiting, diarrhoea, ileus, erythema, and headache, which can all provide important clues to the infectious source.

Aetiology of the disease

Sepsis occurs in 2% of hospitalized patients and up to 75% of intensive care (ICU) patients. The presence of underlying diseases, and

the physiological health status of the patient, are important determinants of the outcome of severe sepsis. Important risk factors for sepsis include the presence of bacteraemia, advanced age (>65), impaired immune system function (due to AIDS, neutropenia, splenectomy, neoplasm, renal or hepatic failure, diabetes, alcohol dependence, or malnutrition), IV drug use, and prolonged use of intravascular and indwelling urinary catheters. A comprehensive list of pathogens causing sepsis is beyond the scope of this chapter; however, some of the most common infections and microbes responsible for causing sepsis in the community and hospitalized patients are shown in Table 309.1.

Natural history, and complications of the disease

The clinical spectrum usually begins with infection (bacteraemia) that leads to sepsis, organ dysfunction, and septic shock. Complications develop as a result of organ damage, and their clinical presentation usually is superimposed on the signs and symptoms of the systemic response. Findings indicative of organ dysfunction may be the first symptoms noticed by clinicians when assessing the patient. Common complications of sepsis include toxic metabolic encephalopathy; acute respiratory distress syndrome; myocardial dysfunction and decreased ejection fraction; renal failure; impaired gut mobility; elevation in the levels of transaminases; hyperbilirubinaemia; disseminated intravascular coagulation; pancytopenia; a rise creatinine kinase levels, together with critical illness myopathy; and adrenal haemorrhage resulting in Addison's disease.

Approach to diagnosis

The cornerstone of the management of sepsis is early recognition and prompt initiation of supportive therapy combined with antimicrobial therapy. Emergency management should be focused on simultaneous evaluation and resuscitation. The evaluation of the patient should begin with a carefully taken history focused on the assessment of any underlying or predisposing disorder such as an impaired immune system, recent surgery, chemotherapy, transplantation, trauma, or any treatment given. Special attention should be devoted to any history of previous infections and antimicrobial treatment, along with any microbiological data that may be available from previous studies. In addition, an accurate travel history, a recreational drugs history, and history of exposure to infectious agents, whether from contacts or in the environment, can be valuable to the clinician in the identification of an infectious process.

A comprehensive physical examination should be undertaken looking for clues to the source of infection. For instance, cutaneous manifestations of Gram-positive or Gram-negative infections, such as cellulitis, erythroderma, bullae, ecthyma, petechia, or splinter haemorrhages, can provide an opportunity for early diagnosis and initiation of specific antimicrobial therapy.

Other diagnosis that should be considered

Non-infectious etiologies of SIRS to be considered include pancreatitis; trauma; burns; pulmonary embolism; anaphylaxis; drug overdose; dissecting or rupture aortic aneurysm; occult haemorrhage; myocardial infarction; and adrenal insufficiency.

Box 309.1 Diagnostic criteria for sepsis syndrome

Infection

Presence of documented or suspected infection

General response

Fever (>38°C)

Hypothermia (<36°C)

Heart rate: >90 beats/min

Tachypnea: >30 breaths/min

Altered mental status

Decrease capillary filling or mottling, chills

Inflammatory parameters

Leukocytosis

Leukopenia

White blood cell count with >10% immature forms

Plasma C-reactive protein >2 S.D. normal parameters

Hyperlactatemia (>3 mmol/l) and acidosis

Organ dysfunction parameters

Arterial hypotension (systolic blood pressure of >90mmHg, mean arterial pressure <70)

Arterial hypoxaemia (PaO₂)

Acute oliguria (urine output <0.5 ml per kg per h)

Creatinine increase

Ileus (absent bowel sounds)

Hyperbilirubinaemia (plasma total bilirubin of more than 70mmol/l)

Coagulation abnormalities (INR>1.5 APTT> 60 s)

Thrombocytopenia (platelet count <100,000/ul)

Abbreviations: APTT, activated partial thromboplastin time; INR, international normalized ratio; PaO₂, partial pressure of oxygen in arterial blood.

Table 309.1 Common organisms		
Suspected focus of infection	Most likely organism	Possible empiric therapy*
Unknown	Gram-negative bacteria Gram-positive bacteria Anaerobe species	Community acquired: third-generation cephalosporin + metronidazole; consider aminoglycoside Hospital acquired: piperacillin–tazobactam + aminoglycoside; add vancomycin if MRSA colonized or suspected
Community-acquired pneumonia	<i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i> <i>Chlamydomphila pneumoniae</i> <i>Mycoplasma pneumoniae</i>	Third-generation cephalosporin + clarithromycin or doxycycline
Hospital-acquired pneumonia	<i>Klebsiella</i> spp. <i>Staphylococcus aureus</i> <i>Pseudomonas aeruginosa</i> Enterobacteriaceae Anaerobes	Piperacillin–tazobactam; add vancomycin if MRSA colonized or suspected; add metronidazole or clindamycin if aspiration pneumonia
Urinary tract infection	<i>Escherichia coli</i> Enterobacteriaceae Enterococci	Co-amoxiclav + aminoglycoside or third-generation cephalosporin
Intra-abdominal sepsis	<i>Escherichia coli</i> <i>Bacteroides fragilis</i> <i>Peptostreptococcus</i> spp. <i>Clostridium</i> spp.	Piperacillin–tazobactam + metronidazole + consider aminoglycoside
Septic arthritis	<i>Staphylococcus aureus</i> Streptococci Aerobic Gram-negative bacilli	Third-generation cephalosporin; add vancomycin if MRSA suspected
Biliary sepsis (cholangitis)	<i>Escherichia coli</i> <i>Klebsiella pneumoniae</i> <i>Pseudomonas</i> spp. <i>Enterococcus faecalis</i>	Piperacillin–tazobactam + aminoglycoside; add metronidazole if severe pancreatitis is present
Skin and soft tissue	<i>Staphylococcus aureus</i> <i>Streptococcus pyogenes</i> Coagulase-negative staphylococci <i>Clostridium</i> spp. in necrotizing infections	Flucloxacillin; add vancomycin if MRSA suspected If necrotizing fasciitis is present, third-generation cephalosporin + clindamycin + aminoglycoside
Meningitis and encephalitis	<i>Neisseria meningitidis</i> <i>Streptococcus pneumoniae</i> <i>Haemophilus influenzae</i>	Third-generation cephalosporin + vancomycin in areas with resistant pneumococci
AIDS	<i>Pneumocystis jiroveci</i> <i>Streptococcus pneumoniae</i> <i>Salmonella</i> spp. <i>Pseudomonas</i> spp.	Co-trimoxazole for pneumocystis pneumonia Third-generation cephalosporin + metronidazole or clindamycin
Neutropenic sepsis	Gram-positive bacteria (<i>Staphylococcus aureus</i> , coagulase-negative staphylococci, enterococci) Gram-negative bacteria (<i>Escherichia coli</i> , <i>Klebsiella pneumoniae</i> , <i>Pseudomonas aeruginosa</i>)	Piperacillin–tazobactam + aminoglycoside

*Local guidelines will differ according to local organisms and variations in practice.

'Gold-standard' diagnostic test

There is no specific test that confirms the diagnosis of sepsis syndrome or severe sepsis. However, the combination of physical, clinical, and laboratory parameters should prompt the clinician to conclude that a patient is 'septic'.

The selection of laboratory studies should be based on the physical findings and the overall clinical presentation. Definitive etiologic diagnosis requires isolation of the microorganism from blood or a local site of infection. An attempt should be made to obtain infected secretions or body fluids or to aspirate an area that is suspicious for infection. Blood cultures are essential, and a minimum of two sets of blood cultures (10 ml each) taken at different venous sites are strongly recommended.

Other relevant investigations

In order to aid the diagnosis and assess the severity of the disease, all patients with suspected sepsis syndrome should be considered for the following investigations:

- a full blood count
- urinalysis
- coagulation profile
- liver function tests
- electrolytes
- blood glucose
- urea
- creatinine
- arterial blood gas
- plasma C-reactive protein
- ECG
- chest X ray
- HIV test

Base excess and blood lactate can be useful as prognostic markers of severity in sepsis and should be included in the initial laboratory screening. Based on the clinical presentation, other investigations may be appropriate; for instance, CSF testing for glucose, protein, cell count, and culture, if meningitis is suspected.

Prognosis

Twenty to thirty-five per cent of patients with severe sepsis, and 50%–75% of patients with septic shock, die within 30 days. Poor prognostic factors are advanced age, impaired host immune status, infection with a resistant organism, poor prior functional status, and an APACHE II score ≥ 25 . Although 50% of patients with severe sepsis have bacteraemia at the time of infection, the presence or absence of positive blood cultures does not appear to influence the outcome. Similarly, case fatality rates are similar for culture-positive and culture-negative severe sepsis.

Treatment

Initial resuscitation

Establishing vascular access and initiating resuscitation are the first priorities when managing patients with severe sepsis or septic shock. Early resuscitation should be initiated as soon as tissue hypoperfusion is recognized and should not be delayed pending ICU admission. There is evidence from randomized control trials that early, goal-directed resuscitation improves survival for patients presenting to emergency with Septic shock. Early resuscitation comprises:

- fluid therapy
- support of respiratory function

Fluid therapy

Large volumes of IV fluids are indicated to correct the relative vascular hypovolaemia typical of sepsis. IV fluids should be administered in rapid infused boluses. Clinical trials have found no consistent difference between colloids and crystalloid in the treatment of septic shock. IV fluid challenges can be repeated until tissue perfusion is acceptable but, in patients at risk of pulmonary oedema, must be done with caution. Target a central venous pressure of ≥ 8 mm Hg, a mean arterial pressure of ≥ 65 mm Hg, and a urine output of ≥ 0.5 ml/kg per hour. The rate of fluid administration should be reduced if cardiac filling pressures increase without concomitant hemodynamic improvement.

Support of respiratory function

Assessment of airway intubation for high-risk patients, as well as oxygen supplementation to all patients with sepsis, is indicated. Oxygenation should be monitored continuously with pulse oximetry.

Antimicrobial treatment

Antimicrobial treatment should be initiated as soon as possible, ideally after cultures have been obtained. The choice of antibiotics would depend on the patient's history, the most likely source of infection, the clinical context (hospital or community acquired) and local resistance patterns (see Table 309.1). Reassessment of antibiotic regime is important to optimize efficacy and minimize toxicity.

Other therapies

Corticosteroids

Corticosteroids do not prevent the development of shock, reverse shock, or improve mortality at 14 days. Therefore, high doses of

corticosteroids should not be used in patients with severe sepsis unless the patient's endocrine or corticosteroid history warrants it. In the presence of severe refractory sepsis shock (unresponsive to fluid resuscitation and vasopressors), corticosteroid therapy may be beneficial.

Recombinant human activated protein C

Recombinant human activated protein C (rhAPC) was a drug therapy proposed for the treatment of sepsis. The first evidence concerning the use of a form of rhAPC, drotrecogin alfa, in adults was based on two randomized control trials that suggested early administration was associated with better outcomes. In those studies, drotrecogin alfa was of greater benefit in the most acutely ill patients (APACHE II score >25). However, a later Cochrane review found that using drotrecogin alfa did not improve survival rates and, instead, increased the risk of bleeding (Martí-Carvajal et al., 2012). The drug was withdrawn from the market in 2011 (Kylat and Ohlsson, 2012).

Control of the sepsis focus

Identification of the site of infection should be achieved as soon as possible. Prompt drainage of abscesses, debridement of infected necrotic tissue, and removal of potentially infected devices are usually in the best interest of the patient but clinical judgement is required to balance risks of source control with those of procedures.

310 Bacterial infection

Tony Bentley

Staphylococci

Staphylococci are Gram-positive cocci which grow in clusters. *Staphylococcus aureus*, which can be distinguished from *Staphylococcus epidermidis* and other less pathogenic species by a positive coagulase test, is capable of producing numerous toxins that act as virulence factors.

Toxins and other pathogenic molecules produced by *Staphylococcus aureus* include:

- teichoic acid: an adhesin responsible for binding the organisms to fibronectin present on epithelial cell membranes
- fibronectin-, fibrinogen-, and collagen-binding proteins: thought to explain *Staphylococcus aureus*'s predilection for diseased tissue
- protein A: binds to the Fc component of immunoglobulin, resulting in resistance to phagocytosis
- catalase: a peroxidase enzyme that helps the organism survive the host's oxygen-dependent bactericidal system
- coagulase: causes a fibrinous capsule to form around the localized infection
- hyaluronidase: causes local tissue destruction
- DNase: causes nucleic acid damage
- haemolysins: cause red-cell damage
- Pantón–Valentine leucocidin (PVL): a pore-forming toxin that results in leakage of leucocyte contents
- enterotoxins A–E: cytotoxins that stimulate receptors in the gastrointestinal tract, interfering with peristalsis and leading to emesis and diarrhoea
- pyrogenic exotoxin: causes fever, intense inflammation, and rash
- exfoliative toxin: causes superficial splitting of the granular layer (scalded skin syndrome in children)
- toxic shock syndrome toxins: act as superantigens

Staphylococcus aureus is well adapted to the human body and colonizes the nasopharynx of approximately 30% of the normal population. It may also colonize the skin, the perineum, the vagina, and the gastrointestinal tract. It is capable of person-to-person spread and causes pyogenic, septicaemic, and superficial cutaneous disease. It is able to survive intracellularly.

Some staphylococcal infections are toxin mediated (e.g. food poisoning (vomiting induced by ingestion of preformed toxin), scalded skin syndrome (extensive skin disease following localized staphylococcal infection), and toxic shock syndrome (systemic symptoms following localized infection)). In other situations, the severity of the infection may be increased due to toxin production by organisms growing in a pyogenic focus (e.g. extensive necrotic skin infection, or pneumonia associated with PVL-positive strains).

Staphylococcus aureus is a major cause of healthcare-associated and true community-acquired bacteraemia. True community-acquired bacteraemia affects younger people, is less frequently associated with a primary focus of infection, is more commonly associated with a secondary focus of infection (such as endocarditis and osteomyelitis), and has a higher mortality. The majority of *Staphylococcus aureus* bacteraemias are healthcare associated. In modern healthcare, however, the majority of these develop in patients living outside hospital. The most common healthcare-associated sources of *Staphylococcus aureus* bacteraemia are vascular catheters and wound, skin, and soft tissue infections.

Staphylococcus epidermidis and other coagulase-negative staphylococci are organisms of much lower virulence but are common causes of infection of intravascular devices and prosthetic joints. They are associated with the production of biofilm, which makes their eradication by antibiotic either difficult or impossible. *Staphylococcus*

saprophyticus is a recognized cause of urinary tract infection in young women.

Staphylococcus aureus infection is most commonly treated with flucloxacillin or co-amoxiclav. Culture and sensitivity testing should be undertaken to confirm any empirical choice. Success relies on the strain being reported by the laboratory as meticillin sensitive. Alternative agents for meticillin-sensitive strains include erythromycin and tetracyclines. MRSA is detected in less than 1% of the overall population but in about 7% of those recognized as being at higher risk (e.g. individuals having multiple comorbidities, individuals having had multiple hospital admissions, and those from residential and nursing homes). Many meticillin-resistant strains are also erythromycin resistant; for these strains, alternative agents include tetracyclines, the glycopeptides vancomycin and teicoplanin, and linezolid. Combination therapy with oral rifampicin and fusidic acid is also commonly used.

Streptococci

Streptococci are Gram-positive cocci that grow in chains. They are catalase negative. When grown on blood agar, streptococci may produce a green-coloured zone (alpha haemolysis) or a clear zone (beta haemolysis), or be non-haemolytic. Streptococci may also be classified according to their Lancefield group antigen. In addition, each strain may be given a species name. This complexity of nomenclature can lead to some confusion.

Most alpha-haemolytic or 'viridans' streptococci are normal inhabitants of the mouth. Common species include *Streptococcus mutans*, *Streptococcus mitis*, *Streptococcus sanguis*, and *Streptococcus salivarius*. *Streptococcus mutans* is the bacterial cause of dental caries. All are potential causes of infective endocarditis, which, when caused by these organisms, is usually subacute in onset.

Streptococcus pneumoniae is a particular alpha-haemolytic streptococcus recognized in the laboratory by its capsulate appearance, bile solubility, and sensitivity to optochin. The pneumococcus causes many types of infection in addition to pneumonia. These include primary bacteraemia, meningitis, brain abscess, acute sinusitis, otitis media, septic arthritis, septic osteomyelitis, peritonitis, and pericarditis. The capsule, of which over 90 different serotypes have been characterized, is the most important virulence factor. Eight to ten capsular types cause about 60% of the serious infections in adults, and 80% of the invasive infections in children. The pneumococcal polysaccharide vaccine contains purified capsular polysaccharide from 23 capsular types and is thought to be 50%–70% effective in preventing pneumococcal bacteraemia but ineffective against non-bacteraemic disease. It is ineffective in children under 2 years of age. It is recommended for adults over 65 years of age in at-risk groups (e.g., those with splenic absence or dysfunction; chronic respiratory, heart, liver, or renal disease; diabetes; or immunosuppression). The pneumococcal conjugate vaccine, however, is immunogenic in children over 2 months of age. It was first introduced into the childhood immunization programme in the UK in 2006 and originally contained polysaccharide from seven capsular types conjugated to a protein molecule. This has recently been replaced by a new conjugate vaccine covering a further six pneumococcal serotypes and which is indicated for active immunization for the prevention of invasive pneumococcal disease in adults aged 50 years and over and for the prevention of invasive disease, pneumonia, and acute otitis media caused by *Streptococcus pneumoniae* in infants and children from 6 weeks to 5 years of age.

Streptococcus milleri is the name commonly applied to a group of three closely related alpha-haemolytic streptococci (*Streptococcus anginosus*, *Streptococcus constellatus*, and *Streptococcus intermedius*).

These organisms are seen as causes of abscess formation in the brain, liver, and other sites.

The most important beta-haemolytic streptococcus is Lancefield Group A or *Streptococcus pyogenes*. This organism is responsible for a wide range of infections, including localized skin infections (impetigo, cellulitis, and erysipelas), more extensive skin infections (e.g. necrotizing fasciitis), tonsillitis, and associated abscess formation (quinsy), puerperal sepsis, wound infection, and, more rarely, overwhelming sepsis. *Streptococcus pyogenes* can be further classified by the serological characteristics of the surface M proteins (which may prevent opsonization) and T antigens (pili used for bacterial attachment). Streptococcal pyrogenic exotoxins A and C are superantigens secreted by many strains of *Streptococcus pyogenes* that are responsible for the rash of scarlet fever and many of the symptoms of streptococcal toxic shock syndrome. Serological evidence of *Streptococcus pyogenes* infection can be sought by detection of anti-streptolysin O and anti-DNAse antibodies. The combination of tests is more sensitive than either alone, and interpretation of single test results, particularly in children, should be undertaken with care due to high background levels in some populations. *Streptococcus pyogenes* can also cause postinfectious, autoimmune-mediated complications such as rheumatic fever and glomerulonephritis.

Group B beta-haemolytic streptococcus or *Streptococcus agalactiae*, originally recognized as a veterinary pathogen causing bovine mastitis, has been reported with increasing frequency as a cause of sepsis in adult patients. In particular, it has been found in those with diabetes and liver disease, as a cause of bone and joint infections and spontaneous bacterial peritonitis. It is a commensal organism of the gastrointestinal tract and vagina and a cause of neonatal sepsis, causing both bacteraemias and meningitis.

The commonest non-haemolytic streptococci are the enterococci (i.e. *Enterococcus faecalis* and *Enterococcus faecium*). Associated diseases include urinary tract infection and, less commonly, endocarditis. Unlike other streptococci, enterococci are resistant to cephalosporins.

Neisseria species

Neisseria are Gram-negative cocci that have a characteristic paired arrangement that resembles coffee beans. Numerous species exist of which two are important human pathogens: *Neisseria meningitidis* and *Neisseria gonorrhoeae*. Antibiotic culture media for the recovery of *Neisseria meningitidis* and *Neisseria gonorrhoeae* are made selective by the use of an antibiotic cocktail to aid recovery from mixed throat and genital tract flora. The organisms are then identified by Gram stain, a positive oxidase test, and by at least two of the following modes of identification: utilization of sugars, detection of specific preformed enzymes, or immunological tests.

Gonorrhoea is a sexually transmitted infection primarily of the mucous membranes of the urethra, the endocervix, the rectum, the pharynx, and the conjunctiva. Common symptoms include urethral and/or cervical discharge and dysuria, but infection may be asymptomatic in up to 50% of cases. Complications include epididymitis, pelvic inflammatory disease, and haematogenous spread. In addition to routine microscopy and culture methods, molecular amplification techniques are increasingly being used for the detection of *Neisseria gonorrhoeae*. However, only culture enables sensitivity tests to be performed. As resistance profiles continue to change over time, these are a key part of the management of both the individual patient and his or her contacts, and the maintenance of up-to-date local and national treatment guidelines.

Meningococcal infection most commonly presents as either meningitis or septicaemia or a combination of both. Haematogenous spread can result in arthritis, pneumonia, and cardiac infection. Localized infection of mucous membranes can occur. Disease usually occurs from 2 to 7 days after acquisition of the organism in the nasopharynx. However, approximately 10% of adults, and a higher proportion of adolescents, carry meningococci without developing disease. When disease occurs, there may be a prodrome, but the disease is often acute with symptoms that include pyrexia, malaise, headache, neck stiffness, photophobia, and vomiting. A petechial or purpuric non-blanching rash may accompany meningococcal

septicaemia. In developed countries, overall mortality remains at around 10% with a further 10%–20% developing permanent sequelae.

Meningococci remain fully sensitive to penicillin. Treatment should be initiated promptly upon suspicion with either IV benzyl penicillin given in high and frequent doses such as 2.4 g 4 hourly or with one of the long-acting cephalosporins such as ceftriaxone 2 g 12 hourly or cefotaxime 2 g 6 hourly. Secondary cases of meningococcal disease are known to occur. The local consultant in communicable disease control should be informed immediately on clinical suspicion of meningococcal disease. The consultant in communicable disease control will make arrangements for all recent close family and other contacts to receive antibiotic prophylaxis aimed at eradicating *Neisseria meningitidis* from the nasopharynx. The most common agents used in adults are rifampicin 600 mg orally 12 hourly for 2 days, single-dose ciprofloxacin 500 mg orally, or cefotaxime 500 mg intramuscularly.

Of the 13 distinct serogroups of meningococci, the most common in the UK are B and C, while A, Y, and W135 occur less frequently. The decline in the number of cases of serogroup C disease seen since the introduction of the MenC conjugate vaccine in 2000–2 should be regarded as a major achievement of the UK immunization programme. Group B strains now account for 80% of laboratory confirmed isolates in the UK. Group A strains are seen predominantly in sub-Saharan African. In the countries of this 'meningitis belt', the disease is seasonal occurring in sudden, severe epidemics at the end of the dry season.

Haemophilus influenzae

Haemophilus influenzae is a pleomorphic, Gram-negative bacillus that is fastidious in its cultural requirements, needing the cofactors haemin and NAD for growth. These are provided in routine culture media by the heating of horse blood to 56°C—a process that changes the pigmentation from red to brown, producing so-called chocolate agar. Capsulate strains (typed as a–f) are more virulent than non-capsulate ones, the capsular polysaccharide of serotype b *Haemophilus influenzae* being recognized as a major virulence factor in relation to invasive disease such as bacteraemia, meningitis, pneumonia, and epiglottitis. Non-capsulate strains of *Haemophilus influenzae* are a commonly recognized cause of both pneumonia and acute exacerbations of chronic obstructive pulmonary disease.

The *Haemophilus influenzae* type b vaccine (Hib vaccine) was introduced to the UK in late 1992. The Hib vaccine was the first where the capsular polysaccharide, extracted from Hib cultures, was conjugated to a carrier protein molecule to increase the immunogenicity particularly in young children. In the previous 3 years, there had been approximately 900 cases reported of invasive Hib disease in England and Wales. By 1995, this had been reduced to fewer than 100.

Due to the production of beta-lactamase by many strains of *Haemophilus influenzae*, antibiotic therapy is usually with co-amoxiclav or a cephalosporin.

Bacterial enteric pathogens

Acute infectious diarrhoea may be caused by any one of a number of bacterial pathogens. Each one requires a somewhat different culture technique to recover it from a faecal sample, making the routine microbiological investigation of this common syndrome both complex and expensive. Nevertheless, the importance of understanding the cause of acute infectious diarrhoea both for the patient and for epidemiological purposes justifies routine investigation.

The commonly sought bacterial causes are *Campylobacter* spp., *Salmonella* spp., *Shigella* spp., and enterohaemorrhagic (verocytotoxin-producing) *E. coli* O157. Additionally, laboratories will attempt culture of *Vibrio* spp., provided appropriate clinical details are made available, and will test for *Clostridium difficile* toxins in hospital patients and those with a history of recent antibiotic use. In order for laboratories to comprehensively yet cost-effectively search for relevant bacterial, viral, and protozoal pathogens, faecal samples must be accompanied by appropriate clinical detail, including the patient's age

and location, the duration of the patient's symptoms, and a travel and antibiotic history.

Campylobacter spp. are the most frequently identified cause of acute gastroenteritis. They are curved or spiral Gram-negative rods that require a culture medium made selective by antibiotics, an atmosphere of 5%–10% oxygen (microaerophilic), and incubation at 42°C for 48 hours. The common species that cause human gastrointestinal infection are *Campylobacter jejuni* and *Campylobacter coli*. These pathogens cause acute diarrhoea which is often associated with severe abdominal pain and malaise. *Campylobacter* species do not multiply in food. However, the infective dose is small, and transmission to humans usually occurs from undercooked poultry or unpasteurized milk. There is an unexplained seasonality associated with *Campylobacter* infection, with a peak incidence in late spring.

Salmonella species (other than *Salmonella typhi* and *Salmonella paratyphi*) cause gastrointestinal infection via the consumption of contaminated food. As *Salmonella* bacteria colonize the gastrointestinal tracts of many farm animals, food contamination can occur in uncooked or undercooked meat, poultry, eggs, and unpasteurized milk. In addition, contamination of green vegetables and fruit can occur on the farm, and contamination of shellfish can occur from the contamination of seawater with sewage. *Salmonella* are sought by examination of faecal samples for non-lactose fermenting coliforms on selective agar plates. Faecal samples are also enriched by using a specialized broth and then subculture, to ensure any small numbers of *Salmonella* bacteria present are recovered. *Salmonella* species are identified using serological tests to confirm the antigenic structure of the capsule and flagellae. The most commonly isolated serotypes are *Salmonella enteritidis* and *Salmonella typhimurium*. Many other serotypes are known, often bearing the name of the place where that strain was first identified. Some less common species can be acquired from the gastrointestinal tracts of reptiles kept as pets. *Salmonella* species are capable of infecting patients of all ages. Infants, the elderly, and the immunosuppressed are at greater risk of more serious infection.

The four species of *Shigella* responsible for bacillary dysentery are *Shigella dysenteriae*, *Shigella flexneri*, *Shigella boydii*, and *Shigella sonnei*. All are non-lactose fermenting and are sought from faecal samples in much the same way as *Salmonella* spp. The common clinical feature of infection is bloody diarrhoea. *Shigella sonnei* accounts for most cases of bacillary dysentery seen in the UK. It produces a more mild disease and is often caught by faecal–oral spread from household or institutional cases, particularly children. Since the peak of an epidemic seen in the early 1990s, the incidence in the UK has fallen significantly to under 1000 reported cases per annum. The other strains are most commonly seen in the UK as imported cases. Infection with *Shigella dysenteriae* may be severe and be complicated by haemolytic–uraemic syndrome, due to the production of Shiga toxin.

A toxin closely related to Shiga toxin is produced by some strains of *E. coli* serotype O157. Infection with these verocytotoxin-producing organisms is the commonest cause of haemolytic–uraemic syndrome in the UK. Infection can occur in any age group but is more severe in young children. The inoculum required for infection with these organisms is small compared to that for other enteric pathogens. Infection is associated with contaminated milk, contaminated water, undercooked minced beef, and undercooked beef burgers. Children have acquired *E. coli* O157 infection by petting small animals at open farms. *E. coli* O157 are sought using a selective agar and can be recognized by their inability to ferment sorbitol.

Uropathogens

Urinary tract infection accounts for 1%–3% of GP consultations in the UK and affects half of all women at some time during their life. Sexually active women aged 20–50, pregnant women, the elderly, diabetics, and young girls are particularly susceptible to urinary tract infections. Prostatic enlargement in older men may cause obstruction of the urinary tract, thereby increasing the risk of infection. Urinary tract infections are most commonly caused by coliforms, including *E. coli* and *Proteus* spp. (which, together, cause about 83% of urinary tract infections); *Enterococcus* spp. and Group B beta-haemolytic

streptococci (which cause about 10% of urinary tract infections); *Staphylococcus epidermidis* and *Staphylococcus saprophyticus* (which cause about 4% of urinary tract infections); and *Pseudomonas aeruginosa*.

Urinary tract infection is confirmed by a combination of microscopy and semi-quantitative culture. Laboratory microscopy is now frequently undertaken by an automated system, either one based on flow cytometry or one based on high-speed microphotography with image recognition. The key elements reported are white blood cells, red blood cells, epithelial cells, and casts. Some automated systems perform a 'small particle' count that may act as a surrogate for an estimate of the number of bacteria present. This will not be reported but, together with the cell counts, may aid the laboratory in determining the chance of bacterial growth being found on culture and, therefore, the utility of performing a full culture.

Semi-quantitative culture usually relies on the use of a calibrated bacteriological loop. If a loop delivers 1 µl on to a CLED or chromogenic agar plate, and more than 100 colonies of the same organism are grown after 18 hours incubation, then the original specimen can be said to have >10⁵ colony-forming units/ml. This number is said to represent significant bacteriuria (i.e. lesser numbers than this may be regarded as not significant and dismissed as contaminants). It must be remembered, however, that, with suprapubic aspirates or other surgically obtained urine samples, a pure growth of 10⁴ colony-forming units/ml may be clinically significant.

It is not necessary to send a urine specimen to the laboratory from every patient. Non-pregnant women who are between teenage years and menopause and who have urinary tract infection symptoms (e.g. dysuria, frequency, urgency, or nocturia) may instead have an early morning midstream urine specimen tested using a multitest dipstick. The four principal analytes are nitrite (bacteria reduce dietary nitrates to nitrites), leucocyte esterase (an enzyme present in white blood cells), protein, and blood. While these tests have very low sensitivity and specificity individually, the negative predictive value of an overall negative test (i.e. when all four indicators are negative) is very high. In patients with a negative urine dipstick, other causes of the patient's symptoms should be considered (e.g. candidal vulvovaginitis or chlamydial urethritis).

The ability of the multitest dipstick to predict a positive culture result is lower. However, in premenopausal non-pregnant women with clear symptoms of urinary tract infection, the positive dipstick test can be seen as confirmation of infection and empirical antibiotic therapy can be started. A 3-day course of either trimethoprim 200 mg twice daily, nitrofurantoin 50–100 mg four times per day, co-amoxiclav 625 mg three times per day, or cephalexin 500 mg twice daily can be prescribed. These agents are active in vitro against approximately 70%–90% of urinary tract infection isolates.

Urinary tract infection occurring in pregnant women, children, men, or the elderly, or one that either recurs or ascends to the upper tract, should be considered complicated. Infection of the upper tract produces symptoms such as fever, nausea, malaise, or loin pain. All patients with complicated urinary tract infection should have a midstream urine sample sent for microscopy, culture, and sensitivity, and treatment should be based on the results. In general, treatment of complicated urinary tract infection should be for 7 days. This should be extended to 14 days for acute pyelonephritis, for which nitrofurantoin should not be used but ciprofloxacin 500 mg twice daily may be considered.

A midstream urine sample should be sent if symptoms of urinary tract infection occur in a pregnant woman and 7 days of treatment begun with either cephalexin or nitrofurantoin. If cultures remain positive after treatment, or symptoms recur, then prophylaxis may be indicated for the remainder of the pregnancy. Pregnant women who develop a urinary tract infection due to Group B beta-haemolytic streptococcus (*Streptococcus agalactiae*) should, in addition to treatment being given at the time of infection, be offered intrapartum antibiotic prophylaxis against neonatal Group B beta-haemolytic streptococcal infection.

In older women, clinical symptoms may be less specific (e.g. fever, anorexia, or confusion). Furthermore, up to 20% of elderly women may have asymptomatic bacteriuria that does not justify treatment. Consequently, the diagnosis requires both bacteriological evidence and careful clinical judgement prior to treatment. Similar care is

needed when prescribing for catheterized patients, who will almost certainly have bacteriuria; antibiotic therapy will not eradicate this and will select resistant organisms.

311 Mycobacterial infection other than tuberculosis

Stephen Aston, Geraint Davies, and Nick Beeching

Introduction

Mycobacteria are aerobic bacilli with a lipid-rich cell wall and are widespread both in the environment and in animals. Many species within the genus cause disease in humans, most notably those of the *Mycobacterium tuberculosis* complex, which cause tuberculosis, and *Mycobacterium leprae*, the causative agent of leprosy. Several other species, termed non-tuberculous mycobacteria, can cause chronic cutaneous, pulmonary, and disseminated infections. This chapter will briefly review infection with non-tuberculous mycobacteria and *Mycobacterium leprae*; tuberculosis is the focus of Chapter 130.

Non-tuberculous mycobacterial infection

Definition and aetiology of non-tuberculous mycobacteria infections

Non-tuberculous mycobacteria (NTM) are resilient microorganisms widely distributed in both soil and water. The number of recognized species is steadily rising, with more than 125 catalogued to date, although most human disease is due to a relatively limited number of species (Table 311.1). NTM infection is rare, with an estimated incidence in industrialized countries of 4.0–6.1 cases per 100 000. Significant under-reporting is probable, since the condition is not notifiable.

Natural history of NTM infections

Infection is acquired from environmental sources via respiratory, gastrointestinal, or cutaneous routes. Human-to-human transmission of NTM has traditionally been considered unlikely, although recent studies suggest this may be an important mechanism for acquisition of *M. abscessus* by individuals with cystic fibrosis. As for *Mycobacterium tuberculosis* infection, macrophages are key to an effective host immune response. Resident macrophages phagocytose the invading mycobacteria, but then require stimulation with interferon gamma and other cytokines to activate intracellular killing mechanisms and eradicate the infection. Most infections are asymptomatic and, unlike the case with tuberculosis, latent infection with NTM has not been shown to occur. Many NTM species are of low pathogenic potential and, if identified to be the cause of symptomatic illness, would indicate significantly impaired host immunity.

Typical disease syndromes of NTM infections, and their management

NTM lung disease

Aetiology and natural history of NTM lung disease

Lung disease is the most common clinical manifestation of NTM infection. There is some geographic variation in the predominant causal species, but *Mycobacterium avium* complex (MAC), *Mycobacterium kansasii*, *Mycobacterium abscessus*, and *Mycobacterium xenopi* are frequently implicated (Table 311.1). Classically, NTM lung disease has been recognized as complicating chronic lung conditions such as COPD and bronchiectasis. More recently, it has been described in individuals without structural lung disease and, in this setting, postmenopausal Caucasian women are predominantly affected.

Typical symptoms of NTM lung disease

The clinical features of NTM lung disease are highly variable, influenced by the presence of concurrent lung disease, the immunological status of the individual, and the virulence of the relevant NTM species. Virtually all patients have chronic cough. Sputum production, dyspnoea, haemoptysis, chest pain, and weight loss are variably reported; systemic feature become more prominent as the disease progresses.

Approach to diagnosing NTM lung disease

Diagnosis of NTM lung disease requires the demonstration of persistently positive sputum culture results in the presence of compatible clinical and radiological features. Investigation of a patient suspected of having NTM lung disease should include a chest X-ray, high-resolution CT of the chest, and examination of three or more sputum specimens. However, the diagnosis of NTM lung disease is frequently challenging. The clinical features may resemble those of concurrent chronic lung disease, and radiological changes may be equally non-specific. Environmental contamination of clinical specimens yielding false positive results is common, and even repeatedly positive sputum culture may occur in the absence of progressive clinical or radiological features. The following techniques may be used in the diagnosis:

- Radiology:
 - Two main patterns of pulmonary disease are recognized: nodular/bronchiectatic disease, characterized by nodules and bronchiectasis predominantly affecting the mid- and lower lung fields; and fibrocavitary disease that resembles the typical upper zone changes of post-primary TB.

Table 311.1 Main non-tuberculous mycobacterial species causing human disease

Lung disease	Skin, soft tissue, and bone disease	Disseminated disease	Lymphadenitis
<i>Mycobacterium avium</i> complex	<i>Mycobacterium marinum</i>	<i>Mycobacterium avium</i> complex	<i>Mycobacterium avium</i> complex
<i>Mycobacterium kansasii</i>	<i>Mycobacterium ulcerans</i>	<i>Mycobacterium kansasii</i>	<i>Mycobacterium malmøense</i>
<i>Mycobacterium xenopi</i>	<i>Mycobacterium abscessus</i>	<i>Mycobacterium chelonae</i>	<i>Mycobacterium scrofulaceum</i>
<i>Mycobacterium abscessus</i>	<i>Mycobacterium chelonae</i>	<i>Mycobacterium abscessus</i>	<i>Mycobacterium genavense</i>
<i>Mycobacterium malmøense</i>	<i>Mycobacterium avium</i> complex	<i>Mycobacterium haemophilum</i>	
<i>Mycobacterium fortuitum</i>	<i>Mycobacterium kansasii</i>	<i>Mycobacterium genavense</i>	
	<i>Mycobacterium terrae</i>		

- The features of any underlying chronic lung disease will also be evident.
- It is not possible reliably to distinguish NTM lung disease from pulmonary TB on the basis of radiological features alone.
- Microscopy:
 - Sputum microscopy may reveal acid-fast bacilli (AFB); nucleic acid amplification tests can then be employed to rapidly differentiate NTM species from those of the *Mycobacterium tuberculosis* complex.
 - In areas of low TB endemicity, AFB seen in sputum are more likely to be NTM.
- Culture:
 - NTM commonly contaminate microbiological samples; therefore, a single positive sputum culture sample in isolation is insufficient to prove a diagnosis of NTM lung disease.
 - At least three sputum samples should be collected on separate days.
 - Consistently culture-positive specimens are predictive of NTM disease, but need to be correlated with clinical and radiological features.
- Histology:
 - Granulomatous inflammation evident on biopsy provides further supportive evidence of NTM disease in individuals with NTM culture-positive sputum specimens.

Treatment of NTM lung disease

The management of NTM lung disease varies according to the species involved and the clinical presentation of the disease. Generally, medical therapy with combinations of antimicrobial agents is used and continued for at least 12 months after achieving negative sputum cultures. Preferred regimens for disease due to MAC and *Mycobacterium kansasii* are defined. For MAC pulmonary disease, these are combination regimens which include a macrolide, ethambutol, a rifamycin, and, for patients with cavitary or previously treated disease, an aminoglycoside is added. For other NTM species, treatment regimens are generally extrapolated from those used for MAC. It should be remembered that, for many NTM species, the results of in vitro drug susceptibility tests do not correlate with the clinical response to therapeutic agents.

For symptomatic individuals with AFB-positive sputum and presenting with progressive pulmonary disease, commencement of empirical TB treatment while awaiting the results of sputum culture or nucleic acid amplification testing is often appropriate (see Chapter 130). Conversely, treatment may be deferred for individuals whose sputum cultures are persistently positive for NTM but who have no relevant symptoms or radiological evidence of disease progression. These patients should be observed closely with repeated sputum cultures and appropriate interval lung imaging. For patients with disease predominantly localized to one lung, there is a role for resectional surgery in the circumstances of inadequate response to drug therapy, infection with resistant organisms, or the development of significant local complications (e.g. haemoptysis).

Skin and soft tissue NTM disease

Skin and soft tissue NTM disease develops after direct inoculation of mycobacteria into the skin as a result of local trauma. It is most commonly due to *Mycobacterium fortuitum*, *Mycobacterium abscessus*, *Mycobacterium chelonae*, *Mycobacterium marinum*, and *Mycobacterium ulcerans* (Table 311.1). It typically manifests as a chronic, nodular, ulcerating eruption. Deeper inoculation of mycobacteria may occur through accidental trauma or surgery and may result in tenosynovitis, arthritis, or osteomyelitis. The diagnosis of NTM disease is confirmed by biopsy of the skin or affected tissue, in which AFB and granulomata are usually evident. Recommended antimicrobial treatment regimens vary with the NTM species involved and the extent of disease. Surgical debridement may be indicated for extensive disease, abscess formation, or circumstances where adequate drug therapy is difficult. For small isolated lesions, surgical excision alone may be curative.

Disseminated NTM disease

Disseminated NTM disease is only seen in severely immunocompromised individuals, most commonly those with advanced HIV

infection. Prior to the introduction of highly active antiretroviral therapy (HAART), it was noted in 40% of patients with advanced HIV. The widespread use of HAART has led to significant falls in incidence. In non-HIV patients, disseminated NTM disease has been described in the context of malignancy, chemotherapy, long-term corticosteroids, and genetic defects of the interferon gamma pathway. More than 90% of cases of disseminated NTM cases are caused by MAC (Table 311.1).

Disseminated NTM disease typically presents with fever, night sweats, weight loss, and malaise. Hepatosplenomegaly and lymphadenopathy are often evident on imaging, if not detectable on clinical examination. Laboratory tests reveal non-specific abnormalities, including anaemia, leucopaenia, and elevated alkaline phosphatase levels. In more than 90% of cases, blood cultures are positive. For the remaining cases, disseminated NTM disease may be established by culture of a bone marrow or liver biopsy specimen. The possibility of multiple concurrent infectious pathologies should always be remembered, as the affected patients are usually highly immunocompromised.

Disseminated MAC disease is treated with either azithromycin or clarithromycin in combination with ethambutol. Rifabutin may be added for highly immunocompromised or symptomatic patients. For HIV-infected patients, HAART should be initiated promptly after diagnosis. Following the completion of treatment, secondary prophylaxis with either azithromycin or clarithromycin should be continued until adequate immune reconstitution has occurred. The mortality rate due to disseminated NTM infection is around 30% in both HIV-infected and uninfected patients.

Lymphadenitis due to NTM

Lymphadenitis due to NTM is most commonly seen in young children and usually involves the submandibular, cervical, and preauricular lymph nodes. In the absence of HIV infection, it rarely occurs in adults. MAC currently accounts for approximately 80% of culture-proven cases of NTM lymphadenitis (Table 311.1).

The typical clinical presentation of non-tender, unilateral lymphadenopathy with minimal systemic symptoms is largely indistinguishable from that of tuberculous lymphadenitis which is the main differential diagnosis. In a low TB endemicity setting such as the UK, tuberculous lymphadenitis accounts for only 10% of mycobacterial lymphadenitis in children, but more than 90% in adults. For both tuberculous and NTM disease, histological examination of lymph node material typically shows caseating granulomata with or without visible AFB. A definitive diagnosis may be made on mycobacterial culture, but results are delayed by several weeks and, frequently, no organism is cultured. Lack of reactivity to a tuberculin skin test is supportive of disease due to NTM.

Complete surgical excision of the affected lymph nodes is the recommended treatment for most localized NTM lymphadenitis. Antimycobacterial chemotherapy is usually reserved for recurrent disease or cases where surgical excision is impossible or incomplete.

Leprosy

Definition and aetiology of leprosy

Leprosy is a chronic granulomatous infection of the skin and peripheral nerves caused by the intracellular bacillus *Mycobacterium leprae*. It is characterized by anaesthetic skin lesions and peripheral neuropathy with nerve thickening. Left untreated, affected individuals may develop disfiguring and disabling deformities as a result of repeated trauma and secondary infection of anaesthetic areas.

Demographics of leprosy

The WHO reports the global prevalence of leprosy as the number of individuals currently on registered treatment programmes. Following the introduction of multidrug treatment, the global prevalence of leprosy has fallen dramatically from an estimated 12 million registered cases in 1985 to fewer than 200 000 at the start of 2011. However, disease transmission continues to occur at substantial levels in some countries. In recent years over 200 000 new cases of leprosy have been detected each year, with over 80% occurring in four countries—India, Brazil, Indonesia, and the Democratic Republic

Box 311.1 WHO diagnostic criteria for leprosy

The presence of one or more of these features is considered diagnostic of leprosy:

- One or more hypopigmented or reddish patches with definite loss of sensation
- Thickened peripheral nerves
- Acid-fast bacilli identified in slit-skin smears or biopsy

Reproduced with permission of Public Health England

of Congo. Persistent disability resulting from nerve damage adds to the global burden of disease and means that leprosy remains a leading cause of neurological disability in developing countries. About ten new cases are currently diagnosed each year in the UK, all imported. The last documented case of transmission within the UK occurred over 50 years ago.

Natural history of leprosy

The means of transmission and natural history of *Mycobacterium leprae* infection are not completely understood. Individuals with lepromatous disease produce minute particles laden with bacilli that are presumed to be the vehicle of airborne person-to-person transmission. Only a small minority of exposed individuals develop clinical disease. Bacilli are taken up via the upper respiratory tract mucosa and then demonstrate a specific tropism for Schwann cells and macrophages, to establish a slowly replicating intracellular infection. The emergence of mycobacterial antigens from infected cells induces a specific host immune response, which may result in a chronic inflammatory process affecting the skin and peripheral nerves.

Typical symptoms of leprosy, and less common symptoms

The cardinal diagnostic features of leprosy are summarized in Box 311.1.

The nature of the host cell-mediated immune response determines the clinical manifestations of leprosy. The Ridley–Jopling classification categorizes leprosy into five types on the basis of clinical and histological features and the bacillary load. This is shown in Table 311.2, together with the simplified WHO case definition, which divides the clinical spectrum into paucibacillary disease (≤ 5 lesions) and multibacillary disease (≥ 6 lesions in the skin and/or the nerves).

Cutaneous features of leprosy

Tuberculoid leprosy

A robust cell-mediated immune response results in tuberculoid leprosy (the ‘TT’ form in the Ridley–Jopling classification), which is characterized by localization of infection within one or few nerves, and/or a small number of well-demarcated, hypopigmented, anaesthetic patches; this is also termed paucibacillary disease by the WHO. Histological examination demonstrates well-formed granulomas with an abundance of CD4⁺ T-lymphocytes surrounding dermal nerves, and an absence of visible bacilli.

Lepromatous leprosy

Unlike tuberculoid leprosy, lepromatous leprosy (the ‘LL’ form in the Ridley–Jopling classification) occurs when the cell-mediated immune response is poor. Lesions are generally macular, poorly defined, and widely and symmetrically distributed. Diffuse dermal infiltration and skin thickening may result in a classical ‘leonine facies’ appearance. Histological examination demonstrates diffuse infiltration of the deeper dermis with foamy macrophages laden with bacilli but few granulomata.

Borderline forms of leprosy

Between these polar extremes, several forms of disease are recognized which have intermediate clinical and histological features (the ‘BT’, ‘BB’, and ‘BL’ forms in the Ridley–Jopling classification). Moving from tuberculoid towards lepromatous disease, there is a reduction in the cellular immune response and a corresponding increase in the bacillary load and the number of skin lesions present. Histological examination reveals small granulomata that become more diffuse on progression towards lepromatous disease. The skin lesions of intermediate forms are highly variable and may be macular, papulonodular, plaque-like, or geographic. The term ‘multibacillary disease’ includes lepromatous disease and borderline disease states near the lepromatous end of the disease spectrum (see Table 311.2).

Nerve involvement in leprosy

Peripheral nerve involvement in leprosy is extremely common. Sensory nerve dysfunction usually predominates, characterized by anaesthetic skin lesions. Motor and autonomic nerves may also be affected, resulting in weakness and reduced sweating, respectively. Affected nerves are usually thickened and palpable but, occasionally, significant nerve dysfunction occurs in the absence of obvious inflammation. Some patients have purely neural leprosy, without visible skin lesions.

Eye involvement in leprosy

Blindness is a relatively common complication of leprosy. Motor and sensory damage lead to impaired eye closure and reduced corneal sensation, predisposing to corneal ulceration, repeated trauma, and secondary cataract formation.

Reactional states in leprosy

The immune response in leprosy is dynamic, and spontaneous fluctuations can result in rapid alterations in clinical status. Type 1 (reversal) reactions follow spontaneous increases in T-cell reactivity and are characterized by inflammation of skin lesions and acute neuritis, often associated with rapid deterioration in nerve function. Inflammation must be rapidly controlled in order to prevent permanent nerve damage. Type 1 reactions occur in one-third of individuals with borderline disease and may be evident at presentation.

Erythema nodosum leprosum (Type 2) reaction is an acute onset systemic disorder with multiple organ involvement that typically occurs in individuals with multibacillary disease. It arises as a result of extravascular deposition of immune complexes and consequent complement and neutrophil activation. Typical features include fever, painful skin nodules, uveitis, arthritis, and dactylitis.

Table 311.2 Classifications and features of leprosy

WHO Classification	Paucibacillary (PB)		Multibacillary (MB)		
	0	0–1+	1–3+	3–5+	5–6+
Bacteriological Index	0	0–1+	1–3+	3–5+	5–6+
Type of leprosy	Polar tuberculoid		Borderline		Polar lepromatous
Ridley–Jopling Classification	TT	BT	BB	BL	LL
Skin lesions	Increasing number of skin lesions →				
Nerve lesions	Increasing number of enlarged nerves & nerve involvement →				
Stability	Stable	Unstable—may develop reactions and new nerve damage			Stable

Reproduced with permission of Public Health England.

Table 311.3 WHO-recommended multidrug therapy regimens

Type of leprosy	Drug treatment		Minimum duration of treatment (months)
	Monthly supervised	Daily, self-administered	
Paucibacillary	Rifampicin 600 mg	Dapsone 100 mg	6
Multibacillary	Rifampicin 600 mg	Clofazimine 50 mg	12
	Clofazimine 300 mg	Dapsone 100 mg	12

Reproduced with permission of Public Health England.

Approach to diagnosing leprosy

In an endemic area, leprosy should be considered in any patient presenting with peripheral neuropathy or persistent skin lesions. In the UK, leprosy is frequently missed and should be considered in any patient who has ever lived abroad and who presents with peripheral anaesthesia and nerve thickening (which should always be sought in immigrants with supposed diabetic neuropathy), unusual skin lesions, or unexplained acute rheumatological presentations. All suspected patients should be referred to a national specialist in leprosy (see https://www.gov.uk/government/uploads/system/uploads/attachment_data/file/334363/Memorandum_on_leprosy_2012.pdf for a list of UK consultant advisers in leprosy).

Histological diagnosis is the gold-standard test, with the presence of neural inflammation distinguishing leprosy from other granulomatous disorders. Microscopy of slit-skin smears for bacilli is useful for identifying infectious patients and to monitor the response to treatment, but is of little value in diagnosis since it is negative in many patients with leprosy. The bacillary load is measured by counting the average number of bacilli seen in 6–8 slit-skin smear preparations, yielding a ‘bacterial index’ (BI). In this semi-quantitative logarithmic scale, a BI of 1+ indicates at least 1 bacillus per 100 microscopic fields, and the maximum possible BI of 6+ found in polar lepromatous leprosy indicates 1000 or more bacilli per field (Table 311.2).

Other diagnoses that should be considered aside from leprosy

The varied manifestations of leprosy lead to a broad differential diagnosis including sarcoidosis, cutaneous leishmaniasis, post-kala-azar dermal leishmaniasis, cutaneous TB, syphilis, granuloma annulare, vitiligo, post-inflammatory hypopigmentation, pityriasis versicolor, dermatophyte infection, and hereditary neuropathies associated with nerve thickening.

Treatment of leprosy, and its effectiveness

Antimicrobial therapy for leprosy

All patients diagnosed with leprosy should receive multidrug combination treatment. WHO recommends two first-line regimens corresponding to its simplified classification system (Table 311.3).

Prior to the adoption of current treatment guidelines, 24 months of antimicrobial therapy was recommended for multibacillary disease but this has been reduced to 12 months for field use in endemic settings. Reported relapse rates following directly observed multidrug therapy are very low. All treatment should be managed in conjunction with a leprosy specialist. Contact details for designated consultant advisers in leprosy in the UK are available at https://www.gov.uk/government/uploads/system/uploads/attachment_data/file/334363/Memorandum_on_leprosy_2012.pdf.

Management of reactional states in leprosy

Reactional states require urgent assessment and treatment in order to prevent permanent nerve dysfunction. Type 1 reactions are treated with oral corticosteroids, which are gradually tapered over 3–5 months. Decompressive surgery is occasionally used to relieve mechanical obstruction caused by nerve oedema if nerve dysfunction persists despite medical treatment. Similarly, high-dose corticosteroids are initially used to treat erythema nodosum leprosum reactions but alternative agents such as thalidomide may be required to achieve sustained control. Reactions may continue to occur for years after successful antimicrobial therapy, and patients must be educated about the possibility and nature of reactions and the need to contact their physician immediately if symptoms arise.

Prevention of disability in leprosy

Rapidly identifying nerve dysfunction and early institution of steroid therapy are essential in preventing disability. Hence, a detailed neurological assessment should be performed at each clinical encounter. If neuropathy occurs, prevention of secondary tissue damage is the primary objective. Patients should be educated to avoid activities that put neuropathic areas at risk, provided with appropriate orthotics, and advised to undertake regular self-examination. Secondarily infected tissues require prompt antibiotic treatment and possibly surgical debridement to minimize tissue damage.

312 Spirochaetal infection (non-syphilis)

Lucy Cottle and Mike Beadsworth

Introduction

Spirochaetes are slender, helical, Gram-negative rods. The group includes *Treponema*, *Leptospira*, and *Borrelia*, which are further classified as summarized in Table 312.1. This chapter focuses on leptospirosis and Lyme disease; syphilis is covered in Chapter 313. Discussion of the non-venereal treponematoses and relapsing fevers is beyond the scope of this text; they are rarely encountered in the UK.

Leptospirosis

Definition of leptospirosis

Leptospirosis is a zoonotic infection caused by *Leptospira interrogans*. There are over 250 serovars associated with infection in different animals, for example *Leptospira interrogans icterohaemorrhagiae* (rats) and *Leptospira interrogans hardjo* (cattle).

Aetiology of leptospirosis

Animals excrete leptospires in their urine. Humans are incidental hosts and acquire infection through contact with animal urine or contaminated fresh water. Transmission occurs across mucous membranes or damaged skin and possibly via ingestion or inhalation of contaminated water.

Typical symptoms of leptospirosis, and less common symptoms

Most infections are asymptomatic or only mildly symptomatic and self-limiting. The incubation period is usually 7–12 days (range 2–30 days). Illness typically follows a biphasic course, with an acute bacteraemic phase, which lasts for approximately 1 week, and then an immune phase. During the bacteraemic phase, patients may present with a flu-like illness with headache, fever, and vomiting. Conjunctival suffusion and myalgia, often affecting the calves, are characteristic. Less frequent findings include hepatosplenomegaly, meningism, and a rash.

Patients may show signs of recovery before progressing to the immune phase, when fever and rigors recur with clinical deterioration. Aseptic meningitis is common, while Weil's disease (jaundice, acute renal failure, and haemorrhage) develops in only a minority.

Demographics of leptospirosis

Leptospirosis occurs worldwide, with the highest incidence in tropical and subtropical regions. In the UK, infection is associated with

occupational or recreational activities carrying a risk of exposure, such as farming, fishing, sewer work, canoeing, windsurfing, and freshwater swimming. Imported cases in adventure travellers are increasingly recognized.

Natural history of leptospirosis, and complications of the disease

The bacteraemic phase may resolve without treatment, and only a minority develop biphasic disease. The immune phase can last up to 30 days, and recovery may take up to 3 months after severe disease; however, most patients recover within 2–6 weeks with appropriate treatment. Complications include renal failure, haemorrhage, hepatic dysfunction, myocarditis, rhabdomyolysis, pulmonary haemorrhage, and acute respiratory distress syndrome.

Approach to diagnosing leptospirosis

Diagnosis requires a high index of suspicion in a febrile patient with headache, myalgia, conjunctival suffusion, or jaundice, and possible exposure to leptospires.

Other diagnoses that should be considered aside from leptospirosis

Depending on the travel history, the differential diagnosis may include influenza, dengue, yellow fever, hantavirus, malaria, typhoid fever, rickettsial disease, viral hepatitis, meningococcal disease, and relapsing fever.

'Gold-standard' diagnostic test for leptospirosis

Most cases of leptospirosis are identified through serology. Antibodies to leptospires may be detected 5–10 days after symptom onset. An IgM ELISA is used to screen all sera, with positive results confirmed by a microscopic agglutination test. At least two serum specimens are required, taken at least 7 days apart.

Acceptable diagnostic alternatives to the gold-standard test for leptospirosis

PCR is used on clinical samples (e.g. blood, urine, CSF, bronchoalveolar lavage, and tissue) taken within 7 days of symptom onset. *Leptospira* culture can be performed from blood culture and samples of blood, CSF, and tissue. Culture is performed on clinical samples that have tested PCR positive.

Other relevant investigations for leptospirosis

Patients may have a leucocytosis or leucopenia, and about half have mild-to-moderate elevations in hepatic transaminases and creatine kinase. In Weil's disease, the bilirubin may be very high, and there is often thrombocytopenia and renal impairment. CSF may show raised white cells and protein, and normal glucose.

Prognosis of leptospirosis, and how to estimate it

For leptospirosis, mortality is <1% in anicteric disease, 5%–15% in Weil's disease, and even higher in severe pulmonary haemorrhage. Acute renal failure, respiratory insufficiency, hypotension, arrhythmias, and altered mental status are poor prognostic factors. Males suffer more severe illness.

Treatment of leptospirosis, and its effectiveness

The value of antimicrobial therapy is debated due to a lack of evidence. We strongly recommend early initiation of antibiotics, whenever there is clinical suspicion of leptospirosis. Mild disease can be

Table 312.1 Principal spirochaetes associated with human disease

Genus	Species	Clinical disease
<i>Treponema</i>	<i>Treponema pallidum</i> subspecies <i>pallidum</i>	Syphilis
	<i>Treponema pallidum</i> subspecies <i>pertenue</i>	Yaws
	<i>Treponema pallidum</i> subspecies <i>endemicum</i>	Bejel

<i>Leptospira</i>	<i>Leptospira interrogans</i>	Leptospirosis
<i>Borrelia</i>	<i>Borrelia burgdorferi</i>	Lyme disease
	<i>Borrelia recurrentis</i>	Epidemic relapsing fever
	Various <i>Borrelia</i> spp.	Endemic relapsing fever

treated with oral doxycycline (100 mg twice daily) or amoxicillin (500 mg four times daily) for 7–10 days. IV benzylpenicillin (600 mg (=1 million IU) every 4 hours) or ceftriaxone (1 g once daily) should be used in severe cases. Adequate supportive care is essential, including renal replacement therapy and ventilation if required. A Jarisch–Herxheimer reaction, which is a reaction to bacterial antigens released from disrupted organisms, may complicate the early phase of treatment. It usually manifests as abrupt worsening of the patient, with hypotension and sometimes features of immune-complex disease, typically within the first 24–48 hours after starting antimicrobial therapy.

Lyme disease

Definition of Lyme disease

First described in Lyme, Connecticut, Lyme disease is the most common tick-borne infection in Europe and North America. It is caused by *Borrelia burgdorferi*, a spirochaete transmitted by *Ixodes* ticks. Ticks are only just visible at the time of attachment and are easily missed by the patient, so a definitive history of tick bite is often absent.

Aetiology of Lyme disease

Several pathogenic species of *Borrelia* have been identified in Europe, principally *Borrelia garinii*, *Borrelia afzelii*, and *Borrelia burgdorferi sensu stricto*. In North America, the disease is caused exclusively by *Borrelia burgdorferi sensu stricto*.

Typical symptoms of Lyme disease, and less common symptoms

Infection may be asymptomatic. The most common manifestation is erythema migrans, an expanding rash which spreads from the site of a tick bite after 3–30 days. Central clearing develops producing an annular pattern. Fever, myalgia, arthralgia, and headache may accompany the rash.

Without treatment, infection may disseminate to the nervous system, joints, and heart. In the UK the most common complications involve the nervous system (neuroborreliosis). Unilateral or bilateral facial nerve palsy, lymphocytic meningitis, and radiculoneuritis are seen in adults, usually within 3–12 weeks of infection. Radiculoneuritis may not be apparent until several months after infection and produces severe shingles-like pain with altered sensation or paresis. Less commonly, neuroborreliosis may present as an encephalitis or myelitis.

Lyme carditis mainly presents with conduction defects within a few weeks of infection. Lyme arthritis usually affects the knee, producing synovitis, effusion, and pain. It is more frequently associated with *Borrelia burgdorferi sensu stricto* infection acquired in North America or central Europe.

Demographics of Lyme disease

Lyme disease occurs predominantly in temperate regions of Europe, North America, and Asia. Woodland areas are the usual habitat for ticks, as well as animal species which act as reservoir hosts for *Borrelia burgdorferi*. Occupational and recreational activities associated with exposure to tick bites include forestry, farming, deer handling, hiking,

and mountain biking, particularly in highly endemic areas such as central and eastern Europe.

Natural history of Lyme disease, and complications of the disease

Clinical Lyme disease can be considered to consist of three stages: early localized disease, early disseminated disease, and late disease. Only a minority of untreated patients develop late-stage disease, which arises months to years later and affects the skin, the musculoskeletal system, and/or the nervous system. Neuroborreliosis complicates 5%–10% of infections. It is classified as early (i.e. neurological symptoms lasting for <6 months) or late (i.e. lasting for >6 months).

Approach to diagnosing Lyme disease

Erythema migrans can be diagnosed reliably by clinical examination alone, if a typical rash occurs following potential exposure to ticks. Patients may not recall having been bitten. Antibody tests are positive in only 30%–70% of patients at this early stage, and are not recommended unless the rash is atypical. All other manifestations of Lyme require laboratory confirmation.

Other diagnoses that should be considered aside from Lyme disease

Anaplasmosis, babesiosis, Q fever, and tick-borne encephalitis are also transmitted by tick bites in areas where these infections are endemic. The differential diagnosis for rashes resembling erythema migrans includes cellulitis, insect/tick-bite reactions, ringworm, granuloma annulare, and erythema multiforme.

'Gold-standard' diagnostic test for Lyme disease

Lyme disease is usually diagnosed by serology. Samples should be sent to the national reference laboratory at Public Health England at Porton Down, where a validated, two-tier testing methodology is used. The screening test is a C6-antigen-based ELISA (combined IgG and IgM), followed by a confirmatory Western blot (separate IgG and IgM). Antibodies develop slowly; thus, negative serology in early disease does not exclude infection. A second sample taken 2–4 weeks later may confirm seroconversion.

Acceptable diagnostic alternatives to the gold-standard test for Lyme disease

Detection of borrelial DNA in synovial fluid by PCR is useful in suspected Lyme arthritis. PCR examination of CSF has a low yield, and detection of intrathecal antibodies specific to *Borrelia burgdorferi* is more useful in suspected neuroborreliosis.

Other relevant investigations for Lyme disease

In neuroborreliosis, the CSF leucocyte count is typically 10–1000 cells/mm³ and the protein count often elevated.

Prognosis of Lyme disease, and how to estimate it

More than 90% of patients with early disease respond to treatment. Patients with late manifestations usually respond to antibiotics but improvement may take weeks to months.

Table 312.2 Management of Lyme disease

Clinical manifestation	Preferred antibiotic regimens	Comments
Erythema migrans or isolated facial palsy	Doxycycline* 100 mg twice daily orally for 14 to 21 days, or amoxicillin 500 mg three times per day orally for 14 to 21 days	
Neuroborreliosis [†]	Ceftriaxone 2 g once per day IV for 14 days	Treat for 21 days if late neuroborreliosis
Lyme arthritis	Doxycycline* 100 mg twice per day orally for 28 days, or amoxicillin 500 mg three times per day orally for 28 days	Ceftriaxone 2 g once per day IV 14–28 days if arthritis progresses despite oral therapy
Lyme carditis	If the patient is hospitalized: ceftriaxone 2 g once per day IV for 14 to 21 days If the patient does not require admission: treat as for erythema migrans	Admit for cardiac monitoring if the patient is symptomatic, there is second-/third-degree heart block, or the PR interval is ≥ 300 milliseconds Temporary pacing may be required

*Avoid in pregnancy and breastfeeding.

[†]In light of recent evidence, European guidelines recommend that oral doxycycline (200 mg daily) can be used as an alternative to IV ceftriaxone for patients with neurological involvement confined to the meninges, cranial nerves, nerve roots, or peripheral nerves. Patients with myelitis, encephalitis, or cerebral vasculitis should receive IV ceftriaxone.

Neurological sequelae following neuroborreliosis are more common if symptoms are prolonged prior to treatment and in those with CNS involvement.

Treatment of Lyme disease, and its effectiveness

Table 312.2 summarizes antibiotic recommendations for Lyme disease in adults. Treatment success should be judged on clinical response, as antibodies can persist for years. Antibiotics may not hasten the resolution of facial palsy or carditis but should be given to prevent further sequelae. Complete heart block usually resolves within 1 week, and lesser conduction disturbances within 6 weeks.

313 Syphilis

Martyn Wood and Marilyn Bradley

Definition of the disease

The term 'syphilis' describes the wide-ranging clinical manifestations of infection with the slowly dividing spirochete bacterium *Treponema pallidum* subsp. *pallidum*.

Aetiology and demographics of the disease

T. pallidum infection is mainly sexually acquired; it is thought the bacterium enters through microabrasions in the skin or mucosa. Congenital infection via mother-to-child transmission is also recognized. The driving force of the clinical manifestations of all stages of syphilis is an underlying and often multisystem vasculitis.

The incidence of syphilis in the general British population rapidly declined following the widespread introduction of penicillin in the 1940s. Increasing levels of syphilis were seen again in the 1960s and 1970s, mainly in men who have sex with men (MSM). With the emergence of the HIV epidemic in the 1980s, syphilis infections declined, along with other sexually transmitted infection rates, as people adopted safer sexual practices.

The end of the twentieth century again saw large rises in syphilis incidence, reaching epidemic proportions, which continue today. The majority of cases are seen in MSM. However, infection levels continue to rise in heterosexual men and women, the majority acquiring their infection in the United Kingdom.

Natural history of the disease

Acquired syphilis can be divided into early and late presentations. In early stage infection, the *T. pallidum* infection has been acquired within 2 years of the diagnosis. This early stage includes the symptomatic primary and secondary stages of infection, and the asymptomatic early latent stage. Late infection of over 2 years' standing includes all the manifestations of tertiary syphilis, and asymptomatic late latent infection.

T. pallidum has an incubation period of approximately 9–90 days. The primary stage of infection often goes unnoticed or is truly asymptomatic. Classically, primary syphilis presents with a painless indurated ulcer (chancre) at the site of *T. pallidum* inoculation in genital areas such as the penis, the vulva, the cervix, and the rectum. Regional lymphadenopathy soon follows, with systemic spread of infection then occurring. Atypical presentations such as painful lesions, balanitis, vulvitis, oral lesions, or multiple lesions are frequently described and often go undiagnosed.

Secondary syphilis occurs approximately 4–10 weeks after the primary infection. In the majority of cases, it presents as a rash which is commonly maculopapular but can have many appearances, including psoriaform or pustular. The rash preferentially affects the trunk in most cases and occurs on the palms and soles in around half of infections. The primary lesion may not have healed by the time secondary syphilis symptoms develop, and the two may be present simultaneously. There are multiple other potential, less common, but clinically significant presentations of secondary syphilis; these are summarized in Table 313.1.

Complications of the disease

Tertiary stage syphilis is the result of untreated, long-standing infection. Pre-antibiotic-era studies suggest that 40% of untreated individuals will advance to tertiary stage infection. If the tertiary stage occurs, it can present anywhere from 2 to 15 years after the initial infection. This stage includes gummatous, cardiovascular, and neurological

syphilis. Gummatous syphilis is often erroneously referred to as benign tertiary syphilis, but lesions can be destructive or infiltrative and can cause significant organ or tissue damage, depending on which system is involved. Neurosyphilis (encompassing tabes dorsalis and general paralysis of the insane) presents as small vessel vasculitis, with meningeal or cortical involvement. Syphilitic retinitis is classified as neurosyphilis due to optic nerve involvement but can present early as part of the secondary syphilis stage. Cardiovascular syphilis involves the aortic arch and root, leading to aortic aneurysm and valve dysfunction. Coronary ostial involvement can also precipitate myocardial ischaemia.

Approach to diagnosing the disease

If syphilis is suspected or a patient's presentation is unexplained, a sexual history should be taken, specifically assessing timing and type of sexual risk. This will guide the clinician as to which diagnostic tests to perform and will allow correct interpretation of results. In those individuals who are at higher risk for syphilis acquisition, regular serological screening should be undertaken. To interpret serological tests appropriately, a history of previous syphilis testing and treatment and the current timing of symptoms should be ascertained. Other treponemal infections can give rise to false-positive serological screening tests and should be enquired about.

Other diseases that should be considered

Syphilis can present very non-specifically and can resemble multiple other pathologies. In general, any systemic vasculitic process should be considered in the differential diagnosis. The risks for HIV and syphilis infection are very similar, and the two often coexist. HIV infection is known to rapidly accelerate and exacerbate syphilis complications. If syphilis testing is undertaken, HIV testing should also be routinely performed.

'Gold-standard' diagnostic test

If a lesion consistent with primary infection is present, appropriately taken samples can be examined for treponemes via dark-field contrast microscopy. Certain manifestations of secondary syphilis can be sampled for microscopy, such as condylomata lata (wart-like genital lesions) and mucous patches. As dark-field microscopy requires an experienced clinician and microscopist, its general application is limited.

The majority of syphilis diagnoses are made via interpretation of a combination of serological investigations, which include specific treponemal antibody/antigen tests (e.g. IgM and IgG EIA, and TPHA/TPPA) and non-specific cardiolipin tests (VDRL/RPR), which can be used to diagnose and assess response to treatment. Common test results corresponding to stages of infection are summarized in Table 313.1.

Acceptable diagnostic alternatives to the gold standard

For syphilis, there is no substitute for diagnosis made by serology, but PCR techniques are starting to be used in place of dark-field microscopy. Specimens analysed by PCR are less susceptible to sampling error and transport conditions; in addition, PCR analysis allows testing of lesions at non-genital sites. Multiplex PCR is available, allowing combination testing for several infective genital ulcerative conditions to be carried out on a single sample.

Clinical stage	Symptoms/signs	IgM EIA	IgG EIA	TPHA/TPPA	VDRL/RPR
Primary	Balanitis or vulvitis Oral lesions Painless indurated ulcer (chancre; single or multiple) Regional lymphadenopathy	Positive	Positive in majority	Negative in majority or positive at low titre	Positive at low titre
Secondary or early latent (i.e. asymptomatic and infected <2 years)	Alopecia Anterior uveitis Arthralgia/periosteitis Cranial nerve palsies Fever Glomerulonephritis Hepatitis Lymphadenopathy Meningitis Mucous lesions Rash Retinitis Snail-track ulcers	Positive Can be negative in latent infection	Positive	Positive at high titre	Positive at high titre
Tertiary (40% of untreated) or late latent (asymptomatic and infected >2 years (60% of untreated cases))	Gummatous (15% of untreated): skin and joint involvement common Cardiovascular (15% of untreated): aortic root, aortic arch, and coronary ostial involvement Neurological (10% of untreated): meningovascular (stroke syndromes), parenchymal (general paresis and tabes dorsalis)	Negative	Positive	Positive at low titre	Positive at low titre, or negative
Treated or incompletely treated (from previous antibiotic exposure)		Negative	Positive	Positive at low titre	Negative or positive at low titre

Other relevant investigations

When late latent syphilis is suspected, an assessment for end-organ damage should be made, specifically cardiovascular involvement with ECG and chest X-ray, proceeding to echocardiography as necessary. If neurological syphilis is suspected (and the patient has positive serum serological tests), neurological imaging and CSF sampling should be undertaken. The majority of patients with symptomatic neurosyphilis have a raised CSF white-cell count (>5 cells/mm³). A negative direct treponemal test (TPPA or TPHA) on CSF (without blood contamination) excludes neurosyphilis in the majority of cases; however, it can be negative in cortical disease. A positive test has a high sensitivity for CNS infection. It must be noted that CSF TPPA/TPHA tests are prone to false-positive results (poor specificity) due to immunoglobulins crossing the blood–brain barrier.

Prognosis and how to estimate it

If treated in the early stages of infection, syphilis has an excellent prognosis and is curable. If treatment is delayed for several years, disabling and life-threatening complications can result; therefore, individuals at high risk should undergo regular screening.

Treatment and its effectiveness

The mainstay of treatment is parenteral penicillin, given for a sufficiently long period to cover the slow replication time of *T. pallidum*. Other agents such as cephalosporins and tetracyclines have also been shown to be effective. Treatment duration is based on the stage of clinical infection. National guidelines for the treatment of syphilis exist, and an expert opinion should also be sought prior to initiating treatment.

314 Rickettsial infection

Tom Fletcher and Nick Beeching

Introduction

Rickettsial infections are caused by a variety of obligate intracellular, Gram-negative bacteria from the genera *Rickettsia*, *Orientia*, *Ehrlichia*, and *Anaplasma*. *Rickettsia* is further subdivided into the spotted fever group and the typhus group. *Bartonella* and *Coxiella burnetii* bacteria are similar to rickettsiae and cause similar diseases. The range of recognized spotted fever group infections is rapidly expanding, complementing long-recognized examples such as Rocky Mountain spotted fever (*Rickettsia rickettsii*) in the US, and Australian tick typhus (*Rickettsia australis*), as well as those in southern Europe and Africa.

Animals are the predominant reservoir of infection, and transmission to people is usually through ticks, mites, fleas, or lice, during blood-feeding or from scarification of faeces deposited on the skin. In this chapter, we will focus on the two of the most relevant infections encountered in UK practice: African tick typhus, and Q fever.

African tick typhus

Definition of African tick typhus

African tick typhus is a collective name used for two distinct spotted fever group rickettsial infections that occur in Africa: African tick-bite fever and Mediterranean spotted fever (MSF; also known as 'fièvre boutonneuse'). There has been considerable overlap historically between the two, but it is now well recognized that they are distinct diseases, with different epidemiology, bacteriology, and disease presentations.

Aetiology of African tick typhus

African tick-bite fever is caused by *Rickettsia africae* and is transmitted by hard ticks (*Amblyomma* spp.) that feed on a wide range of domestic and wild animals. MSF is caused by *Rickettsia conorii* and is transmitted by the brown dog tick (*Rhipicephalus sanguineus*). The ticks act as both vectors and reservoirs of the disease, and humans are accidental hosts.

Typical symptoms of African tick typhus, and less common symptoms

The majority of patients with African tick typhus present with features common to most rickettsial infections, including fever, severe headache, and malaise. Inoculation eschars (ulcerated lesions with a central dark scab or 'tâche noire' at the site of the tick bite) are present in the majority of patients but can be easily overlooked, especially within the hairline. In addition, in African tick-bite fever there is often prominent neck muscle myalgia, regional lymphadenitis (43%), and multiple eschars (49%). A generalized cutaneous rash is much more common in MSF (97% vs 49%), and generally occurs on day 3 of the illness.

Demographics of African tick typhus

Epidemiological data suggest that *Rickettsia africae* exists widely throughout sub-Saharan Africa and the eastern Caribbean. It is the most widespread and commonest of the pathogenic spotted fever group of rickettsiae. It is thought that most rural indigenous populations are infected in childhood with mild clinical disease. However, it is increasingly reported amongst travellers to endemic areas, and seroprevalence studies in travellers have shown incidence rates of up to 5%.

In Africa, *Rickettsia conorii* occurs mainly in Algeria, Morocco, Egypt, and Libya, but has also been isolated in countries such as Kenya, Zimbabwe, and South Africa. Infection in humans in

sub-Saharan Africa is much less common, however, as the ticks are more host specific.

Natural history of African tick typhus, and complications, of the disease

The mean incubation period is usually 6 days for both infections and, in African tick-bite fever, complications, such as reactive arthritis, are rare. However, in MSF, severe forms of the infection occur in up to 6% of cases; in addition, neurological, renal, and cardiovascular complications are common, with a mortality rate as high as 2.5%.

Approach to diagnosing African tick typhus

African tick typhus should be considered in any febrile traveller returning from sub-Saharan Africa, particularly when an eschar, lymphadenitis, or rash is present.

Other diagnoses that should be considered aside from African tick typhus

Common infections in febrile returning travellers must be considered, particularly malaria (which does not cause a rash or lymphadenopathy), typhoid, other rickettsioses, and meningococcal disease. A risk assessment should also be undertaken for the possibility of a viral haemorrhagic fever.

'Gold-standard' diagnostic test for African tick typhus

Serology with immunofluorescence is the most commonly utilized technique for diagnosing African tick typhus and is available in specialist centres. Diagnostic antibody titres are often only seen in convalescent samples and may not appear in those treated early with appropriate antibiotics.

Other diagnostic methods for African tick typhus

PCR of serum and in tissue, such as from a biopsy or swab of an eschar site, is increasingly utilized in diagnosing African tick typhus. Cell culture can also be performed from clinical specimens but has several limitations and is not routinely undertaken.

Other relevant investigations for African tick typhus

In African tick typhus, elevated levels of C-reactive protein and liver enzymes are often seen in combination with mild thrombocytopenia and lymphopenia.

Treatment of African tick typhus, and its effectiveness

The treatment of African tick typhus should be based on clinical suspicion and should not be delayed for confirmatory serology. The tetracycline class of antibiotics is most commonly utilized, with a high degree of efficacy and minimal toxicity. A standard regimen is doxycycline 200 mg daily for up to 14 days. Alternatives include chloramphenicol and macrolides.

Q fever

Definition of Q fever

Q (for 'query') fever is so called because, for many years, its cause was unknown. It is a zoonosis caused by the Gram-negative intracellular coccobacillus *Coxiella burnetii*. Its diagnosis can be difficult, due to the variety of clinical presentations, and the delay involved in serological confirmation.

Aetiology of Q fever

Coxiella burnetii is widespread globally, except in New Zealand, and has a resistant spore-like form which survives for prolonged periods in the environment. A wide variety of ticks, birds, rodents, and wild mammals can be infected, but domestic ruminants (sheep, cattle, and goats) are the most frequent sources of human infection.

Aerosols are the major route of transmission to humans, either from direct exposure to infected tissues or from indirect exposure through contaminated dust. However, direct contact with animals is not required.

Typical symptoms of Q fever, and less common symptoms

The most typical manifestation of Q fever is an undifferentiated febrile illness similar to influenza, but other common presentations include atypical pneumonia and hepatitis. The hepatitis is usually asymptomatic; however, patients with only mild biochemical abnormalities may have significant histological changes, and hepatic coma and death has been reported.

Neurological symptoms are recognized in 4%–22% of all Q fever cases, with meningoencephalitis, meningitis, and myelitis being the most common neurological presentations. Chronic malaise and fatigue may persist for months after the acute illness.

Demographics of Q fever

In the UK, 5% of the population have serological evidence of past exposure to Q fever, rising to ~15% in farmers. However only 50–100 cases of Q fever are reported each year, due to many cases being asymptomatic, or mild and under-investigated. Outbreaks have occurred in a variety of settings.

Q fever is associated with certain risk occupations, including farming, working in an abattoir, and meat packing, but, frequently, there is no history of obvious exposure. Pregnancy, valvular heart disease, and immunosuppression are factors associated with more severe disease and progression to chronic infection.

Natural history of Q fever, and complications of the disease

The incubation period of Q fever is between 7 and 30 days; most patients make a complete recovery, and death is rare. The main complication is chronic infection that presents months to several years after the initial infection. This occurs in 1%–5% of patients, and in 60%–70% results in endocarditis, which develops more slowly than other forms of infective endocarditis and which frequently relapses, despite prolonged antibiotic treatment.

Approach to diagnosing Q fever

Q fever should be considered in any acute febrile illness, atypical pneumonia, or aseptic meningitis. Laboratory clues include raised transaminases and thrombocytopenia. Chronic infection should also be considered in all those with a 'culture-negative' endocarditis.

'Gold-standard' diagnostic test for Q fever

Serology using indirect immunofluorescence is the most accurate and readily available diagnostic test for Q fever. Antibodies may be detected 2–3 weeks after the onset of the disease, and tests should be performed on both acute and convalescent samples. Phase I IgG of $\geq 1:800$ at 6 months is considered diagnostic of chronic infection and is one of the major modified Duke criteria for endocarditis.

Other diagnostic methods for Q fever

Culture for Q fever is not routine, and requires Biosafety Level 3 laboratories, but is available from specialist laboratories. PCR can also identify *Coxiella burnetii* in blood, urine, and tissue samples. Complement fixation tests are available but are less specific and sensitive.

Other relevant investigations for Q fever

All patients with confirmed Q fever should have a transthoracic echocardiogram, but it is recognized that cardiac vegetations are evident in only 12% of patients with chronic infection. Repeat serological testing looking for evidence of progression to chronic infection should be undertaken.

Prognosis for Q fever

Death is rare in acute infection and, with effective antibiotic therapy for endocarditis, mortality is less than 10%. However, relapse rates of over 50% after cessation of antibiotic therapy can occur, and delay in diagnosis has an important effect on the prognosis of chronic Q fever.

Treatment of Q fever, and its effectiveness

Tetracycline or doxycycline is the treatment of choice in acute Q fever, but fluoroquinolones should be used for patients with neurological symptoms because of their better penetration of the CNS. Co-trimoxazole is used in women who are pregnant or breast feeding, and in children under 12.

Rarely, severe cases of hepatitis may require additional treatment with corticosteroids. The first line treatment of Q fever endocarditis is a combination of doxycycline and hydroxychloroquine, for a minimum of 18 months depending on serological response.

315 Fungal infection

Stacy Todd and Nick Beeching

Introduction

Fungi, comprising yeasts, moulds, and higher fungi have a worldwide distribution and are uncommon causes of disease in healthy individuals. However, over the last 20 years invasive fungal disease (IFD) has become an increasing cause of morbidity and mortality. This is probably due to the increasing numbers of patients with underlying host conditions, which predispose to opportunistic IFD (e.g. transplant and anti-tumour necrosis factor immunosuppression, HIV, or chronic lung disease), and to increased recognition of endemic IFD (e.g. histoplasmosis), which cause disease in both immunocompetent and immunocompromised hosts in selected geographic locations.

Diagnosis of IFD remains a challenge. Symptoms are often non-specific, and a definite diagnosis requires invasive sampling with appropriate laboratory testing of these samples. Non-invasive tests are being developed, but their positive and negative predictive values still need validation. Diagnostic criteria ('proven, probable and possible' (see Table 315.1) established primarily for use in research, and clinical trials can also prove useful in clinical environments. However, the most important step in identifying patients with IFD is to consider the diagnosis in those at risk.

This chapter will focus on the commonest causes of IFD: *Candida* spp., *Aspergillus* spp., *Cryptococcus* spp., and histoplasmosis.

Aspergillus infection

Definition of aspergillosis

Aspergillosis is classically divided into invasive, saprophytic, and allergic disease. Invasive aspergillosis typically enters via the respiratory tract, sinuses, or skin, and can reach other tissues via direct extension or haematogenous spread. Saprophytic disease includes otomycotic disease and aspergilloma. Allergic disease includes aspergillus sinusitis and allergic bronchopulmonary aspergillosis (ABPA).

Aetiology of aspergillosis

Aspergillus spp. comprise a globally recognized family of moulds which grow in oxygen-rich environments such as air-conditioning units, hospital environments, and decaying vegetation. *Aspergillus fumigatus* is

the most common pathogenic species, but an increasing number of non-*fumigatus* species are known to cause disease.

Typical symptoms of aspergillosis, and less common symptoms

Invasive aspergillosis typically presents with non-specific features of pneumonia, such as fever, cough, and dyspnoea. Pleuritic chest pain and haemoptysis are reported, particularly when there has been vascular invasion. Tracheobronchitis can cause lobar collapse if pseudomembranes develop. In neutropenic patients, persistent fever may be the only symptom of invasive aspergillosis.

Extra-pulmonary aspergillosis can cause sinusitis or skin lesions, progressing to local invasion to cause meningitis, renal, and hepatic dysfunction. Chronic saprophytic disease presents with haemoptysis, or may be found incidentally when imaging is performed for other reasons. Osteomyelitis, prosthetic device infections, and endophthalmitis have been reported.

ABPA presents with wheeze, chronic productive cough, fever, and anorexia, or may be suspected due to inappropriately high eosinophilia in asthmatics.

Demographics of aspergillosis

Host factors which predispose to invasive aspergillosis include:

- decreased quantity or function of neutrophils due to myeloablative chemotherapy and corticosteroids
- immunological biological agents such as anti-tumour necrosis factor agents
- haemopoietic stem cell transplant patients, particularly those who have acquired cytomegalovirus or have severe graft versus host disease
- solid organ transplant patients.

Invasive aspergillosis has also been reported in critically ill patients without preexisting immunocompromise.

Conditions which increase the risk of other forms of aspergillus disease include preexisting structural lung disease (bronchiectasis/previous tuberculosis) leading to a chronic necrotizing aspergillosis, and/or aspergilloma. Patients with asthma and cystic fibrosis are at increased risk of ABPA, although there is likely to be a genetic component involved in whether a patient will go on to develop ABPA after colonization.

Natural history of aspergillosis, and complications of the disease

Invasive aspergillosis is almost universally fatal if it is not identified and if appropriate treatment is not commenced early. The initial presentation is normally with pulmonary disease, which can progress to haemorrhagic infarction and necrotizing pneumonia. Inadequate therapy can lead to CNS involvement or direct extension into intrathoracic structures. Recent improvements in survival have been due to alterations in the levels of immunosuppression used for transplantation, increased awareness of the disease, use of prophylaxis, and early empirical treatment.

Approach to diagnosing aspergillosis

There is a high index of suspicion of aspergillosis in patients who are potentially at risk of the disease.

Other diagnoses that should be considered aside from aspergillosis

Other diagnoses that should be considered aside from aspergillosis are other causes of pneumonia, including bacterial community and

Table 315.1 Diagnostic classification of non-endemic invasive fungal disease

Diagnostic Classification of IFD	Diagnostic Criteria
PROVEN (a OR b)	a. Histopathological documentation of infection
	b. Culture of fungal species from a normally sterile site
PROBABLE (c, d AND e) POSSIBLE (2 from c, d OR e)	c. Host factors including immunosuppression (neutropenia, corticosteroid use, anti-TNF agents)
	d. Clinical manifestations
	e. Microbiological evidence (direct/indirect tests, not meeting proven diagnostic criteria)

Abbreviations: IFD, invasive fungal disease; TNF, tumour necrosis factor.

Reproduced with permission from Ben De Pauw et al., Revised Definitions of Invasive Fungal Disease from the European Organization for Research and Treatment of Cancer/Invasive Fungal Infections Cooperative Group and the National Institute of Allergy and Infectious Diseases Mycoses Study Group (EORTC/MSG) Consensus Group., Clinical Infectious Diseases, Volume 46, Issue 12, pp. 1813–21, Copyright © 2008 Oxford University Press.

nosocomial organisms (e.g. *Nocardia* spp.), mycobacterial, and viral causes. Pulmonary emboli and adult respiratory distress syndrome can also present with similar symptoms in critically ill patients.

'Gold-standard' diagnostic test for aspergillosis

The gold-standard diagnostic test for aspergillosis is a fungal culture and/or histopathology from tissue samples, typically taken at bronchoscopy or rhinoscopy, or samples taken from a normally sterile environment (e.g. pleural fluid).

Acceptable diagnostic alternatives to the gold-standard test for aspergillosis

Chest X-rays are often normal, so it is important to perform a chest CT early. Characteristic (but not pathognomonic) changes of invasive aspergillosis include early pulmonary nodules, macro-nodules with surrounding ground-glass changes ('halo sign'), and air crescent signs. Other non-specific pulmonary signs include consolidation, infarcts, and cavitation. In patients with tracheobronchitis, collapse and pseudomembranes are seen, along with 'tree and bud' appearances. Fungal balls and cavities can also be seen on CT, when investigating aspergillomas.

Increasing availability of galactomannan antigen testing provides a useful adjunct to diagnosis of invasive aspergillosis. It can be measured in bronchoalveolar lavage fluid, CSF, plasma, and fluid, with a sensitivity of 71% and specificity of 89% in serum for patients with haemopoietic stem cell transplants. False positives occur with concomitant use of piperacillin/tazobactam, and there is cross-reactivity with other fungal species. Serial testing is preferred.

Identification of fungal elements in sputum, bronchoalveolar lavage fluid, and sinus aspirate can also indicate invasive aspergillus disease.

Other relevant investigations for aspergillosis

CT of the head and sinuses may also be helpful. Bronchoscopy is useful, not only to obtain samples for culture and histology, but also to look for typical macroscopic appearances of tracheobronchitis.

Elevated IgE aspergillus-precipitins are useful for the diagnosis of ABPA, but not for the diagnosis of invasive aspergillosis. Blood cultures are seldom positive, even in cases of endocarditis.

Prognosis of aspergillosis, and how to estimate it

Invasive aspergillosis can rapidly be fatal. Improved outcomes at 6 weeks are reported in those not having myeloablative treatments, and those not requiring invasive ventilation or renal support.

Treatment of aspergillosis and its effectiveness

First-line treatment for invasive aspergillosis is normally with voriconazole, which is superior to liposomal amphotericin B. Newer agents such as caspofungin and other echinocandins can be used as salvage therapy. Oral itraconazole has been used particularly in chronic cavitary pulmonary aspergillosis. Fluconazole is not effective against *Aspergillus* spp., but there may be a role for newer agents such as posaconazole or isavuconazole in some patients.

Aspergillomas do not respond to antifungal medication and may require surgical resection. ABPA is usually treated with corticosteroids alone; occasionally, systemic antifungal drugs such as itraconazole are used, but only in the context of severe disease and after consultation with experts.

Candida infection

Definition of candidiasis

Candidiasis can be divided into mucocutaneous disease, focal infection in specific organs, or fungaemia/invasive disease.

Aetiology of candidiasis

Candida spp. are the commonest cause of IFD worldwide. Although the dominant pathogen has been *C. albicans*, other species including *C. glabrata*, *C. tropicalis*, and *C. krusei* have emerged over the last 15 years. *Candida* spp. are commensal organisms of the gastrointestinal tract and, occasionally, of the skin. Infection is normally due to invasion by these commensal organisms, rather than new infection.

Typical symptoms of candidiasis, and less common symptoms

Typical symptoms depend on the site of infection. In mucocutaneous disease, classical white plaques are seen on the hard palate; dysphagia and odynophagia are the hallmarks of oesophageal candidiasis. Genitourinary candidiasis presents with dysuria, vaginal discharge, and itch. Visual loss is a presenting feature of endophthalmitis.

Invasive candidiasis normally presents as fever and/or sepsis syndrome with no obvious source. Some patients, particularly those who are neutropenic, can present with a disseminated papulonodular rash, which is a sign of disseminated disease.

Demographics of candidiasis

As the pathogen is normally a commensal, the precipitating factor is a change in the patient's own host defences, especially the development of neutropenia. Others at a higher risk include those who have had broad-spectrum antibiotics, or who have total parenteral nutrition, recent gastrointestinal surgery, haemodialysis, or indwelling vascular catheters. Although mucocutaneous candidiasis is relatively common in HIV, invasive candidiasis only tends to occur when a patient is extremely immunosuppressed.

Natural history and complications of candidiasis

Untreated candidaemia has a high mortality. Even with treatment, mortality can be as high as 50% in neutropenic patients. Candidaemia which is not detected early can result in dissemination to other tissues, leading to endophthalmitis, endocarditis, bone and joint involvement, and meningitis.

Chronic mucocutaneous candidiasis can be a sign of underlying immunosuppression, and should prompt further investigation. Depending on the cause, it does not normally affect mortality, but can cause considerable morbidity and distress to patients.

Approach to diagnosing candidiasis

There is a high index of suspicion of candidiasis in patients who are potentially at risk of this disease. Ophthalmoscopy should be performed in all patients with suspected or proven candidaemia.

Other diagnoses that should be considered aside from candidiasis

Other diagnoses that should be considered aside from candidiasis are other causes of fever in neutropenic patients, including bacteria (community and nosocomial organisms (e.g. *Nocardia* spp.)), mycobacteria, and viruses. Non-resolving mucocutaneous lesions should also prompt investigations for underlying malignancy, HIV, and diabetes mellitus.

'Gold-standard' diagnostic test for candidiasis

Candida spp. grow readily in standard culture media and on blood agar plates, as well as special media such as Sabouraud's agar. Identification of these organisms in normally sterile fluids such as blood or CSF should prompt early treatment. Production of germ tubes in culture is a simple test to distinguish *C. albicans* from other species, which are more likely to have antifungal resistance.

Acceptable diagnostic alternatives to the gold-standard test for candidiasis

Identification of *Candida* spp. in environments such as sputum, bronchoalveolar lavage fluid, urine, and skin swabs should be interpreted with caution, as most isolates will be commensals rather than pathogens. When *Candida* spp. have been isolated, clinicians should consider whether the patient is in a high-risk group, whether the organism has been isolated on more than one occasion, and whether there are any other causes for the symptoms.

Other relevant investigations for candidiasis

Histological findings consistent with candidiasis, such as hyphae and pseudohyphae in tissue samples, can help with diagnosis. However, there is no role at present for serological assays in the diagnosis of candidiasis, although tests are in development.

Prognosis of candidiasis, and how to estimate it

Invasive candidiasis has a poor outcome. Patients with a *Candida* spp. isolated from blood cultures have a twofold higher mortality rate than those with non-candidal blood stream infection. Worse outcomes are associated with delayed commencement of therapy and inadequate antifungal regimens.

Treatment of candidiasis and its effectiveness

Empirical treatment for candidaemia/invasive candidiasis is with an echinocandin agent such as caspofungin. Fluconazole can be considered for non-neutropenic patients who are not critically ill and who are not considered to be at high risk for fluconazole resistance. Liposomal amphotericin B is an alternative in the case of intolerance or lack of availability of other treatments. Best practice is to remove all invasive venous catheters and to treat for a minimum of 14 days after blood culture clearance. Oral step down to fluconazole can be considered once the patient is clinically stable but should be managed in consultation with an infection specialist.

For oesophageal candidiasis, oral fluconazole or amphotericin are the first choice, although echinocandins may be used. A single dose of fluconazole is normally sufficient for uncomplicated vaginal candidiasis.

Cryptococcal infection

Definition of cryptococcosis

Cryptococcosis, also known as cryptococcus disease, is caused by dissemination of *Cryptococcus* spp.

Aetiology of cryptococcosis

Cryptococcus neoformans and *C. gatti* are the major causes of disseminated cryptococcosis. They are encapsulated yeasts, which are inhaled from the environment. *C. neoformans* is found worldwide and, although *C. gatti* was thought to be tropical and subtropical in origin, it has recently been implicated in outbreaks in the north-west United States and Canada. The clinical disease pattern caused by these organisms is similar, and laboratories do not normally speciate further than *Cryptococcus* spp.

Typical symptoms of cryptococcosis, and less common symptoms

The primary route of infection is via inhalation and subsequent haematogenous dissemination. CNS infection is the most dangerous presentation, and often has a prolonged, indolent course with headache, mild confusion, or behavioural change. Focal neurological signs are a sign of late disease and should prompt rapid investigation and treatment. Pulmonary disease can vary from asymptomatic infection, to typical pneumonic symptoms, to disease patterns which can mimic pneumocystis pneumonia. Cutaneous manifestations of disseminated disease are relatively common, with pustular, nodular, umbilicated, or ulcerated lesions.

Cryptococcal infection can also disseminate to other organs, including the long bones, the liver, the kidneys, and the spleen. However, it is unusual for such dissemination to present symptomatically in the absence of other signs. There is a relative lack of inflammation associated with invasive cryptococcosis, so high fever and very high inflammatory markers are not common.

Demographics of cryptococcosis

The majority of patients presenting with cryptococcosis are immunosuppressed in some way, but some patients with invasive disease (particularly *C. gatti*) have a normal immune system. Cryptococcal disease is an AIDS-defining illness, and its increase in prevalence over the last 35 years has mainly followed the HIV pandemic.

Natural history and complications of cryptococcosis

Untreated cryptococcal meningitis is universally fatal. Since the introduction of antiretroviral therapy and combination antifungal treatment, this has improved dramatically, but there is still an acute mortality of 6%–15% related to complications, such as raised intracranial pressure and immune reconstitution

inflammatory syndrome (IRIS). In non-HIV immunosuppressed states, acute mortality is 15%–21%. Up to 40% of patients who survive the initial illness have significant neurological complications such as hydrocephalus, blindness, and cognitive impairment. Relapses can occur in 20%–25% of patients, particularly if they remain immunosuppressed.

Approach to diagnosing cryptococcosis

There is a high index of suspicion in patients who are potentially at risk of invasive cryptococcosis.

Other diagnoses that should be considered aside from cryptococcosis

In CNS disease, other causes of meningoencephalitis with a long prodrome, such as syphilis, toxoplasmosis, and tuberculosis, should be considered, in addition to cryptococcosis. Pulmonary cryptococcosis can easily be confused with pneumocystis pneumonia or other causes of pneumonia in the immunocompromised host. Skin manifestations of cryptococcosis can easily be mistaken for malignancy, molluscum contagiosum, or invasive yeast infections other than cryptococcosis, such as histoplasmosis or talaromycosis (penicilliosis). HIV testing should always be performed.

'Gold-standard' diagnostic test for cryptococcosis

The gold-standard diagnostic test for cryptococcosis is fungal culture from CSF, blood, urine, or skin.

Acceptable diagnostic alternatives to the gold-standard test for cryptococcosis

An acceptable diagnostic alternative to fungal culture is the cryptococcal antigen (CrAG) assay, which is available for testing both serum and CSF. Serum tests are positive in >99% of patients with disseminated invasive cryptococcosis. Although this assay is highly sensitive when used to test the CSF, it may be negative when there is non-meningeal disseminated cryptococcosis.

India ink stains of the CSF are less sensitive than the CrAG assay but may be more readily available in low-income settings.

Other relevant investigations for cryptococcosis

CT or MRI brain scans are useful to rule out cryptococcomas and should be considered prior to lumbar puncture, due to risks associated with raised intracranial pressure. When a lumbar puncture is performed, there is generally a marked increase in opening pressure with mild increase in protein, lymphocytosis (although the white-cell count can be normal), and low glucose ratio.

For pulmonary disease, chest CT should be considered.

Prognosis for cryptococcosis, and how to estimate it

CNS cryptococcosis can be rapidly fatal if not identified. Better outcomes can be expected if immunosuppression can be reversed. Patients with positive CrAG and evidence of disease elsewhere should have a lumbar puncture, even in the absence of CNS symptoms, to assess for evidence of meningitis.

Treatment of cryptococcosis, and its effectiveness

For patients with CNS disease and/or severe respiratory disease, the standard first-line treatment is IV amphotericin (liposomal if high risk of renal disease), with IV/oral flucytosine for a minimum of 2 weeks. This should be followed by up to 8 weeks' oral fluconazole 400 mg daily, to give a total 10-week induction course. This is then followed by long-term prophylaxis oral fluconazole 200 mg daily for at least 12 months, and until the CD4 cell count is $>100 \times 10^6/l$. For mild/moderate pulmonary disease, treatment is with fluconazole 400 mg daily for 6–12 months, and then prophylaxis until the CD4 cell count is $>100 \times 10^6/l$.

In HIV-negative immunosuppression, treat CNS disease with a 10-week induction period. Fluconazole prophylaxis should continue for 6–12 months after this induction phase.

Most immunocompetent people who have only pulmonary disease will settle with no treatment, but some require short courses of fluconazole to prevent haematogenous spread.

Management of complications such as raised intracranial pressure (via therapeutic lumbar puncture, often repeatedly) and IRIS (via corticosteroids) should always be considered.

Histoplasmosis infection

Definition of histoplasmosis

Histoplasmosis is caused by infection with variants of the fungus *Histoplasma capsulatum*.

Aetiology of histoplasmosis

Histoplasma capsulatum is an endemic dimorphic fungus that is found worldwide. The disease is most commonly reported in North and Central America (var. *capsulatum*), and Africa (var. *duboisii*).

Typical symptoms of histoplasmosis, and less common symptoms

Acute pulmonary histoplasmosis most commonly occurs when an individual is exposed to histoplasma organisms for the first time. Symptoms typically include dry cough, chest tightness, fevers, headaches, and malaise. Joint and skin involvement is seen in 5% of patients, and erythema nodosum or erythema multiforme can occur. In more severe cases, it can progress to acute respiratory distress syndrome.

Chronic cavitary histoplasmosis presents with symptoms and signs similar to pulmonary TB with apical cavitary changes. Disseminated histoplasmosis involves an indolent course with progressive hepatosplenomegaly, bone marrow involvement, and non-specific symptoms of fever, malaise, and weight loss.

Less commonly, histoplasmosis can cause pericarditis, meningitis, and granulomatous mediastinitis. Compared with other disseminated fungal diseases, histoplasmosis is more likely to cause peri-oral or mucous membrane involvement. It can present with Addisonism, due to adrenal necrosis. Disseminated skin lesions may be papular or umbilicated.

Demographics of histoplasmosis

Within endemic areas, up to 80% of the population have serological evidence of exposure. The fungus is found in nitrogen-rich soil, in association with bird or bat faeces. Disease tends to occur when a person from an endemic area becomes immunosuppressed, or in non-immune visitors to endemic settings. Outbreaks have been reported when soil has been disturbed on a large scale, causing aerosolization. Exploration of bat-infested caves is a risk factor.

Natural history and complications of histoplasmosis

Histoplasmosis is usually a self-limiting condition which does not require treatment, but is occasionally fatal in severe disease. Chronic cavitary disease is often fatal, because of pulmonary damage, rather than unopposed infection. Progressive disseminated disease is fatal in >90% of patients if untreated.

Approach to diagnosing histoplasmosis

There is a high index of suspicion of histoplasmosis in patients who are potentially at risk of the disease.

Other diagnoses that should be considered aside from histoplasmosis

In acute pulmonary disease, other causes of atypical pneumonia, aside from *Histoplasma capsulatum*, should be considered, including other fungi and *Mycoplasma pneumoniae*. In chronic cavitary disease, major differential diagnoses include TB, non-TB mycobacteria, sarcoidosis, malignancy, and other chronic fungal lung conditions. Disseminated histoplasmosis can mimic a variety of conditions (e.g. miliary TB), particularly in the immunocompromised. Skin lesions due to histoplasmosis can mimic umbilicated lesions from other infections, such as cryptococcosis. HIV testing should be done.

'Gold-standard' diagnostic test for histoplasmosis

The gold-standard diagnostic test for histoplasmosis is fungal culture from blood or body tissue. The CSF usually remains sterile in histoplasma meningitis.

Acceptable diagnostic alternatives to the gold-standard test for histoplasmosis

An acceptable diagnostic alternative to fungal culture is histology of body tissue, as this will often show the characteristic appearances of histoplasmosis (small, oval budding yeasts), especially when silver-based or other special stains are used. Paired antigen testing of urine and serum has proved helpful in diagnoses, but there is cross-reactivity with other fungal diseases; in addition, these tests are not readily available.

Other relevant investigations for histoplasmosis

Other relevant investigations in histoplasmosis include plain chest X-rays or CT scans, as these can show a diffuse reticulonodular picture in acute disease with some perihilar lymphadenopathy. However, these changes are often fleeting, and may be absent by the time the patient presents. Chronic disease typically causes calcified cavities in the apices. In disseminated disease, other infected tissues beyond the lungs can also be abnormal. In meningitis, multiple enhancing lesions are often located around the basal meninges.

Prognosis for histoplasmosis, and how to estimate it

Histoplasmosis is usually a self-limiting condition, but patients on immunosuppressive treatments and those with HIV have a more rapid disease onset and worse prognosis. Even with treatment, up to 50% of HIV-positive patients die from disseminated disease. Other predictors of a worse outcome include fungaemia, renal impairment, and extremes of age.

Treatment of histoplasmosis and its effectiveness

Acute pulmonary histoplasmosis

For mild-to-moderate acute pulmonary histoplasmosis, no treatment is required, unless symptoms persist for >1 month; in this case, use itraconazole 200 mg three times daily for 3 days, and then 200 mg daily for 6–12 weeks. For moderately severe to severe disease, use liposomal amphotericin B (3–5 mg/kg) daily for 1–2 weeks, and then itraconazole 200 mg, initially three times daily for 3 days and then daily for a total of 12 weeks; methylprednisolone should also be used during the first 1–2 weeks if severe respiratory compromise is a problem.

Chronic cavitary pulmonary histoplasmosis

For chronic cavitary pulmonary histoplasmosis, use itraconazole 200 mg three times daily for 3 days, and then once or twice daily for 12 months (some recommend for 18–24 months).

Disseminated histoplasmosis

For mild-to-moderate disseminated histoplasmosis in adults, use itraconazole 200 mg three times daily for 3 days, and then twice daily for 12 months. For moderately severe to severe disease, use liposomal amphotericin B (3 mg/kg) daily for 1–2 weeks, then itraconazole 200 mg three times daily for 3 days, and then daily for total of at least 12 months. Patients may need to stay on long-term suppressive therapy if it is not possible to correct/stop immunosuppression.

Complications, such as joint involvement and skin manifestations, should be treated with NSAIDs or prednisolone if uncontrolled.

316 Protozoal infection: Gut organisms

Pavithra Natarajan and Nick Beeching

Definition of the diseases

Protozoa are single-celled (unicellular) eukaryotic organisms. There are many protozoa causing parasitic infection in humans. This chapter will concentrate on the three that most commonly cause gastrointestinal disease worldwide and have the biggest impact in the UK: *Giardia lamblia*, *Cryptosporidium* spp., and *Entamoeba histolytica*.

These three infections are of great significance worldwide, but are less common in Western settings. In the UK, they tend to be seen in more commonly in travellers returning from endemic countries, migrant populations, men who have sex with men, and the immunocompromised. The clinical features of all three infections vary from asymptomatic small- or large-bowel carriage with passage of cysts to infect others, to more serious manifestations.

Giardiasis

Aetiology of giardiasis

Giardia lamblia (also known as *Giardia intestinalis* and *Giardia duodenalis*) is a flagellated, binucleated protozoan that attaches to the small bowel mucosa and can cause subtotal villous atrophy. Infection is complicated by transient lactase intolerance. Transmission is by ingestion of cysts that are relatively resistant to chlorination and remain viable for several weeks in water, and is most commonly from contaminated water. Person-to-person spread can occur in settings of poor faeco-oral hygiene; less commonly, food-borne spread can occur. Chronic recurrent infections complicate inherited disorders of immunoglobulin production (e.g. Bruton's disease.) but not HIV infection.

Typical symptoms of giardiasis, and less common symptoms

The incubation period for giardiasis is 1–2 weeks. The spectrum of disease ranges from asymptomatic infection to chronic diarrhoea or steatorrhoea, with cramping upper abdominal pain and flatulence. This may result in malabsorption and weight loss, especially in children with a poor underlying level of nutrition, or those with preexisting lactase small bowel deficiency. Prolonged illness can cause folate and vitamin B₁₂ deficiency.

Demographics of giardiasis

Giardiasis has a worldwide distribution, with an estimated 2–3 million infections per year. It is a common cause of post-travel diarrhoea.

Natural history of giardiasis, and complications of the disease

Infection is usually self-limiting, but it has been suggested that giardiasis may trigger functional irritable bowel disease.

Approach to diagnosing giardiasis, and other diagnoses that should be considered

Apart from other bowel infections, causes of malabsorption should be considered, including coeliac disease and pancreatic disease.

'Gold-standard' diagnostic test for giardiasis, and acceptable diagnostic alternatives

Microscopic examination of concentrated faecal samples is the gold standard for all three of these infections. This is labour intensive and requires specific expertise, and intermittent excretion of cysts can

hamper diagnosis and require examination of multiple stool samples. The laboratory request should always include travel history or other reasons to request parasitological investigation. Multiplex real-time PCR tests are being introduced by many laboratories to detect all three pathogens simultaneously.

Giardia cysts and trophozoites can usually be seen on faecal microscopy, the sensitivity of which is improved using direct antibody fluorescence. Faecal antigen detection (e.g. by EIAs) is more sensitive, and a variety of molecular assays are increasingly being used. Serology has no role in diagnosis. Trophozoites may be seen in aspirates of contents or biopsies from small bowel.

Treatment for giardiasis, and its effectiveness

Giardiasis is often self-limiting, but treatment of symptomatic patients reduces the severity and duration of the disease. Metronidazole or tinidazole are the treatments of choice, and alternatives include paromomycin, albendazole, or nitazoxanide. Rarely, mepacrine (called quinacrine in the US) is used, for severe cases. Refractory cases may respond to exclusion of dietary lactose for 2 weeks during treatment, and treatment of close contacts to prevent reinfection.

Cryptosporidiosis

Aetiology of cryptosporidiosis

Cryptosporidium parvum and *Cryptosporidium hominis* are the two most common species causing human infections. They are acquired through the faeco-oral route, by ingestion of oocysts containing infective sporozoites. Oocysts are highly resistant to chlorination and can survive for prolonged periods in water and damp soil. Person-to-person spread can also occur. Cryptosporidiosis is a zoonosis which can be contracted from contact with a variety of animals, especially calves in petting zoos and other farm animals, or by ingestion of water contaminated by animal faeces. The sporozoites of cryptosporidia invade the epithelial cells of the small bowel and undergo a complex life cycle that includes auto-reinfection, as well as a sexual life cycle leading to shedding of oocysts in faeces. Severe infections occur in a variety of immunosuppressive states, including severe combined immunodeficiency (SCID), advanced HIV, and inherited immunoglobulin deficiency states, as well as in transplant and chemotherapy patients. In some of these patients, biliary carriage occurs and is difficult to eradicate.

Typical of cryptosporidiosis, and less common symptoms

The typical incubation period of cryptosporidiosis is 3–6 days. The spectrum of disease ranges from asymptomatic infection to watery diarrhoea, which is often associated with abdominal cramps and sometimes with nausea and vomiting. It is more severe than most types of childhood gastroenteritis, and symptoms typically continue for 10–12 days, with prolonged cyst shedding. In immunosuppressed patients, persistent, frequent large-volume watery stool output may be life-threatening. In these patients, especially those with SCID or HIV, biliary involvement can present as pancreatitis or cholangitis leading to biliary stenosis.

Demographics of cryptosporidiosis

Cryptosporidiosis occurs worldwide and is the most common protozoal cause of acute gastroenteritis in the UK, with 3000–6000 laboratory-confirmed cases annually. It can be responsible for large waterborne outbreaks caused by contaminated drinking water (as

ordinary water disinfection processes do not kill cryptosporidia), as well as outbreaks associated with swimming pools. It can affect any age group, although it is more common in children under 5 years of age, and more severe in the immunosuppressed. The incidence in people with HIV has decreased since the introduction of highly active antiretroviral therapy.

Natural history of cryptosporidiosis, and complications of the disease

In the immunocompetent host, cryptosporidiosis lasts for about 12 days and then tends to settle. Recurrence of symptoms can occur in up to a third of cases, due to relapse or reinfection. Immunocompromised hosts suffer from intractable diarrhoea that can be very difficult to treat and can lead to substantial weight loss and occasional biliary or pancreatic disease.

Approach to diagnosing cryptosporidiosis, and other diagnoses that should be considered

Cryptosporidiosis should be considered in the differential diagnosis of any community-acquired diarrhoea, especially when prolonged. Coeliac disease should be considered.

'Gold-standard' diagnostic test for cryptosporidiosis, and acceptable diagnostic alternatives

Detection of oocysts in faeces by microscopy requires special stains such as auramine, modified Ziehl–Neelsen, or trichrome stains. Such staining is not part of routine faecal microscopy in many laboratories and may need to be requested specifically. Sensitivity is improved by direct antibody fluorescent techniques and/or examination of multiple samples. Faecal antigen detection by EIA, and direct detection by PCR, are increasingly used in many laboratories. The organisms can be seen in small bowel biopsies, or in brushings from the biliary tree in immunosuppressed patients with biliary complications. Serology has no role in clinical diagnosis.

Treatment for cryptosporidiosis, and its effectiveness

Cryptosporidiosis is self-limiting in immunocompetent hosts, and treatment is not usually required. In immunosuppressed patients, reducing the degree of immunosuppression is the key to management. In patients with immunoglobulin deficiency, replacement immunoglobulin therapy stops the diarrhoea, as does raising the CD4 cell count by 50×10^6 cells/l in patients with HIV, by giving antiretroviral therapy. Protease inhibitors may have additional direct anticryptosporidial activity. Although combinations of paromomycin and azithromycin have been used in the past in severely immunosuppressed patients, there is no direct effect of these or most antimicrobials. Nitazoxanide, a cheap, broad-spectrum, antiparasitic agent available in the tropics, is effective in children and in patients with less severe immunosuppression. It is less easy to obtain and more expensive in Europe and other Western settings.

Amoebiasis

Aetiology of amoebiasis

In amoebiasis, *Entamoeba histolytica* invades the colonic mucosa, producing characteristic ulceration and dysentery (bloody diarrhoea). The first stage is attachment of the trophozoite to the human target cell. Infective cysts are passed in the stool, and transmission is by the direct faeco-oral route. Patients with abnormal lower bowel mucosa (e.g. those with inflammatory bowel disease) are more likely to experience invasive disease, especially if using topical and/or systemic steroids. There is no direct link with other types of immunodeficiency.

Typical symptoms of amoebiasis, and less common symptoms

Most *Entamoeba histolytica* infection is asymptomatic, and only a small proportion of patients go on to develop clinical disease. Intestinal

manifestations include amoebic colitis, which causes diarrhoea with blood and mucus, tenesmus, and colicky abdominal pain.

Up to 10% of patients infected with *Entamoeba histolytica* may develop invasive amoebic disease. Amoebic liver abscess (ALA) is the most common form of extra-intestinal disease. This is caused by spread of infection via the portal vein to the liver, and further haematogenous spread. Patients with ALA are usually acutely unwell, presenting with symptoms including upper abdominal pain, right shoulder tip pain, and fever.

Demographics of amoebiasis

There are 48 million clinical cases of amoebiasis per year, with at least 70 000 deaths worldwide. It can be responsible for outbreaks in schools.

Natural history of amoebiasis, and complications of the disease

Amoebic dysentery is usually self-limiting, but fulminant amoebic colitis carries a high mortality. ALA can cause thoracic complications, such as pleural effusion and rupture into the bronchial tree or pericardium. In addition, ALA may rupture into the abdomen or become secondarily infected. Uncommonly, an amoeboma may develop as a granuloma, often localized in the ascending colon.

Approach to diagnosing amoebiasis, and other diagnoses that should be considered

When diagnosing amoebiasis, exclude other infections that can cause blood in stool, such as shigellosis or campylobacteriosis. Intestinal amoebiasis may mimic inflammatory bowel disease, from which it must be distinguished, because giving corticosteroids to patients with amoebic infection can have disastrous consequences, such as toxic megacolon, or perineal invasion. The main differential diagnoses of ALA are pyogenic liver abscess, and liver neoplasm.

'Gold-standard' diagnostic test for amoebiasis, and acceptable diagnostic alternatives

Invasive colonic disease is confirmed by immediate examination of fresh faeces or scrapings of rectal mucus (i.e. within 30 minutes or less after stool passage (the 'hot stool')). This is essential to visualize mobile trophozoites containing ingested red cells: these rapidly encyst once exposed to the cold. Cysts of *Entamoeba histolytica* are morphologically identical to those of the non-pathogenic amoeba *Entamoeba dispar*, which is much more common, and a frequent reason for over-diagnosis of amoebiasis. The two can be distinguished using commercial antigen detection kits or PCR.

Serology is useful in diagnosis of ALA and severe colonic disease, but may be negative in uncomplicated dysentery. In ALA, peripheral neutrophilia is common, and changes at the right lung base are common on chest X-ray. Ultrasonography of the liver is essential if ALA is suspected. Faecal examinations have no role in diagnosing or excluding ALA.

Treatment for amoebiasis, and its effectiveness

Asymptomatic carriers should be treated with a bowel luminal agent to minimize the spread of disease. The most effective agents are diloxanide furoate or paromomycin, which are poorly absorbed from the intestine and reach optimal amoebicidal concentrations within the intestinal lumen. Symptomatic colonic or liver disease is treated with 'tissue amoebicides' such as metronidazole or tinidazole, which are efficiently absorbed from the small intestine and reach high tissue concentrations. These do not work against remaining intra-luminal amoebae, which must then be eliminated with a bowel luminal agent.

ALA cure can usually be managed with medical therapy alone, but therapeutic aspiration may be needed for large cysts (>10 cm in diameter), especially the minority that involve the left lobe of the liver and have a risk of sudden rupture into the pericardium, causing tamponade.

317 Protozoal infection: Malaria

Nick Beeching, Lynsey Goodwin, and Joanna Peters

Definition of the disease

Malaria is a devastating protozoal infection that affects more than 200 million people worldwide each year, killing up to a million. Five species of *Plasmodium* are recognized causes of human disease: *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, *Plasmodium malariae*, and *Plasmodium knowlesi*. In the UK, malaria is the most common imported tropical infection.

Aetiology of the disease

Malaria parasites ('sporozoites') are injected into the human bloodstream by the bite of female *Anopheles* mosquitoes (see Figure 317.1). The sporozoite is rapidly taken up by the liver, where it can multiply silently for weeks to months (extra-erythrocytic schizogony) to form a cyst-like 'pre-erythrocytic schizont' containing thousands of 'merozoites'. Eventually, the schizont ruptures, releasing merozoites into the bloodstream to invade red blood cells, where they mature and multiply in a cyclical pattern, lasting from 24 hours (*Plasmodium knowlesi*) to 72 hours (*Plasmodium malariae*). This culminates in development of intra-erythrocytic schizonts containing 8–32 merozoites,

depending on the species. The erythrocytes and schizonts are then disrupted, releasing merozoites to invade further red cells and start another multiplicative cycle. After several cycles, some intra-erythrocytic parasites differentiate into gametocytes, which fuse and undergo further multiplication within a mosquito to complete the infection cycle.

Symptoms that occur during the erythrocytic cycle are related to red-cell lysis; the release of parasite toxins/antigens; red-cell sequestration; and related tissue anoxia. The degree of parasitaemia (percentage of infected red cells) rarely exceeds 1% for all species except *Plasmodium falciparum*, which can rapidly multiply from a 1% parasitaemia to a >30% parasitaemia and also induces red-cell sequestration in the capillaries of organs such as the brain, the liver, and the kidneys, resulting in organ dysfunction. This combination of massive parasite load and red-cell sequestration makes *Plasmodium falciparum* potentially lethal in non-immune patients (i.e. those seen in the UK).

Malaria may also be transmitted by blood products, needle-stick injury, and IV drug use; in addition, occasionally, it can be transmitted transplacentally. Both perinatal transmission and the deleterious effects of malaria on intrauterine fetal growth are exacerbated by concurrent maternal HIV infection. Heterozygous haemoglobinopathies

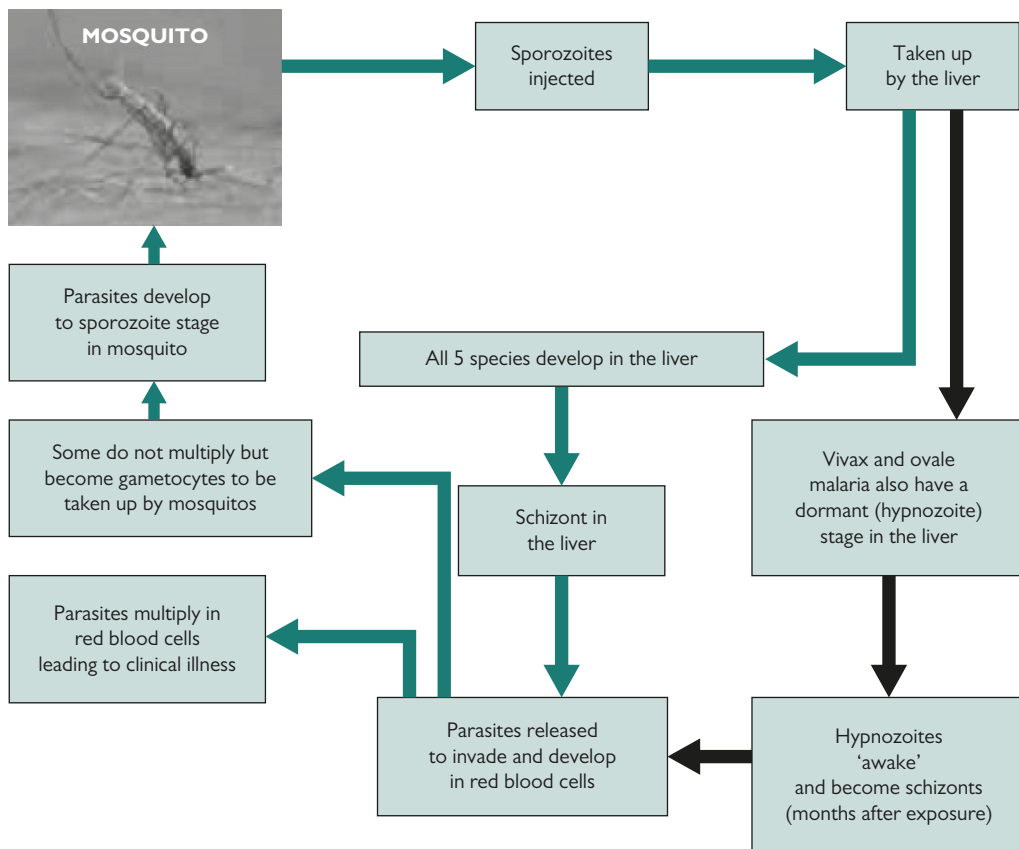

Figure 317.1 Simplified life cycle of malaria.

such as sickle trait (haemoglobin AS) confer partial protection against *Plasmodium falciparum*, but homozygous sickle cell patients may still have lethal infections. In West Africa, most populations lack the Duffy red-cell antigen, which is used by *Plasmodium vivax* merozoites to attach to and enter the erythrocyte, so vivax infections are rare in these countries.

Typical symptoms of the disease, and less common symptoms

In an endemic area, partial immunity develops in survivors of repeated childhood infection, and asymptomatic parasitaemia is not uncommon. The main effects on children in these settings are fever with severe anaemia, respiratory distress, or coma. Rarer sequelae of chronic malaria include hyper-reactive splenomegaly and malarial nephropathy (the latter is caused by *Plasmodium malariae*).

In non-immune people who are returning to Europe from countries where malaria is endemic, the symptoms of uncomplicated malaria are similar those for influenza and may include the abrupt onset of malaise, intermittent rigors, chills, myalgia, and headache. Cough, diarrhoea, and jaundice may also be seen, and patients may not have fever at presentation. The symptoms of malaria are protean. The classical fever patterns (tertian, quartan, etc.) related to the cycle of red-cell lysis and parasite release may not be present in the first 7–10 days of infection. However, severe malaria can rapidly develop in *Plasmodium falciparum* infections, with failure of one or more organs, and may manifest as renal failure, acidosis, haemolytic anaemia, liver failure, respiratory distress syndrome, or brain involvement leading to convulsions and/or coma. Altered consciousness may also occur, due to unrecognized hypoglycaemia (see Box 317.1).

Vivax malaria can occasionally cause severe disease; this is usually respiratory distress syndrome or renal, or brain involvement. Splenic rupture is also reported. The pathophysiology of severe non-falciparum infection is poorly understood but does not relate to erythrocyte sequestration.

Demographics of the disease

Malaria is found throughout the tropics, and is making a comeback in areas where control programmes have failed. Local transmission in Greece in 2012 served as a reminder that malaria used to be endemic around the whole Mediterranean basin, extending as far north as the UK until the 1920s. Seventy-five per cent of cases in the tropics occur in children, especially in Africa. In European settings, the majority of cases occur in people who travel to visit friends or relatives in the tropics. Other tourists, business travellers, and special groups such as military personnel account for about 25% of approximately 2000 cases imported to the UK each year. Overall, about 75% of these are *Plasmodium falciparum* infections, related mostly to travel to sub-Saharan Africa, in contrast to the case in the 1970s and 1980s, when the majority of malaria cases were *Plasmodium vivax* infections imported from South Asia.

Box 317.1 Features of severe falciparum malaria in the European setting

Parasitaemia > 2%
 Acidosis (pH < 7.3)
 Acute renal failure
 Acute Respiratory Distress Syndrome/pulmonary oedema
 Coagulopathy/Disseminated Intravascular Coagulation
 Haemoglobinuria
 Hypoglycaemia (<2.2mol/L)
 Reduced consciousness
 Severe anaemia (haemoglobin < 80g/L)
 Shock secondary to complicating bacteraemia/sepsis syndrome (algid malaria)

Reprinted from *Journal of Infection*, Volume 72, issue 6, David G. Lalloo, Delane Shingadia, David J. Bell, Nicholas J. Beeching, Christopher J.M. Whitty, Peter L. Chiodini, UK malaria treatment guidelines 2016, pp. 635–649, Copyright (2016), with permission from Elsevier

Natural history and complications of the disease

The minimum incubation period for malaria is 7–8 days, but is typically up to 2 months for *Plasmodium falciparum* infections, with exceptional cases occurring up to a year after exposure. Incubation periods for other species may be similar but are often longer, especially in vivax and ovale infections, due to the longevity of the dormant 'hypnozoite' liver stages. It is common for the first vivax symptoms to appear 9–10 months after the patient has left the tropics, and this interval may extend for up to 2 years. Untreated non-falciparum infections are usually self-limiting but may recur. In contrast, patients with falciparum malaria can appear deceptively well at presentation but be unconscious 24 hours later, with significant mortality.

Hypoglycaemia is a common complication of falciparum malaria, especially in children, in pregnant women, and in patients treated with quinine. Clinical features compatible with the more severe complications listed in Box 317.1 should be anticipated. Splenomegaly is clinically detectable in less than 50% of imported malaria cases. Malaria does not cause lymphadenopathy. Rashes and clinical bleeding diatheses are rare, although laboratory features of disseminated intravascular coagulation are common in severe malaria.

Approach to managing the disease

Malaria is a medical emergency and should be treated accordingly.

A detailed travel history extending back for at least 2 years is essential in diagnosis. Any ill traveller who has been to the tropics should have blood tests for malaria, with results available in less than half a day (preferably 2 hours). The infecting species should be determined—at least to differentiate falciparum from other species—and the degree of parasitaemia estimated.

All features of severe or complicated malaria (see Box 317.1) should be sought, including observation of respiratory rate to identify underlying respiratory distress syndrome or unrecognized metabolic acidosis, which is a marker for poor prognosis. Patients should be admitted to hospital for initial care, unless a confident diagnosis of uncomplicated non-falciparum malaria is confirmed. Patients with possible or severe falciparum malaria should be managed in a high-dependency or intensive care unit, with advice from an infection specialist if transfer to a regional infection unit is not possible. Common mistakes in such settings are delay in initiating some form of parenteral therapy, over-vigorous infusion of colloids and other IV fluids, and unnecessary transfusions of blood or platelets (see Box 317.2).

Box 317.2 Common errors in recognition and management of malaria

- delayed presentation by patient
- failure of healthcare worker to take a travel history
- failure of healthcare worker to consider malaria in symptomatic patient
- belief that chemoprophylaxis prevents all malaria
- belief that malaria is unlikely to be present, if patient does not remember being bitten by mosquitoes
- belief that absence of splenomegaly excludes malaria
- belief that absence of regular fever pattern excludes malaria
- failure to recognize non-specific clinical presentations of malaria
- failure to obtain good-quality blood film diagnosis immediately (with species diagnosis)
- failure to obtain repeat films or use ancillary diagnostic tests, if first films are negative
- failure to prescribe adequate and appropriate chemotherapy immediately
- failure to anticipate or recognize complications
- failure to treat complications
- failure to follow patient up after treatment

Other diagnoses that should be considered

In addition to malaria, many other causes of imported fever should be considered, including HIV seroconversion illness, influenza, respiratory infections, and various other tropical infectious possibilities, depending on the area visited. The pre-blood-test probability of a patient having malaria if admitted to hospital is about 60% if returning from sub-Saharan Africa, but only about 10% from South Asia. All patients with imported fever should be risk assessed for the rare possibility of a viral haemorrhagic fever, which can be excluded if the interval between the last possible exposure and the onset of symptoms is more than 21 days.

'Gold-standard' diagnostic test, and alternatives

The gold-standard diagnostic test for malaria is expert microscopy of thick and thin blood films, repeated two to three times over 24 hours if the first film is negative. Few labs have the expertise to examine thick films, which are more sensitive because more blood is examined in the microscopic field. In routine practice, rapid diagnostic tests (RDTs), which are almost as sensitive, are used to detect malarial antigens, such as parasite-specific lactate dehydrogenase, aldose, or histidine-rich protein, in a blood sample. Concurrent thin blood film examination is essential for identification of the parasite and for estimation of the parasitaemia rate. Most RDTs have good sensitivity and specificity for falciparum and vivax infections, but vary for other species, and false-negative results are possible. Molecular techniques are more sensitive and less operator-dependent, but PCR tests for malaria have not yet been standardized enough for use in routine diagnostic practice in the UK. All positive and suspected cases should be confirmed by a reference laboratory.

Other relevant investigations

Routine tests include a full blood count, renal and liver function tests, plasma/blood glucose, blood cultures, and a serum save for possible serology. Blood gas analysis, clotting, and lactate are also important investigations when assessing the severity of falciparum malaria. Thrombocytopenia is common in all forms of malaria, and liver function is often slightly disturbed. There should be a low threshold for performing chest X-ray and other tests, as appropriate.

Patients with vivax or ovale malaria need estimation of glucose-6-phosphate dehydrogenase (G6PD), to exclude deficiency prior to initiation of primaquine therapy.

Prognosis and how to estimate it

The mortality of untreated falciparum infections is high, falling to 1%–2% in the UK when treated. Factors implicated in high mortality include infection in young children, pregnancy, age >60, late presentation, delays in diagnosis and treatment initiation, parasitaemia of 2% or more at presentation, elevated lactate, metabolic acidosis, and presence of other complications (see Box 317.1).

Treatment and its effectiveness

Current national guidelines for treatment of malaria (in the UK, summarized in the British National Formulary) should always be consulted as recommendations change frequently.

Uncomplicated non-falciparum malaria in adults is treated with oral chloroquine or oral artemisinin combination therapy, such as artemether/lumefantrine (Riamet®) or dihydroartemisinin-piperaquine (DHA-PPQ) (Eurartesim®). These options should be accompanied by daily oral primaquine for 2 weeks in patients with vivax or ovale malaria (started as soon as G6PD deficiency has been excluded), to eliminate liver hypnozoites and prevent relapse. Adequate doses of primaquine must be prescribed, typically 30 mg daily for an adult with *Plasmodium vivax* infection. In the US, the same dose is recommended for ovale infections; in the UK, however, a smaller dose of 15 mg daily is considered adequate.

When prescribing chloroquine, check the tablet formulation and base compound content, as many different strength preparations are available. Chloroquine resistance is documented in some cases of vivax malaria, especially cases from Papua New Guinea, Indonesia, and the Solomon Islands, and artemisinin combination therapy may be more appropriate in these cases.

In cases of complicated non-falciparum malaria or dual infection, the current UK guidelines suggest treating as for falciparum malaria, with parenteral therapy.

Chloroquine should never be used to treat imported falciparum malaria, which is usually resistant.

Treatment options for uncomplicated *Plasmodium falciparum* fall into three main categories: artemisinin combination therapy, such as artemether/lumefantrine (Riamet®) or DHA-PPQ (Eurartesim®); atovaquone/proguanil (Malarone®); or quinine plus doxycycline or clindamycin.

Severe or complicated falciparum malaria requires IV therapy. The preferred first-line agent is artesunate, which clears circulating parasites faster than quinine and has fewer side effects. This drug remains off-licence in the EU, but is now available in many British infectious disease units and can be readily supplied to other centres if the patient cannot be transferred.

If artesunate is not available, IV quinine should be started, together with oral doxycycline or clindamycin. A loading dose will be required if the patient has not been taking mefloquine prophylaxis or already received oral quinine in the previous 12 hours. If parenteral therapy is not available, do not delay but give oral quinine (available on any geriatric ward!) immediately, until parenteral preparations can be obtained. ECG monitoring is recommended if there is any history of cardiac problems or arrhythmias. After at least 24 hours of IV therapy and if there are clear signs of improvement, the patient may be switched to a full course of oral artemisinin combination therapy.

Monitor patients with severe malaria closely for hypoglycaemia. Complications are managed conventionally, but avoid overenthusiastic fluid infusion, or respiratory distress will follow in the intensive care unit. Thrombocytopenia resolves after a few days of successful treatment, and platelet transfusion is rarely necessary (or useful, due to immediate consumption). Similarly, anaemia does not need correcting by transfusion, unless very severe or symptomatic. Anticonvulsants are needed for seizures related to cerebral malaria, but steroids or mannitol are not indicated, and prophylactic anticonvulsants have no role in primary seizure prevention. Concurrent bacteraemia should be excluded, especially Gram-negative infections in children, and some experts prescribe broad-spectrum cover anyway in severe malaria (e.g. a third-generation cephalosporin). There is no evidence to support the use of exchange transfusion or red-cell apheresis to reduce circulating parasite load. Daily blood films for parasitaemia counts should be performed to ensure appropriate clearance is occurring, although the parasitaemia may not drop or may even rise during the first 24 hours of successful therapy.

In complex cases, such as malaria during pregnancy and in paediatric populations, specific guidance is available, and urgent specialist infectious disease/tropical medicine advice should be sought on management.

Prevention

Patients who have had acute malaria should be informed they will continue to be at risk in the future when travelling to malarial areas, and appropriate precautions should be taken. This includes maximum measures to reduce the risk of being bitten by mosquitoes, as well as specific and appropriate chemoprophylaxis, the recommendations for which change rapidly. Evidence-based current advice should be sought before travel, from travel clinics or the websites listed in 'Further Reading'.

Public health considerations

All cases of malaria in the UK should be notified promptly to the relevant public health authority.

318 Worm infection (including hydatid disease)

Sherine Thomas and Nick Beeching

Filarial infections

The main clue to the diagnosis of all helminth infections is peripheral blood eosinophilia, the presence of which should always prompt taking a full travel history. Filarial infections are unusual in the UK, and the main pathogenic groups are summarized in Table 318.1. The most common imported filariasis is *Loa loa* infection from West Africa, characterized by transient 'Calabar swellings', particularly on the face, arms, and upper limbs.

Schistosomiasis

Definition of schistosomiasis

Schistosomiasis, also known as bilharzia, is a parasitic disease caused by the trematode worms of the genus *Schistosoma*. It affects millions worldwide and is considered to be the second most important parasitic infection after malaria. It has a low mortality rate, but causes chronic illness, which can be socio-economically devastating.

Aetiology of schistosomiasis

There are three main species of schistosomes that affect humans (see Table 318.2).

Typical symptoms of schistosomiasis, and less common symptoms

Cercariae penetrating the skin can cause a papular itchy rash, referred to as swimmer's itch. Symptoms with acute infection a few weeks later can include fever, urticaria, splenomegaly, hepatomegaly, cough, and wheeze. This is referred to as Katayama fever.

For other symptoms and complications see Table 318.2.

Approach to diagnosing schistosomiasis

Schistosomiasis should be considered in anyone who has come from or visited endemic areas and had freshwater exposure, including showering in unfiltered lake or river water. Eosinophilia is prominent during the invasive phase, and mild eosinophilia is common in chronic infection. Diagnosis relies on identifying the eggs from adult worms. *Schistosoma haematobium* eggs can be identified from the urine. Bladder activity means that most eggs are voided at around midday; therefore, a 10 am to 2 pm urine collection is likely to yield the best results. Rectal biopsies can also be useful, to directly identify infection. Concentrating stool is more sensitive than direct smear examination in *Schistosoma mansoni* and *Schistosoma japonicum*. Serological tests available from specialist centres are essential, but cannot be used to evaluate treatment effectiveness, as they remain positive for months to years.

Treatment and prognosis of schistosomiasis

Praziquantel is the first-line treatment for schistosomiasis. It is effective, is easily administered, and has very little in the way of side effects, apart from nausea. Clearance of infection needs to be monitored and, in some cases, such as heavy infections, further courses of praziquantel may be required. There are isolated reports of cases of praziquantel resistance and, in the future, artemisinin combined therapy may have a role in treatment.

The fibrotic changes caused by the immunological reactions to trapped eggs can lead to irreversible damage, such as portal hypertension and liver fibrosis, which may need continued monitoring

for ongoing complications despite treatment of the underlying infection.

Hydatid disease

Definition of hydatid disease

Hydatid disease or echinococcosis is a zoonotic parasitic infection that affects humans and animals.

Aetiology of hydatid disease

In hydatid disease, humans inadvertently become the secondary host in the life cycle of dog or fox tapeworms. There are two main forms of hydatid disease: cystic disease, which is caused by *Echinococcus multilocularis* (which lives in dogs, wolves, etc., with sheep and other animals being the usual secondary host), and alveolar disease, which is caused by *Echinococcus granulosus* (which lives in foxes, with rodents as the secondary host). Dogs or foxes infected with adult worms release eggs in their faeces. When these are ingested by an intermediate host, oncospheres liberated in the bowel enter the circulation and get trapped in the capillaries of various organs, where they form cysts. The animals are reinfected when they eat the carcasses of infected dead animals. *Echinococcus granulosus* is present worldwide, and humans are accidental intermediate hosts that become infected by handling soil, dirt, or animal hair that contains eggs. *Echinococcus granulosus* cysts are clearly demarcated with a thick cyst wall lined by a germinal layer that can produce internal daughter cysts. *Echinococcus multilocularis* tissue stages have an external germinal layer and spread through tissue like a cancer.

Typical symptoms of hydatid disease, and its complications

The incubation period for all types of echinococcosis is months to many years. About 70% of *Echinococcus granulosus* cysts in humans form in the liver, and around 20% occur in the lungs. Hepatic cysts are usually asymptomatic; however, if they are symptomatic, the symptoms are usually related to growing mass effects. Alternatively, if the contents of a cyst discharge into the biliary tree, the resulting cholangitis and obstructive jaundice may be mistaken for gallstone disease. Symptoms also occur if secondary bacterial infections occur, mimicking hepatic abscesses. Fluid leaking from cysts can cause a hypersensitivity reaction including urticaria, pruritus, fever, or even anaphylactic reactions.

Cysts in the lungs are usually discovered as an incidental finding, but they may cause dyspnoea, coughing, chest pain, or, occasionally, haemoptysis. Cysts can, rarely, get trapped elsewhere in the body. Cysts in the bone can lead to pathological fractures, and, rarely, cysts in the brain can present with convulsions.

Alveolar hydatid disease presents with a painful, hard liver, weight loss, and fever, resembling liver cancer.

Approach to diagnosing hydatid disease

Imaging is useful for making the diagnosis of hydatid disease. Ultrasound and CT scans of the liver can show typical findings, and MRI scans can be useful for visualization of liquid areas within the tissue. Radiologists with experience of hydatid imaging should be consulted. Serology is useful as an adjunct to imaging and the clinical picture, but lacks sensitivity for extra-hepatic cysts, and specificity is variable. Eosinophilia is not usually a feature of infection but may be present, especially after cyst rupture.

Table 318.1 Main features of filarial infections

Causative species	Vector	Geographical distribution	Natural history and complications of the disease	Diagnosis	Treatment
<i>Lymphatic filariasis</i>					
<i>Wuchereria bancrofti</i>	Mosquitoes: ● <i>Aedes</i> spp. ● <i>Anopheles</i> spp. ● <i>Culex</i> spp. ● <i>Mansonia</i> spp.	Mainly around the equatorial belt: Africa, South America, Turkey, India, and South East Asia	The adult worms live in the lymphatics of the pelvis. Their sheathed microfilariae migrate into the bloodstream where they are present nocturnally. They disappear into the pulmonary capillaries by day and, therefore, the vectors that transmit these filariae tend to be night biters; the exception is in some Polynesian islands where the vectors are day biters. The mosquitoes then take up the microfilariae when they feed; these are then injected into human hosts when they feed again. The incubation period is variable, but usually 8–16 months. Symptoms of early disease include recurrent episodes of lymphangitis and transient oedema associated with fever. Lymphatic obstruction can occur after many years of recurrent episodes, leading to persistent lymphadenopathy, hydrocoele in males, and elephantiasis.	Eosinophilia is usually marked in the early stages of infection. Microfilariae can be identified in a thick blood film stained with Giemsa (blood taken nocturnally for <i>Wuchereria bancrofti</i>). Filarial serology is available at larger tropical centres (Liverpool and London). Ultrasound scans can sometimes identify adult worms in the lymphatics.	An experienced tropical medicine or infectious diseases physician should be consulted. Treatment options include: ● diethylcarbamazine citrate, which has activity against microfilariae and can damage adult worms ● albendazole, which has microfilaricidal activity ● ivermectin, which has microfilaricidal activity ● doxycycline, which kills the endosymbiotic <i>Wolbachia</i> bacteria in the worm, increasing the effectiveness of other therapies. Chemotherapy typically includes doxycycline for up to 8 weeks followed by a single dose of ivermectin. Other combinations may be used, and repeated courses may be required.
<i>Brugia malayi</i>	Mosquitoes: ● <i>Aedes</i> spp. ● <i>Anopheles</i> spp. ● <i>Mansonia</i> spp.	South and South East Asia			
<i>Brugia timori</i>	Mosquitoes: ● <i>Anopheles</i> spp.	Lesser Sunda Islands of Indonesia			
<i>Subcutaneous filariasis</i>					
<i>Onchocerca volvulus</i>	Black fly (<i>Simulium</i> spp.)	Sub-Saharan Africa and isolated areas of south and central America. Black flies breed in rapidly flowing freshwater; therefore, onchocerciasis tends to be concentrated around river areas.	Female <i>Onchocerca volvulus</i> worms live in subcutaneous tissue, sometimes within nodules, where they produce microfilariae that can migrate through the skin and often to the eyes. The microfilariae then only develop further when they are taken up by the black fly and can then be transmitted to another human. The adult worms can survive for up to 17 years, but the microfilariae only survive for about 1 year. The incubation period is usually 15–18 months. Symptoms can be divided into early skin manifestations, including intense itching and papular eruptions, and late skin manifestations, including thickening, oedema, lichenification, and blackening of the skin. Regional lymph nodes may be enlarged. Subcutaneous nodules containing adult worms are occasionally present. Eye disease is the most important feature, with itching, redness, and excess lacrimation occurring early. Late disease can lead to varying degrees of visual loss and blindness, hence the name African river blindness.	Female <i>Onchocerca volvulus</i> worms live in subcutaneous tissue, sometimes within nodules, where they produce microfilariae that can migrate through the skin and often to the eyes. The microfilariae then only develop further when they are taken up by the black fly and can then be transmitted to another human. The adult worms can survive for up to 17 years, but the microfilariae only survive for about 1 year. The incubation period is usually 15–18 months. Symptoms can be divided into early skin manifestations, including intense itching and papular eruptions, and late skin manifestations, including thickening, oedema, lichenification, and blackening of the skin. Regional lymph nodes may be enlarged. Subcutaneous nodules containing adult worms are occasionally present. Eye disease is the most important feature, with itching, redness, and excess lacrimation occurring early. Late disease can lead to varying degrees of visual loss and blindness, hence the name African river blindness.	An experienced tropical medicine or infectious diseases physician should be consulted. Treatment options include: ● ivermectin, which has microfilaricidal activity ● doxycycline, which has been shown to kill the endosymbiotic <i>Wolbachia</i> bacteria in the filariae; killing these bacteria can maintain freedom from microfilaria for up to 2 years. Combination therapy of doxycycline and ivermectin is usually recommended, as above.
<i>Loa loa</i>	Deer fly (<i>Chrysops</i> spp.)	Rainforest and swamp areas of western Africa (especially Cameroon, on the Ogooue River)	Subcutaneous tissues. Can cause transient subcutaneous swellings due to localized angioedema called Calabar swellings. Can survive for up to 17 years. Adult worms can sometimes be seen crawling across the eye surface, and are referred to as the African eye worm.	Subcutaneous tissues. Can cause transient subcutaneous swellings due to localized angioedema called Calabar swellings. Can survive for up to 17 years. Adult worms can sometimes be seen crawling across the eye surface, and are referred to as the African eye worm.	Treatment options include: ● diethylcarbamazine citrate, but patients need to be monitored closely due to the risk of severe and life-threatening side effects ● ivermectin, which has microfilaricidal activity

Table 318.2 Features of the three main schistosome species

Schistosoma species	Geographical distribution	Natural history	Symptoms of infection, and complications
<i>Schistosoma haematobium</i>	Middle East and Africa	Parasite eggs are released from infected individuals They hatch on contact with fresh water to release the free-swimming miracidia These then infect freshwater snails and transform into sporocysts, which divide and eventually release cercariae from the snail host into the water These penetrate human skin and transform into migrating schistosomula about 8–10 days later The parasites then migrate to the liver and ultimately to the bladder (the perivesical venous plexus), the ureters, and the kidneys Parasites reach maturity in 6–8 weeks, at which time they begin to produce eggs The eggs can migrate to different parts of the body and can become trapped The immunological response to these eggs underlies the pathological features of this infection	Terminal haematuria Dysuria Altered semen Perineal discomfort Vaginal nodules Eggs can be deposited in the bladder and other pelvic organs, where they can lead to a granulomatous reaction, which in turn can lead to an obstructive uropathy, and hydroureter Calcification of the bladder is common, as is a higher risk of bladder cancer Genital tract involvement has also been documented, with occasional cases of secondary infertility due to infection
<i>Schistosoma mansoni</i>	South America, the Caribbean, Africa, and the Middle East	Worm pairs relocate to the mesenteric or rectal veins Adults pairs may produce up to 300 eggs per day during their reproductive lives	Most patients have little in the way of symptoms, but severe manifestations include granuloma of the large bowel, which may ulcerate and bleed Long-standing infections can lead to liver fibrosis and portal hypertension, with associated complications such as variceal bleeds and ascites
<i>Schistosoma japonicum</i>	China and the Philippines	Worm pairs relocate to the mesenteric or rectal veins Adult pairs may produce up to 3000 eggs per day Many of the eggs pass through the walls of the blood vessels, and through the intestinal wall; these eggs are then passed out of the body in faeces	As with <i>Schistosoma mansoni</i> , but infection tends to be more severe

Treatment of hydatid disease, and its effectiveness

Albendazole is the mainstay of treatment, either as definitive treatment for a minority of patients with small uncomplicated cysts or in preparation for surgery or controlled aspiration known as PAIR (for percutaneous aspiration, instillation (of hypertonic saline), and re-aspiration). In the UK all patients should be discussed with an experienced specialist. Medical treatment may need to be prolonged for years in inoperable patients. Success of therapy is mirrored by internal changes in cysts, seen on ultrasound. Surgery or PAIR is best done in a few experienced centres in the UK.

Alveolar hydatid is usually controlled by long-term albendazole therapy, which has transformed the prognosis from inevitable death to control of disease.

Toxocariasis

Definition of toxocariasis

Toxocara canis and *Toxocara cati* are parasitic roundworms that are found in dogs and cats, respectively, and can infect humans.

Aetiology of toxocariasis

Infections in humans occur following ingestion of eggs, usually from sand or soil contaminated by affected faeces; therefore, children appear to be at highest risk of infection. The larvae are released in the intestine and then wander through tissues in the body for 1–2 years.

Typical symptoms of toxocariasis, and its complications

Clinical symptoms are uncommon with this infection, but the symptoms that manifest are due to the migrating larvae. Features of visceral larva migrans (VLM) include fever, abdominal pain, pneumonitis,

lymphadenopathy, and behavioural disturbance. Ocular larva migrans (OLM) occurs when the larva invades the eye, producing a granulomatous reaction that can lead to visual disturbances and blindness. Occasionally, the appearance of the retina can be mistaken for a retinoblastoma.

Approach to diagnosing toxocariasis

Eosinophilia may be present, and serological diagnosis can be established using an ELISA.

Treatment and prognosis of toxocariasis

The treatment for VLM is albendazole 10 mg/kg per day for 5 days. Topical or systemic steroids are indicated for the treatment of OLM, with little evidence for the benefit of using concurrent anthelmintics.

319 Prion disease

Richard Knight

Definition of the disease

Prion diseases (also known as transmissible spongiform encephalopathies (TSEs)) affect animals and humans, although only the human diseases will be discussed here (Table 319.1). Despite TSEs having somewhat disparate causes and effects, there are unifying features: TSEs are brain diseases with neurodegenerative pathology, which is typically associated with spongiform change, and, most characteristically, there is tissue deposition of an abnormal structural form of the prion protein. Some of the TSEs are naturally acquired infections and, while others are not, they are potentially transmissible in certain circumstances (Table 319.1).

Aetiology of the disease

Human prion diseases have three broad categories of causes: idiopathic causes, genetic causes, and acquired causes (Table 319.1). The commonest form of prion disease, sporadic Creutzfeldt–Jakob disease (sCJD), is of unknown cause, appearing to be a spontaneous neurodegenerative disease. Genetic prion disease results from pathogenic mutations of *PRNP*, the prion protein gene (located on Chromosome 20). Acquired forms are infections that relate to oral consumption of infected material; surgery; medical treatments; and blood transfusion.

Typical symptoms of the disease, and less common symptoms

Different prion diseases tend to have different clinical manifestations. However, they are all encephalopathic illnesses, typically, dementias with other neurological features (especially cerebellar ataxia and myoclonus). There are no systemic or non-neurological features. **sCJD** usually presents with rapidly progressive dementia, cerebellar ataxia, visual impairment, and myoclonus. Less common presentations include progressive focal abnormalities (especially isolated cerebellar ataxia or cortical blindness) before a more general brain illness ensues. **Genetic prion disease** has a very varied clinical profile, partly dependent on the underlying mutation. Many cases are clinically indistinguishable from sCJD (e.g. the commonest form of genetic Creutzfeldt–Jakob disease; associated with the *PRNP* E200K mutation). Some cases present with a progressive cerebellar ataxia

(e.g. typical Gerstmann–Sträussler–Scheinker disease). Rarely, cases present with severe sleep and autonomic disturbances (e.g. fatal familial insomnia). Patients with **iatrogenic Creutzfeldt–Jakob disease** usually present in the same way as the donor of the infective material does (e.g. with variant Creutzfeldt–Jakob disease (vCJD) in the case of blood transfusion transmissions, and sCJD in the case of dura mater transmissions), the distinction being in the history of relevant exposure. However, human-growth-hormone-related Creutzfeldt–Jakob disease is an exception, consisting of progressive cerebellar ataxia; cognitive or other features are late and may be minor. **vCJD** typically presents with psychiatric or behavioural disturbances. Painful sensory symptoms may also occur. Cerebellar ataxia and clear cognitive impairment occur later (at a mean of around 6 months). Most cases of vCJD have been relatively young (median age at onset: 26 years) compared to sCJD cases (median age at onset: 65 years).

Demographics of the disease

sCJD has a worldwide distribution, with an annual mortality rate of 1–2 per million population per year. Genetic prion disease is also found worldwide but there are foci of relatively high prevalence, for example in Slovakia, Chile, and Israel.

In principle, iatrogenic CJD may occur anywhere. However, most cases related to cadaveric-derived pituitary growth hormone have occurred in the UK, France, and the US, and most cases related to human dura mater grafts in Japan.

vCJD arose as a zoonotic infection, resulting from bovine spongiform encephalopathy (BSE) contamination of food. The majority of cases of vCJD have occurred in the UK (which had the greatest number of cattle affected by BSE) and France but other countries have reported cases (the Netherlands, Italy, the US, Canada, Japan, Spain, Portugal, Eire, Saudi Arabia, and Taiwan).

Natural history and complications of the disease

All prion diseases are invariably progressive and fatal. Increasing neurological impairment leads to total dependence, immobility, and unresponsiveness that will prevent normal fluid and food intake with the expected complications: bronchopneumonia, urinary tract infections, and pulmonary embolism.

Table 319.1 Human prion diseases

Type	Disease	Cause	Comments
Idiopathic	Sporadic Creutzfeldt–Jakob disease	Unknown Currently classed as a spontaneous neurodegenerative disease	Worldwide distribution Mostly affects the middle aged and elderly Annual mortality rate is around 1–2/million
Genetic	Genetic Creutzfeldt–Jakob disease Gerstman–Sträussler–Scheinker disease Fatal familial insomnia	Mutations of the prion protein gene (<i>PRNP</i>) Autosomal dominant inheritance	Very varied clinic-pathological phenotypic expression Family history absent in up to 40% of cases
Acquired	Kuru	Cannibalistic funeral rites	Confined to Eastern Highlands of Papua New Guinea
	Iatrogenic Creutzfeldt–Jakob disease	Accidental transmission from person to person, by medical or surgical treatments	Most cases related to cadaveric-derived human growth hormone and dura mater grafts
	Variant Creutzfeldt–Jakob disease	Originally resulting from contamination of human diet by bovine spongiform encephalopathy	Most cases in the UK and France Three cases of secondary transmission via red blood cell transfusion

Table 319.2 Investigations supporting the clinical diagnosis of sporadic and variant Creutzfeldt–Jakob disease

Type of disease	Cerebral MRI*	CSF 14-3-3	CSF RT-QuIC	EEG	Tonsil biopsy
Sporadic	High signal in the putamen and caudate High signal in some cortical areas	Often positive	Nearly always positive	In many cases, generalized, periodic discharges	Not indicated (normal)
Variant	High signal in the posterior thalami (the 'pulvinar sign')	Positive in less than half of cases	Negative	Non-specific changes	Shows deposition of the disease-related abnormal prion protein

*Diffusion-weighted imaging and FLAIR sequences are the most sensitive.

Approach to diagnosing the disease

The general diagnostic approach has three components:

- consider the diagnosis (this requires familiarity with the typical clinical features of the disease)
- exclude other diagnoses (a wide variety of brain disease may present in similar ways)
- undertake tests that will support or confirm the diagnosis (see Table 319.2).

In general, investigation of suspect cases of prion disease will require a wide variety of blood tests, cerebral imaging (e.g. MRI), other imaging (e.g. chest radiology), lumbar puncture with CSF examination, and EEG recording.

Other diagnoses that should be considered

The differential diagnosis for prion disease is potentially very wide, including any cause of a rapidly progressive encephalopathy. The list of potential conditions is long and varied, including infections (e.g. viral encephalitis, progressive multifocal leukoencephalopathy, subacute sclerosing panencephalitis, and HIV), malignancies (e.g. primary brain tumours, cerebral secondaries, and non-metastatic encephalopathies), autoimmune/inflammatory disorders (e.g. Hashimoto's encephalitis and cerebral vasculitis), and atypical, relatively rapidly progressing neurodegenerative brain disease (such as Alzheimer's disease). Many of these are suggested by the history (e.g. symptoms of infection, a known malignancy, a family history), the presence of specific signs (e.g. pyrexia), or the results of initial haematology and biochemistry tests. Cerebral imaging will suggest others (e.g. tumours), and certain CSF results may be helpful (e.g. pleocytosis or identification of infectious agents). The main diagnostic problems tend to start when one is faced with a serious, rapidly progressing brain disease, with no clear clues from the history, no non-neurological signs, and normal or non-specific initially abnormal initial investigations (e.g. a slightly raised CSF total protein).

'Gold-standard' diagnostic test

There is only one absolute diagnostic test for prion disease: neuropathological examination of the brain. This is usually at autopsy; brain biopsy is rarely performed, and its main indication is the confirmation/exclusion of another, potentially treatable diagnosis (e.g. isolated cerebral vasculitis). A brain biopsy that fails to show characteristic prion disease abnormalities does not absolutely exclude the diagnosis. In addition, an appropriate neuropsychiatric

illness in someone with a confirmed *PRNP* mutation makes genetic prion disease virtually certain.

Acceptable diagnostic alternatives to the gold standard

There are tests that are supportive of a clinical diagnosis of sCJD and vCJD (Table 319.2). Established clinical diagnostic criteria for prion diseases, based on clinical features and these tests, allow a very confident diagnosis without neuropathology (see <http://www.cjd.ed.ac.uk>). These criteria define categories of 'probable' prion disease that are very reliable clinical diagnoses. The CSF RT-QuIC test is highly specific for sCJD. Tonsil biopsy may be indicated in suspect vCJD cases, where the clinical picture and the cerebral MRI findings do not meet the criteria for 'probable vCJD'.

Other relevant investigations

The exclusion of other diagnoses may involve a variety of tests, depending on the clinical context.

Prognosis and how to estimate it

All prion diseases are progressive and fatal. The life expectancy in individual cases depends on a number of factors, including the type of prion disease and the intensity of medical supportive management (e.g. the use of gastrostomy feeding and treatment of intercurrent infections). The average duration of sCJD is around only 4 months; occasionally, survival of a year or two is seen. Variant CJD has a slower course, with a median duration of around 14 months. Factors affecting prognosis have been analysed and reported (see Pocchiari et al., 2004).

Treatment and its effectiveness

There is, currently, no proven effective disease-modifying therapy in prion disease.

320 Sexually transmitted disease (gonorrhoea)

Martyn Wood and Marilyn Bradley

Definition of the disease

Gonorrhoea is the term used to describe the clinical manifestations of infection with the bacterium *Neisseria gonorrhoeae*.

Aetiology of the disease

Neisseria gonorrhoeae is a Gram-negative diplococcus which usually infects the columnar epithelium of mucous membranes, including the lower male and female genital tracts, the rectum, the pharynx, and the conjunctivae. Transmission is by direct exposure of a mucous membrane to infected secretions, classically via sexual contact. Mother-to-child transmission at birth is also well recognized.

Typical symptoms of the disease, and less common symptoms

The majority of men with urethral *Neisseria gonorrhoeae* infection are symptomatic with either purulent urethral discharge or dysuria, and frequently have both. A small proportion (<10%) are asymptomatic. Fifty per cent of women with endocervical and urethral infection are asymptomatic. Symptomatic women commonly experience altered or increased vaginal discharge, dysuria, lower abdominal pain, and, rarely, intermenstrual or post-coital bleeding. Pharyngeal infection in men and women is usually asymptomatic. The majority of rectal infections in women occur via transmucosal spread and are usually asymptomatic. Rectal infection can occur by direct sexual inoculation in men and women and can cause proctitis or anal discharge.

Less common presentations of gonorrhoea include conjunctivitis from direct inoculation, or disease resulting from haematogenous spread, including arthralgia and localized skin lesions. Disseminated *Neisseria gonorrhoeae* infection is rare and can clinically resemble disseminated *Neisseria meningitidis* infection.

Demographics of the disease

The rate of gonorrhoea infection in the UK peaked in the mid-1970s, with a rapid decline in incidence over the next decade, coinciding with public health campaigns addressing the HIV epidemic. Since the 1990s, the annual incidence of gonorrhoea has increased again. Those who are most at risk of infection include younger age groups (15–29 years), inner-city residents, ethnic minority groups, and men who have sex with men.

Natural history, and complications of the disease

The incubation period for *Neisseria gonorrhoeae* ranges from 2 to 30 days, and infection is usually localized to the lower genital tracts; however, infection can ascend to the upper genital tracts in the form of pelvic inflammatory disease in women, and epididymo-orchitis or prostatitis in men. Both of these conditions can lead to infertility and chronic pelvic pain. Disseminated disease can result in septic arthritis and septicaemia but is uncommon (<1% of infections).

Neisseria gonorrhoeae can be the precipitant of sexually acquired reactive arthritis, which is a condition resulting from infection at a distant (usually genital) site precipitating an autoimmune-mediated sterile inflammation of synovial membranes, tendons, and fascia. In

those who carry HLA-B27, susceptibility is increased fiftyfold, with men being most affected.

Approach to diagnosing the disease

Any person presenting with genital symptoms and a history of arthralgia, conjunctivitis, or skin lesions suggestive of *Neisseria* infection should have a full sexual history taken to assess risk and timings for sexual infection exposure. Information from the history should guide which genital and extra-genital areas are sampled for microbiological specimens.

Other diagnoses that should be considered

Chlamydia trachomatis can present in an identical fashion to gonorrhoea infection and should be considered in the differential diagnosis.

'Gold-standard' diagnostic test

The long-established method for detecting gonorrhoea has been the presumptive diagnosis made from observing Gram-negative intracellular diplococci on microscopy of stained discharge or secretions. Subsequent culture on selective media allows identification of *Neisseria gonorrhoeae* and specifically allows determination of antibiotic sensitivities. The detractors to this method are that specimen collection, storage, and preparation require easily accessible microbiology laboratory facilities, and this is not always practicable in a community-screening setting.

Acceptable diagnostic alternatives to the gold standard

There has been a shift from traditional culture methods to nucleic acid amplification test technology (NAATs), which could potentially supplant culture as the gold-standard diagnostic test. These tests are less intolerant of sampling and transportation inconsistencies than culture is. NAATs allow more convenient and flexible testing arrangements, the use of non-invasive testing methods (urine samples and self-taken swabs), and dual testing for *Neisseria gonorrhoeae* and *Chlamydia trachomatis* on the same specimen. Their disadvantage is that antibiotic sensitivities cannot be determined; this is important, as *Neisseria gonorrhoeae* antibiotic resistance remains a significant clinical problem. Rectal and pharyngeal specimens contain higher levels of other *Neisseria* species and potentially may give rise to more false-positive results than standard culture methods.

Other relevant investigations

When suspecting gonorrhoea clinically, a symptomatic patient should always be screened for other sexually acquired pathogens, including *Chlamydia trachomatis*, HIV, and *Treponema pallidum*, as the mode of acquisition is often similar for each of these infections, and gonorrhoea infection facilitates HIV transmission.

Prognosis

Gonorrhoea is a completely curable condition, but late diagnosis and long-standing infections can lead to long-term sequelae

such as chronic pain, urethral strictures, and infertility in both men and women.

Treatment and its effectiveness

UK national guidelines recommend that treatment for gonorrhoea be given in any of the following situations:

- presumptive diagnosis made with microscopy
- positive culture for *Neisseria gonorrhoeae*
- positive nucleic acid test (confirmation of the diagnosis by culture is recommended prior to or at the time of treatment)
- on epidemiological grounds, if a recent sexual partner has confirmed gonococcal infection

Antimicrobial resistance has become a significant problem in the last decade, with ciprofloxacin resistance in England and Wales detected in 28% of all cultured samples, and high-level resistance to penicillin and tetracycline also being recognized. As a result, the

current recommended first-line treatment for uncomplicated gonorrhoea is dual antibiotic therapy with the third-generation cephalosporin ceftriaxone, given intramuscularly, and the oral macrolide azithromycin. Decreased susceptibility to third-generation cephalosporins and macrolides has been reported, leading to concerns regarding future treatment options.

In all cases, an expert sexual health opinion should be sought when *Neisseria gonorrhoeae* infection is suspected or confirmed, and appropriate sexual contact tracing undertaken.

PART 16

Cancers

321 Cancers related to infection

Daniel Ajzensztejn

Introduction

The development of a cancer is often complex and multifactorial. Environmental factors such as smoking, diet, asbestos exposure, and sun exposure are important causes of cancer, with smoking alone responsible for 25%–30% of cancers. Up to 10% of cancers have a genetic component. Infectious agents are implicated in the development of approximately 15% of cancers. Viruses, bacteria, and parasites can all cause cancers. Cervical, Head & Neck, and hepatocellular carcinoma are the three commonest cancers related to infections.

The role of infectious agents in cancer

Francis Peyton Rous first proposed that an infectious agent could cause cancer in 1911. He was able to demonstrate transmission of sarcoma from chicken to chicken through injection of a cell-free filtrate. Although ridiculed at the time, his work won him a Nobel Prize 57 years later. The infectious agent he discovered is now known as the Rous sarcoma virus. This was the first of several identified cancer-causing viruses, which are also known as oncoviruses.

Viruses that can cause cancer in humans

HPV

For many years, it had been postulated that an infectious agent was involved in the development of cervical cancer. Epidemiological studies linked the disease to early onset of sexual activity and number of sexual partners. Other factors are also important. Smoking, for example, doubles a woman's risk of developing the disease.

HPV is a non-enveloped DNA virus which has now been linked to the development of cervical cancer. More than 140 different HPV types have been recognized to date. HPV-16 and HPV-18 are of particular importance in cervical cancer. Via PCR-based techniques, HPV-16 and HPV-18 have been demonstrated in approximately 70% of cervical cancers. Other high-risk HPV types, including HPV-31, HPV-33, HPV-35, HPV-45, HPV-52, and HPV-58, have also been demonstrated in cervical cancers but to a lesser degree.

Carcinogenesis, the development of cancer, is a multistep process. HPV is important in the initiation of this process, with other factors required for progression to cancer.

HPV viruses replicate in squamous epithelial cells. HPV has also been implicated in several other squamous cell cancers in the anogenital region (penile, vulval, vaginal, and anal carcinomas), the head and neck region, and in some skin cancers (particularly in immunosuppressed individuals, such as renal transplant patients). In the case of oropharyngeal head and neck cancers, tumour HPV status is strongly associated with therapeutic response and survival, with HPV-associated cancers having better outcomes than HPV-negative oropharyngeal cancers.

HPV vaccines

Understanding the viral aetiology of cervical cancer has led to the development of more reliable cervical screening. More importantly, HPV vaccination can prevent some HPV-associated cancers.

To date, there are two commercially available vaccines against HPV. These include virus-like particles which are able to generate a durable immune response to specific HPV types. Both protect against HPV-16 and HPV-18, which cause approximately 70% of cervical cancers. The quadrivalent vaccine also immunizes against HPV-6 and HPV-11, which cause genital warts. Trials are currently also underway with a nonavalent HPV vaccine protecting against HPV-31,

HPV-33, HPV-45, HPV-52, and HPV-58 as well as those protected by the quadrivalent vaccine. To be most effective, the vaccine needs to be given prior to infection with HPV. Many countries have introduced vaccination programmes for school-aged girls. In the UK, it is offered to all girls aged 12 and 13. In some countries, the vaccination programme has been extended to include both sexes.

Hepatitis B and hepatitis C viruses

Chronic infection with the hepatitis B virus (HBV) or the hepatitis C virus (HCV) can lead to the development of hepatocellular carcinoma. Although this is a relatively rare disease in the West, it has a high prevalence in sub-Saharan Africa and South East Asia. This means that, on a global scale, it is actually one of the commonest cancers.

HBV

HBV is a hepadnavirus (hepatotropic DNA virus). It has a circular genome composed of partially double-stranded DNA. Viral replication occurs in hepatocytes. The virus then spreads to the blood, where viral antigens and antibodies can be detected in infected individuals.

Acute infection with HBV can cause either an acute liver injury presenting with jaundice, or a subclinical infection. Most acute infections resolve with clearance of the virus from both the liver and blood, with resulting natural immunity to reinfection. In approximately 5% of patients, acute infections are not cleared; such individuals develop persistent viraemia. Globally, there are approximately 400 million individuals with chronic HBV infection. From epidemiological studies, it is known that chronic infection with HBV increases the risk of developing hepatocellular carcinoma a hundredfold.

HCV

HCV is a member of the Flaviviridae family of RNA viruses. In most cases, acute infection with HCV does not cause symptoms. However, in approximately 25% of cases, infected individuals will develop an acute hepatitis presenting with jaundice and malaise. The acute infection is cleared in about 20%–50% of cases. If the infection is not cleared, infected individuals become chronic carriers. Globally, there are approximately 170 million chronic carriers of HCV. Up to 5% of these people will ultimately develop hepatocellular carcinoma. Those at highest risk of developing hepatocellular carcinoma are the approximately two-thirds of chronic carriers who develop a chronic hepatitis, 20% of whom develop liver cirrhosis over a period of 10–20 years. In this subset of patients, there is an annual risk of 1%–4% of going on to develop hepatocellular carcinoma. Infection with particular HCV genotypes, particularly HCV genotype 1b, co-infection with HBV, and alcohol consumption all increase the likelihood of developing hepatocellular carcinoma.

Mechanisms of oncogenesis by HBV and HCV

HBV and HCV both increase the risk of cancer in chronically infected individuals via the host immune response to viral antigens present on the surface of infected hepatocytes. This results in chronic hepatocyte injury similar to that caused by chronic alcohol abuse, alpha-1-antitrypsin deficiency, and Wilson's disease. These conditions all cause chronic liver injury through hepatocyte destruction, regeneration, and fibrosis and are all associated with an increased risk of hepatocellular carcinoma. Although HBV is not directly oncogenic, there is some evidence that HCV is able to independently cause neoplastic transformation of hepatocytes. HCV may also increase the risk of haematological malignancies such as B-cell non-Hodgkin's lymphoma and other lymphoproliferative diseases.

Vaccines and other therapies for HBV and HCV

There is a commercially available HBV vaccine. There is currently no vaccine for HCV. Antiviral therapy can be used in the treatment of chronic carriers. Interferon alfa and antiviral drugs such as lamivudine are used in the treatment of selected chronic HBV carriers. In HCV, treatment with interferon alpha and ribavirin, a synthetic guanosine analogue, can be effective in reducing viral load. It is not yet clear whether this reduces rates of progression to hepatocellular carcinoma. Surgical resection of the tumour and liver transplantation are the only two curative therapies for established hepatocellular carcinoma.

EBV

EBV is a member of the Herpesviridae family of DNA viruses and was the first cancer-causing virus to be identified. The virus was discovered in 1964 and is named after Anthony Epstein and Yvonne Barr, pathologists at the former Middlesex Hospital in London. They identified the virus in cell line cultures taken from pathology specimens collected by a British surgeon, Denis Burkitt, in Uganda. Burkitt had documented the high incidence of B-cell lymphoma in children living in malaria-endemic regions of Africa. This type of lymphoma has since been eponymously named Burkitt's lymphoma. Initial excitement over the identification of a possible cancer-causing virus was soon dampened by the discovery that over 95% of people in the general population had a detectable EBV-specific antibody. Related work led to the link between primary infection with EBV and infectious mononucleosis. Titre levels of EBV-specific antibody were, however, found to be higher in children with Burkitt's lymphoma. This was also seen in some patients with Hodgkin's lymphoma and in Chinese patients with nasopharyngeal cancer, consistent with the original hypothesis of a cancer-causing virus.

Primary infection with EBV is the cause of infectious mononucleosis (also known as glandular fever or 'mono'). The infection is usually spread via saliva and has an incubation period of 4–7 weeks. The virus replicates initially within epithelial cells of the nasopharynx and then infects circulating B-cells. These infected B-cells are recognized and destroyed by T-cells, which account for most of the circulating immune cells during acute infection.

Primary infection is followed by a latent infection characteristic of all herpesvirus infections. During latent infection, the virus is present as episomes in the nuclei of lymphocytes and epithelial cells of the oropharynx, which acts as a reservoir for the virus. B-cells are infected as they circulate through the nasopharynx. Saliva and other secretions contain the virus, thereby enabling viral transmission to uninfected individuals.

EBV latent gene expression codes for several nuclear proteins, certain patterns of which are believed to contribute to cancer development. Their main role is in initiation of oncogenesis. While certain patterns of EBV latent gene expression are associated with cancers, others are associated with healthy carriers of EBV.

In addition to nasopharyngeal carcinoma and Burkitt's lymphoma, several other tumour types, including Hodgkin's lymphoma and gastric cancers, may express EBV at a lower frequency. The sites of these tumours relate to the sites of reservoir of the latent virus.

HHV8

HHV8, also known as Kaposi's sarcoma-associated herpesvirus, is associated with the development of Kaposi's sarcoma (KS). Although the disease was first described in 1872, its causative virus was only identified in 1994. Four epidemiologic patterns of KS have been characterized: (i) AIDS-associated KS is the commonest malignancy in HIV-infected individuals, and development of KS is an AIDS-defining illness; (ii) classic KS, which is predominantly a disease of elderly Mediterranean and East European men; (iii) endemic KS, which is most common in young HIV-seronegative men in sub-Saharan Africa; and (iv) immunosuppression-associated KS, which is related to the suppression of T-cell function. All four types of KS share a degree of underlying immune dysregulation, although, interestingly, individuals with congenital immunosuppression do not appear to be at an increased risk of developing KS.

HIV

Of patients with HIV who develop AIDS, approximately 10% will develop a cancer. This figure includes both AIDS-defining cancers (Kaposi's sarcoma, non-Hodgkin's lymphoma, and cervical cancer) and non-AIDS-defining cancers. The increased risk of cancer development in the context of HIV is believed to be multifactorial, with immunosuppression and co-infection with the other oncogenic viruses described in this chapter playing important roles. A direct oncogenic effect of HIV per se has been hypothesized, particularly with regard to the development of non-EBV-associated lymphomas, but strong evidence for this is lacking.

HTLV-1

Adult T-cell leukaemia (ATL) is an aggressive malignancy of CD4⁺ T-cells. Geographic clustering of the disease, particularly to areas of southern Japan, led to the hypothesis of an infectious aetiology. This was subsequently confirmed when nearly 100% of tested patients were found to be seropositive for HTLV-1. HTLV-1 is a retrovirus which shares several features with HIV, including genetic structure, tropism for CD4⁺ T-cells, and broadly similar routes of transmission. There are, however, marked differences, with over 95% of people infected with HTLV-1 virus going on to become asymptomatic carriers. The mechanism of oncogenesis is complex and multifactorial, as attested to by the fact that only 3%–5% of carriers develop ATL, along with the 30–50-year latency period between infection and development of the disease.

Other viruses that cause cancer in humans

Several other viruses have oncogenic properties. Along with those already discussed, these are summarized in Table 321.1.

Bacteria that cause cancer

Helicobacter pylori

Helicobacter pylori is a Gram-negative microaerophilic bacterium that is found in the upper gastrointestinal tract of approximately 50% of the world's population. *Helicobacter pylori* infection doubles the risk of developing gastric adenocarcinomas of the body and antrum of the stomach. The bacteria can cause an atrophic gastritis, which results in a low-acidity environment that promotes metaplasia and dysplasia. Only 5% of carriers of *Helicobacter pylori* will develop a gastric cancer over a 10-year period; therefore, other factors must also be important. Smoking, infection at a younger age, and male gender all increase the risk, whereas diets rich in fruit and vegetables high in antioxidants, including vitamins C and E, flavonoids, and carotenoids, are protective.

Helicobacter pylori is also associated with the development of gastric mucosa-associated lymphoid tissue (MALT) lymphomas. Gastritis caused by *Helicobacter pylori* results in development of malignant B-cell clones.

Prevention and treatment of cancer associated with *Helicobacter pylori*

The risk of developing gastric cancer can be reduced through eradication of *Helicobacter pylori*, avoidance of smoking, and maintaining a healthy diet. Established gastric cancers associated with *Helicobacter pylori* are treated in the same manner as other gastric cancers. MALT lymphomas limited to the stomach usually resolve completely with eradication of *Helicobacter pylori*. Surgery and radiotherapy can have a curative role where the disease persists. Chemotherapy can be used where there is evidence of distant spread.

Parasites that cause cancer

Schistosoma haematobium

Schistosoma haematobium, which is endemic in much of Africa and the eastern Mediterranean, is associated with the development of bladder cancer. Unlike non-infective bladder cancers, which are predominantly transitional cell carcinomas, *Schistosoma haematobium*-associated bladder cancer is a squamous cell carcinoma. Infection

Table 321.1 Human viruses with oncogenic properties

Virus family	Type	Human tumour	Cofactors
Flaviviruses	HCV	Hepatocellular carcinoma	–
Hepadnavirus	HBV	Hepatocellular carcinoma	Aflatoxin, alcohol, smoking
Herpesviruses	EBV	Burkitt's lymphoma	Malaria
		Immunoblastic lymphoma	Immunodeficiency
		Nasopharyngeal carcinoma	Nitrosamines, HLA genotype
		Hodgkin's lymphoma	–
		Leiomyosarcomas	–
	KSHV (HHV8)	Gastric cancers	–
		Kaposi's sarcoma	HIV infection
Papillomaviruses	HPV-16, HPV-18, HPV-33, HPV-39, others	Anogenital cancers and some upper airway cancers	Smoking,? other factors
		Skin cancer	Epidermodysplasia verruciformis, sunlight, genetic factors, immune suppression
	HPV-5, HPV-8, HPV-17, others		
Polyomavirus	SV40 (monkey virus)	? Brain tumours	–
		? Non-Hodgkin's lymphomas	–
		? Mesotheliomas	–
	JC virus	? Brain tumours	–
	BK virus	? Prostate cancer	–
Retroviruses	HTLV1	Adult T-cell leukaemia/lymphoma	Uncertain

Abbreviations: HCV, hepatitis C virus; HBV, hepatitis B virus; EBV, Epstein–Barr virus; KSHV, Kaposi's sarcoma-associated herpesvirus; HHV8, human herpes virus 8; HIV, human immunodeficiency virus; HPV, human papillomavirus; SV40, simian virus 40; HTLV1, human T-lymphotropic virus type 1.

occurs through swimming in contaminated water. Larvae burrow into human skin, and migrate via the bloodstream to the liver, where they mature into flukes that travel to the bladder. There, the female fluke lays eggs which traverse the wall of the bladder, causing haematuria. Chronic infection is believed to predispose to cancer through chronic inflammation and fibrosis.

Liver flukes

Parasitic infection by liver flukes of the *Opisthorchis* genus is associated with cholangiocarcinoma. The incidence of cholangiocarcinoma in north-east Thailand, where *Opisthorchis viverrini* is endemic, is 45 times higher than the global average. Many parts of South East Asia where *Clonorchis sinensis* is endemic also have higher than expected rates of the disease. Infection occurs through the consumption of undercooked infected fish. The flukes then establish chronic infection of the bile ducts, where they cause cancer through a combination of inflammation, oxidative stress, and cell proliferation.

Summary

Although accounting for only a relatively small percentage of cancers, infections that can cause cancer are important. Treatment aimed

at preventing or eradicating such infections can stop cancer from developing. Vaccinations such as those against HBV and HPV have the potential to dramatically change the epidemiology of diseases. Eradication of *Helicobacter pylori* bacteria can prevent the development of gastric cancer and gastric MALT lymphoma. Eradication of the bacteria is also usually successful as a curative treatment for already established, localized gastric MALT lymphoma. Improved public health measures aimed at reducing contaminated water supplies in parasite endemic regions would bring many health benefits. This would be expected to include a reduction in the incidence of cancers caused by parasites.

322 Principles of oncogenesis

Warren Grant and Martin Scott-Brown

Introduction

It is obvious that the process of developing cancer—oncogenesis—is a multistep process. We know that smoking, obesity, and a family history are strong independent predictors of developing malignancy; yet, in clinics, we often see that some heavy smokers live into their nineties and that some people with close relatives affected by cancer spend many years worrying about a disease that, in the end, they never contract.

For many centuries, scientists have struggled to understand the processes that make cancer cells different from normal cells. There were those in ancient times who believed that tumours were attributable to acts of the gods. Hippocrates suggested that cancer resulted from an imbalance between the black humour that came from the spleen, and the other three humours: blood, phlegm, and bile. It is only in the last 100 years that biologists have been able to characterize some of the pathways that lead to the uncontrolled replication seen in cancer, and subsequently examine exactly how these pathways evolve.

The rampant nature by which cancer invades local and distant tissues, as well as its apparent ability to spread between related individuals led some, such as Peyton Rous in 1910, to suggest that cancer was an infectious condition. He was awarded a Nobel Prize in 1966 for the 50 years of work into investigating a link between sarcoma in chickens and a retrovirus that became known as Rous sarcoma virus. He had shown how retroviruses are able to integrate sequences of DNA coding for errors in cellular replication control (oncogenes) by introducing into the human cell viral RNA together with a reverse transcriptase. Viruses are now implicated in many cancers and, in countries where viruses such as HIV and EBV are endemic, the high incidence of malignancies such as Kaposi's sarcoma and Burkitt's lymphoma is likely to be directly related. There are several families of viruses associated with cancer, broadly classed into DNA viruses, which mutate human genes using their own DNA, and retroviruses, like Rous sarcoma virus, which insert viral RNA into the cell, where it is then transcribed into genes.

This link with viruses has not only led to an understanding that cancer originates from genetic mutations, but has also become a key focus in the design of new anticancer therapies. Traditional chemotherapies either alter DNA structure (as with cisplatin) or inhibit production of its component parts (as with 5-fluorouracil.) These broad-spectrum agents have many and varied side effects, largely due to their non-specific activity on replicating DNA throughout the body, not just in tumour cells. New vaccine therapies utilizing gene-coding viruses aim to restore deficient biological pathways, or inhibit mutated ones specific to tumour cells. The hope is that these gene therapies will be effective and easily tolerated by patients, but development is currently progressing with caution. In a trial in France of ten children suffering from X-linked severe combined immunodeficiency and who were injected with a vector that coded for the gene product they lacked, two of the children subsequently died from leukaemia. Further analysis confirmed that the DNA from the viral vector had become integrated into an existing, but normally inactive, proto-oncogene, LM02, triggering its conversion into an active oncogene, and the development of life-threatening malignancy.

To understand how a tiny change in genetic structure could lead to such tragic consequences, we need to understand the molecular biology of the cell and, in particular, to pay attention to the pathways of growth regulation that are necessary in all mammalian cell populations. Errors in six key regulatory pathways are known as the 'hallmarks of cancer' and will be discussed in the rest of this chapter.

Self-sufficiency in growth signals

To maintain tissue integrity, cells must communicate with each other to initiate and inhibit replication as required. This communication is in the form of growth factors—small protein molecules that are secreted and travel through the intercellular space to initiate biological responses by acting as ligands and docking with receptors on the surface of cells. Once stimulated, these transmembrane receptors go on to initiate a cascade of protein phosphorylation that eventually leads to DNA transcription and growth stimulation. Growth factors exist in a sea of other regulatory proteins that control when growth factors are released from cells, in what quantity, and to which tissue they eventually dock. The interactions between these proteins are complex but, in normal cells, growth factors are controlled in a homeostatic fashion to maintain tissue structure and function.

In recent years, a developing interest into how these growth signalling pathways differ in cancer cells has led to some fascinating suggestions. It has become apparent that many cancers manipulate their response to growth factors by upregulating the expression of the growth factor receptors on their cell surfaces or by mutating them and promoting downstream protein phosphorylation independently of any ligand binding. Other cancers produce their own growth factors and excrete them into the extracellular environment, only to see them immediately bind to the cell's own receptors and repeat this self-stimulatory autocrine process.

In around 30% of breast cancers, the HER2/neu transmembrane epidermal growth factor receptor is overexpressed. Overexpression is associated with more rapidly progressive cancers and a 25%–30% shorter overall survival. Recently, the development of Herceptin, which is a humanized monoclonal antibody to the HER2/neu receptor and is given intravenously every 3 weeks, has significantly improved survival in this selected group of patients by blocking HER2/neu activity and preventing initiation of its downstream pro-growth signalling cascade.

Insensitivity to anti-growth signals

Normal cellular replication follows a tightly controlled cycle of events. This cycle is divided up into the synthetic (or S) phase, when DNA is replicated, and the mitotic (or M) phase, when the cell divides into two daughter cells. Between the M phase and the next S phase is a period called G1, and following the S phase is a period called G2 before the cell enters the next M phase. During G1, or the 'first gap' phase of the cycle, between cell birth and the time when DNA synthesis begins, the cell will make critical decisions about whether to begin replicating or to 'rest' in the G0 phase. Should the balance of replication swing in the direction of replication-promoting, or **mitogenic**, proteins, and away from those proteins involved in halting the replication process, the cell will move into the S, or **synthetic**, phase. Once here, the cell cannot return to G1 and is fully committed to undergoing mitosis. It has crossed what is known as the restriction, or R, point, a key cell cycle checkpoint.

Closely regulated cell cycle checkpoints, like the R point, ensure that any cells containing errors in their DNA or that are stimulated to divide at a time when replication is not required, do not complete the cycle. However, the success of cancer cells often involves developing methods to get round these anti-growth checkpoints.

Retinoblastoma protein (pRb) in its hypophosphorylated form acts as a key growth suppressor. It halts the passage of cells through the R point. Through interactions with members of the cyclin family of proteins, it insures that the error-prone products of disordered DNA synthesis are not allowed to pass through the cell cycle and on

to other cell generations. Retinoblastomas can develop in the eyes of young children when the gene that encodes pRb, RB1, is mutated. Those with the inherited gene mutation have abnormal RB1 in all their cells, including germ cells, and are likely to develop bilateral retinoblastomas. There is also an association with tumours of the pineal gland and osteosarcomas. In the non-inherited form, abnormal genes still play a key part. However, the abnormal RB1 is only present in the cells of the tumour, which is usually a unilateral retinoblastoma and confers no higher risk of other systemic tumours. Normal pRB can also be inactivated by DNA tumour viruses such as HPV, as these promote the production of oncoproteins that bind to and disable RB1, thus allowing affected cells to replicate uncontrollably.

Evading apoptosis

Apoptosis is programmed cell death. It is a highly preserved function of cells to self-destruct in the presence of unprepared DNA damage or uncontrolled mitotic signals. In normal circumstances, when these situations are detected, a spiralling cascade of proteins from the caspase family set in motion a series of catastrophic structural changes leading eventually to cell breakdown and degradation of cellular material. As previously noted, cancers contain many genetic abnormalities that promote independent and uncontrolled growth. For these errors not to result in immediate cell death, a cancer must have some way of getting round apoptosis. This is why the most common gene mutation in human cancers is in the gene that codes for p53. p53 is a transcription factor that promotes activation of pro-apoptotic genes such as APAF1, CASP1, BAX, and BID. Errors in its ability to detect DNA damage and sustained mitotic signals will lead to a failure to initiate apoptosis and subsequent replication of the damaged DNA and a predisposition to develop cancer. Inherited mutations in the p53 gene are linked to Li–Fraumeni syndrome, a disease characterized by an increased risk of osteosarcomas, breast tumours, lung tumours, and brain tumours, as well as leukaemias.

Sustained angiogenesis

In order for a tumour to receive nutrients and exchange metabolites, as it must do to remain viable, it needs to lie within 100–200 µm of a capillary blood vessel. Lying further from an active blood supply will lead to growth arrest and necrosis. So, for cancers to expand, they need not only to artificially stimulate growth and evade cell death, but also to develop their own vasculature.

Angiogenesis depends on a tight balance of pro- and anti-angiogenic factors. The so-called angiogenic switch represents the on–off interaction between factors which stimulate angiogenesis, such as vascular endothelial growth factor (VEGF) and fibroblast growth factor, and those which inhibit the angiogenic process, such as thrombospondin and angiostatin.

Recently, bevacizumab has entered clinical use in bowel and breast cancer trials. It is an anti-VEGF monoclonal antibody that aims to inhibit the chaotic angiogenesis of tumour cell populations. It is unique in current practice in that it acts upon a circulating ligand. Other monoclonal antibodies attack cell membrane-bound receptors, while more traditional agents act on the internal structure of cancer cells. Current trial protocols involve administering the drug intravenously every 3 weeks for periods up to 1 year or until disease progression. Although it has shown some benefit in stabilizing or shrinking disease in the metastatic setting, there is some suggestion that tumour cell growth may accelerate rapidly once bevacizumab is stopped and the angiogenic switch allowed to flick to the 'on' position.

Tumour invasion and metastases

Cancer is a progressive disease. In cancers such as bowel and breast cancer, we see a clear progression of events over time: growth of the primary lesion, spread to local blood vessels or lymphatics, and subsequent involvement of distant organs such as the liver, the lungs, and the bones. In order to behave in this predictable way, cancer cells must detach from the primary tumour site, extravasate into the local blood supply, evade circulating host defence mechanisms, halt at a suitable site for new growth, permeate through the blood vessel wall, and begin again the cycle of tumour and blood vessel development. The steps that lead to the cancer cell, or 'seed,' finding the tissue, or 'soil' in which it can grow are numerous and involve the manipulation of many factors, including cell adhesion molecules, proteinases that enable endothelial membranes and the extracellular matrix to be broken, cellular growth factors, chemokines, apoptotic signals, and the host immune response.

Clinically, it has proven to be very challenging to prevent the process of cancer spread and metastases. This is likely to be due to our lack of understanding of the complex biology involved. In many cancers, we see that the process of metastasizing is highly inefficient. Blood samples from patients with early breast cancer have been shown to contain large numbers of circulating cancer cells, yet not all of these patients go on to develop metastatic disease. Despite investigating tumour biology and host genetics, we cannot predict accurately who will develop metastases and who will not. In the 1990s there was much excitement in this field as a UK firm, British Biotech, announced the development of a broad-spectrum matrix metalloproteinase inhibitor—marimastat. In animal studies, it had been found to halt tumour cells' ability to break down the extracellular matrix in the process of establishing new growth colonies. Unfortunately, clinical trial data revealed unacceptably high musculoskeletal side effects and this finding, together with public controversy over the way data was presented, led subsequently to the downfall of British Biotech and a sudden halt to the development of these drugs.

Limitless replicative potential

In a normal cell, exposed breaks in the DNA initiate a cascade of regulatory proteins that either repair the damage or initiate apoptosis. This leads to a biological quandary: at the end of every chromosome within the cell is an exposed 'broken' end of DNA. How is this not recognized as damage, and why are cells not in a constant state of apoptosis as a result? The answer lies in a complex of regulatory proteins that surround the end of mammalian chromosomes, at a region known as the **telomere**, and protect it from being recognized as 'damaged' DNA. Each time a cell replicates, the telomere loses DNA from its non-coding free end, shortening the chromosome. Eventually, the cell reaches a critical limit, named, eponymously, the Hayflick limit, where no further replication is possible without damaging functional DNA and initiating cell senescence or apoptosis. In normal tissue, this limits the life of a cell and ensures that more mature cells, that are more error-prone, are replaced. Cancer cells manage to prevent this progressive telomere shortening and effectively become immortal by producing telomerase, a key enzyme required to synthesis telomeric DNA. Clinical inhibition of telomerase is currently under early investigation with drug and vaccine programmes.

323 Presentations in suspected cancer

David Cutter and Martin Scott-Brown

Introduction

Malignant neoplastic disease includes a vast range of conditions that can originate from and can directly or indirectly affect virtually every organ system of the body. As a consequence of this, the presentation of malignancy can be similarly varied. While a diagnosis of malignancy may be clinically obvious in some cases, in others diagnosis and investigation may be delayed due to non-specific presentations and the attribution of symptoms to non-malignant conditions. Early diagnosis of cancer has an impact on the success of subsequent treatment and overall survival. It is therefore vital to maintain an appropriate level of clinical suspicion when deciding whether and how much to investigate patients with symptoms that could be secondary to an underlying malignancy.

Symptoms directly related to the primary tumour

Many common cancers present with local symptoms that are easily identifiable as possible symptoms of malignancy, for example a breast mass secondary to breast cancer or haemoptysis secondary to lung cancer. In the UK, this has led to the creation of a series of 'red flag' symptoms that should prompt referral for specialist investigation under the '2-week wait' standard introduced for all cancers in 2000. These symptoms are described in more detail in Chapters 326–8. It should be recognized, however, and always born in mind that cancer does not *always* present with 'classic' symptoms. For example, patients with renal cell carcinoma may present with haematuria, loin pain, or a palpable mass, but this 'classic' triad occurs in <10% of cases. Also, some cancers may present with non-specific symptoms that may be present for prolonged periods prior to diagnosis. The common example is ovarian cancer, where little or no symptoms in early disease and vague presentations with abdominal discomfort and bloating, often misdiagnosed as IBS, have led to it being labelled 'the silent killer'.

Symptoms due to metastatic disease

Cancer can first present with a wide range of symptoms secondary to metastatic disease rather than the underlying primary. The chance of presentation with metastatic disease varies widely between different cancer types and histologies. For example, more than 50% of pancreatic cancer patients have distant metastases at diagnosis, compared to less than 10% of differentiated thyroid cancer patients. The pattern of spread also varies, with certain malignancies demonstrating a predilection to metastasize to certain organs for anatomical and biological reasons. For example, colon cancer typically metastasizes to the liver via the portal venous system, whereas ovarian cancer typically spreads transcoelomically over the peritoneal surfaces.

The symptoms and signs precipitated by metastatic disease obviously depend on the site affected. Sign and symptoms associated with various areas are as follows:

- lymph nodes: palpable masses (neck, axillae, groins), lymphoedema, biliary obstruction (porta hepatitis lymphadenopathy)
- liver: anorexia, weight loss, nausea, fever, pain, jaundice
- bone: pain, pathological fracture
- lung: cough, dyspnoea, haemoptysis
- brain: headache, nausea, seizures, focal neurology
- peritoneum: ascites, nausea, vomiting

Constitutional symptoms

Unintentional weight loss

Significant unintentional weight loss (defined as >5% loss of body weight within 6 months) is often regarded as a concerning symptom. Underlying malignancy only accounts for ~25% of cases, however, and the range of other possible causes is diverse. It has been shown that, in the context of normal, simple, baseline examinations (e.g. clinical examination, routine blood tests, chest X-ray, and abdominal ultrasound), the presence of malignancy, and indeed other significant organic illness, is unlikely. Malignancy that does present primarily with weight loss often implies metastatic disease, and the prognosis is generally poor.

Pyrexia of unknown origin

The likely underlying causes of pyrexia of unknown origin (PUO) vary widely depending upon the definition used and the population studied. The proportion of adult cases diagnosed as secondary to an underlying malignancy has decreased over the decades, presumably due to improved diagnosis, and in modern European hospitals is probably now <10%. Where PUO is secondary to a malignancy, it can be of any histology, but risks of haematological malignancy and sarcoma are most increased. PUO is generally associated with more advanced disease and a worse prognosis.

Venous thromboembolic disease

Active malignancy has been estimated to account for almost 20% of incident venous thromboembolic events. The majority of these, however, occur in patients with a preexisting diagnosis of malignancy. In patients with a first episode of deep vein thrombosis and without a known diagnosis of cancer, the risk of new cancer has been estimated at 1%–2% per year, but is thought to be higher in older patients and in those with no other obvious precipitant cause. Therefore, a detailed history should always be taken and any suspicion of underlying cancer investigated as appropriate.

Paraneoplastic syndromes

Malignancies can uncommonly present with the non-metastatic distant signs or symptoms of paraneoplastic syndromes. The cancer that most frequently causes these is small cell lung cancer (SCLC), which is associated with syndrome of inappropriate antidiuretic hormone secretion in up to 40% of cases. Other rarer syndromes seen with SCLC include paraneoplastic cerebellar degeneration and Lambert–Eaton syndrome. Other malignancies that are associated with paraneoplastic syndromes are non-small cell lung cancer (NSCLC), breast cancer, ovarian cancer, and lymphomas.

Paraneoplastic syndromes can be divided into three main groups:

- neurological
- endocrine
- dermatological

Detailed descriptions are beyond the scope of this chapter, and references are supplied for further reading.

Presentation with oncological emergencies

Malignancy can present for the first time as a medical emergency. This could be due to complications of the primary tumour (e.g.

gastrointestinal bleeding) or complications of metastatic disease (e.g. seizures secondary to cerebral metastases or pathological fracture secondary to bone disease). In addition, there are three 'classic' oncological emergencies that are well recognized to be the manner of presentation of a proportion of cancers: spinal cord compression, superior vena cava obstruction, and hypercalcaemia.

Spinal cord compression

Malignant extradural compression of the spinal cord due to involvement of the bony spinal column or adjacent soft tissues occurs in around 5% of patient with a known diagnosis of cancer. In approximately 20% of cases, spinal cord compression is the first presentation of malignancy. The most common malignancies to present with spinal cord compression are lung, prostate, and renal carcinoma, and also malignancies of unknown primary. It presents with a variable onset of sensory and motor signs and symptoms dependant on the severity and level of compression and also whether there is associated pathological fracture or vascular impairment. Urgent investigation with an MRI whole spine, and rapid referral for emergency treatment, are essential, to try and limit neurological sequelae.

Superior vena cava obstruction

Malignant compression of the superior vena cava can also lead to the first presentation of an underlying malignancy. The vast majority (85%–95%) of cases of superior vena cava obstruction are due to cancer, the most common causative types being SCLC, NSCLC, and lymphoma. The syndrome consists of characteristic swelling and oedema, with fixed engorgement of veins, within the distribution of drainage of the superior vena cava (head, neck, arms, and upper thorax). The patient may report symptoms of fullness, breathlessness, and headache, with the symptoms being exacerbated by bending or lying down and being worse in the mornings. While the syndrome requires rapid investigation so that treatment may be given for symptomatic relief, if superior vena cava obstruction is the first presentation of a suspected malignancy, it is vital to obtain histological confirmation of the diagnosis, if at all possible, prior to the commencement of oncological therapy.

Hypercalcaemia

Hypercalcaemia (corrected serum calcium >3.0 mmol/l) occurs in up to 20% of malignancies and can also lead to the presenting symptoms. The most common malignancies to cause hypercalcaemia are breast, lung, prostate, and renal cancers and haematological malignancies (myeloma and lymphomas). The symptoms of hypercalcaemia are often vague and non-specific, including fatigue, drowsiness, confusion, anorexia, nausea and vomiting, polyuria, dehydration, and abdominal pain. Hypercalcaemia should therefore be excluded in many acute clinical presentations and, if confirmed,

its presence should be investigated thoroughly to exclude an underlying malignancy.

Screening and incidental presentations

Where screening programmes are in place (e.g. for breast and cervical cancer), patients with new diagnoses present with positive test findings, but usually no clinical symptoms at all. For example, the proportion of new breast cancer diagnoses in UK found as a consequence of mammographic screening is approximately 33%.

The increasing use of more sophisticated medical imaging is leading to an increase in the number of asymptomatic cancers diagnosed incidentally as a consequence of investigation for an unrelated medical problem. While still an uncommon occurrence, this manner of presentation is likely to become more prevalent in the future as the number of investigations performed continues to increase.

Presentation with a family history

While it is only the minority (<5%) of cancer patients that have a truly hereditary malignancy, the inherited cancer predisposition syndromes are increasingly well recognized and described. It is important to recognize the possibility of an inherited genetic defect in a family pedigree so that the patient and their relatives may be referred for genetic counselling, testing, and advice on intervention and prevention, where appropriate. Important examples are the hereditary breast cancer genes BRCA1 and BRCA2, which, when mutated, as well as increasing lifetime breast cancer risk by 10–30-fold, also increase the risks of ovarian, pancreatic, and prostate cancers, thereby affecting both males and females in the family. Multiple cases of early-onset breast cancer (<50 years of age) and bilateral breast cancer are characteristic of families with hereditary breast cancer, and such families should be referred.

324 Diagnosis and staging of cancer

David Cutter and Martin Scott-Brown

Introduction

The accurate diagnosis of the precise type and stage of a malignancy is a vital part of cancer management. Treatment options and decisions vary significantly between various stages of the same malignancy (e.g. treatment with radical vs palliative intent) and also between specific histological subtypes of a cancer arising from the same organ (e.g. small-cell lung cancer versus non-small-cell lung cancer (NSCLC)). It is therefore of critical importance that as much accurate information about each individual case is obtained. This is achieved with a variety of diagnostic procedures which allow the multidisciplinary team to reach correct decisions about management. The types of investigations performed typically include radiology and pathology, but clinically important information may also be obtained by other methods, for example surgical staging, clinical examination, endoscopy, and blood tests. As well as directing therapy, accurate staging also allows a more precise estimation of prognosis or the probability of treatment success, knowledge which is of obvious importance to the patient.

Imaging

Imaging plays a vital role in the diagnosis and staging of malignancy. It is often an imaging test that first leads to the suspicion of malignancy, and increasingly sophisticated imaging is being employed more frequently to accurately stage cancer and guide management. Several different modalities are commonly used that have complementary roles.

Plain radiographs

A plain X-ray is a quick, cheap, and relatively simple investigation and therefore forms an early part of the initial investigation of many malignancies. For example, many lung malignancies are detected by a plain chest X-ray either when investigating relevant symptoms or simply as an incidental finding. Mammography is well established as both a screening tool and part of the diagnostic workup for breast cancer. Plain X-rays are insufficient in themselves to guide modern cancer management, and positive findings are usually confirmed and investigated further by other modalities and tests.

Ultrasound

Ultrasound is another relatively inexpensive, non-invasive investigation that is commonly used in the diagnosis and staging of malignancy. It is often used to guide fine-needle aspiration or core biopsy to obtain a histological diagnosis (e.g. in the diagnosis of breast or neck masses). Specialized ultrasound is also used in some circumstances to aid local staging, for example endoscopic ultrasound to assess oesophageal tumours. Ultrasound is also used to examine the liver for hepatic metastases.

CT scanning

CT scanning has become a 'keystone' for the staging of many malignancies. The speed and availability of modern scanners makes CT an extremely useful tool for imaging the whole body, if required, with one test. While the accuracy of CT assessment is generally good, it can reveal inconclusive findings that require further investigation via other modalities (e.g. small liver abnormalities that require assessment by ultrasound or MRI). CT does have some advantages over MRI, however: for example, it can produce superior images of bony structures and is faster and costs less to run than MRI; in addition, it is quieter and less claustrophobic. Incidental cancers are occasionally noticed on CT scans performed for other reasons (e.g. to investigate

suspected renal colic), although the number of non-malignant incidental findings is far greater.

MRI

MRI has much superior soft tissue contrast, compared to CT, and so it allows greater definition of tumours and their relation to fascial planes, bones, vessels, nerves, and adjacent organs. MRI can easily produce images in multiple planes and has the additional advantage of not using ionizing radiation. MRI is commonly used as an adjunct to the local staging of a number of malignancies, including rectal cancer, head and neck cancer, prostate cancer, sarcomas, and CNS malignancies.

FDG-PET scanning

FDG-PET scanning has an evolving role to play in the initial staging of a variety of cancers and also in the assessment of residual/recurrent disease. It has proven to be of particular use in the assessment of NSCLC patients who are otherwise suitable for radical treatment. Prior to the use of FDG-PET in NSCLC staging, up to 50% of operations in apparently early stage disease were proven futile by the presence of disease that was more advanced than had been indicated by other, more conventional staging methods. PET scanning has been demonstrated to reduce the number of futile thoracotomies and this has been proven to be cost effective in CT-node-negative disease. FDG-PET has also been shown to improve diagnostic accuracy and alter patient management in other clinical situations, for example in the staging of colorectal cancer prior to planning metastasectomy, and in the detection of occult primaries in suspected head and neck cancers. There is also some evidence that FDG-PET alters planned radiotherapy treatment volumes in lung, head, and neck cancer, and a trial is underway in early Hodgkin's lymphoma to assess whether a negative FDG-PET after induction chemotherapy can obviate the need for radiotherapy altogether in some cases. The newer technology of FDG-PET/CT is thought to be more accurate than FDG-PET alone by 10%–15% and, as the availability of equipment and expertise improves, it is certain to be put to widespread use.

Pathology

In the majority of cases, a confirmed pathological diagnosis of malignancy is sought before definitive treatment for cancer is undertaken. This is for two main reasons: the first is that benign conditions may mimic malignancy, such that cancer treatment would be entirely inappropriate; the second is that different histological types of malignancy may appear similar clinically and radiologically and yet require very different oncological management, for example lung cancer and lymphoma. As well as confirming the diagnosis, pathological techniques also provide additional prognostic information that can guide management and affect predicted prognosis. The pathologist is, therefore, a vital member of the multidisciplinary team.

Cytology

Cytology is the microscopic examination of stained individual cells and small clusters of cells for diagnosis. The material may be obtained in a number of ways, including via fine-needle aspiration of masses (e.g. of a breast or neck lump), through brushings or scrapes (e.g. bronchial or cervical), and by concentration of fluid samples taken from body cavities (e.g. pleural effusion or ascites) or elsewhere (e.g. sputum or urine). If high-quality cytological samples are available, these are usually sufficient to allow a diagnosis of malignancy and often the major histological type. If the sample is large enough, cells

may also be 'spun down' into a pellet that may be embedded in paraffin to allow examination of cells with techniques such as immunohistochemistry. The main advantages of cytology are that it tends to be simpler and less invasive (and therefore suitable for screening) and that it can give a quick result if a cytologist is immediately available. The main disadvantage is that tissue architecture cannot be assessed and so it can be difficult to distinguish between in situ and invasive disease.

Histopathology

Histopathology is the microscopic examination of tissue, rather than individual cells, for diagnosis. The size of tissue examined may vary from small-core needle biopsies through to large, surgically excised specimens. The technique used to obtain the sample and the answers sought from it vary from a simple confirmation of invasive malignancy through to thorough pathological staging of an entire tumour.

Immunohistochemistry

Immunohistochemistry is the process of identifying and localizing proteins on or within cells by using a specific antibody directed at a protein of interest (the antigen) within a sample. In cancer pathology, it has two main uses. The first is the further molecular differentiation of cells, which may look very similar by conventional light microscopy, in order to better confirm the cell type or to give an indication as to the tissue of origin. A good example of this is the relatively common circumstance of a metastatic adenocarcinoma of unknown primary. Using a panel of immunohistochemical markers (including TTF-1, CDX2, CK7, CK20, CEA, ER, etc.) it is possible to estimate the origin of the primary cancer with reasonable positive predictive value. The second use is to assess whether a particular therapeutic intervention is warranted based on the molecular characteristics of the tumour cells. The best example of this is breast cancer, where assessment of the oestrogen and progesterone receptor status and HER2 expression of a tumour is used to determine whether endocrine therapy or trastuzumab is indicated.

Molecular and genetic techniques

Newer molecular and genetic techniques are increasingly being used to aid diagnosis of pathologically complicated tumours and to provide further prognostic and staging information. An example of the diagnostic use of these techniques is in soft tissue sarcomas, which display specific non-random chromosomal changes that now serve as definitive diagnostic criteria (e.g. t(X:18), forming the SYT-SSX transcription factor, diagnostic of synovial sarcoma). An example of how genetic techniques can affect staging is the detection of N-myc amplification in the paediatric cancer neuroblastoma; the detection of this marker influences the prognosis and has therefore been included in the staging criteria. Such techniques are likely to become increasingly commonplace in modern cancer management.

Surgical staging

Often primary surgery for a malignancy acts as both an initial treatment and a staging procedure. The most common examples of this are axillary node sampling for breast cancer and wide lymphadenectomy during colectomy for colon cancer, both of which provide vital staging information regarding the presence or absence of lymph node metastases and so can indicate whether adjuvant chemotherapy is

needed. For suspected ovarian cancer, surgery often represents a diagnostic as well as therapeutic and staging procedure, as histology is often not known preoperatively.

On some occasions, specific surgical procedures are performed to confirm a diagnosis or to stage a malignancy rather than as a therapeutic procedure. Examples of this include neurosurgical biopsy or debulking of a brain tumour to confirm histological diagnosis, and mediastinoscopy to sample lymph nodes prior to definitive treatment for NSCLC.

Clinical and endoscopic staging

For some malignancies, the staging information is derived largely by clinical examination. An example of this is cervical cancer, where clinical examination under anaesthesia (EUA) to assess tumour size and vaginal, parametrial, and uterosacral involvement forms the basis of the FIGO staging system. EUA is often accompanied by proctoscopy and cytoscopy to provide further information.

Other endoscopic examinations are also used to provide diagnosis and staging of malignancies. For example, colonoscopy for colorectal cancer, to provide a histological diagnosis and exclude other synchronous tumours, and bronchoscopy, to confirm a lung cancer, may also provide some information to stage the primary tumour.

Blood tests

While it is not usually the case that a blood test alone can diagnose cancer, serum markers can prove useful in several ways when used in combination with other diagnostic information. They can provide strong evidence as to the origin of metastatic malignancy of unknown primary. For example, sclerotic bone metastases, in combination with a markedly elevated level of prostate-specific antigen, are virtually diagnostic of prostate cancer. Other tumour markers can also provide diagnostic clues and are used in combination with other factors to define the risk of malignancy and so direct further management. For example, for women with adnexal masses, CA125 is used in combination with menopausal status and ultrasound morphology to derive a 'risk of malignancy index' which, while not diagnostic, can triage women between further local investigation and referral to a gynaecological oncologist.

As well as aiding diagnosis, blood tests can also provide prognostic information. For certain malignancies, this is used as part of the staging system. For example, the International Germ Cell Consensus Group Classification uses, amongst other factors, alpha-fetoprotein, human chorionic gonadotrophin, and lactic dehydrogenase to divide metastatic germ cell tumours into good, intermediate, and poor prognostic groups.

325 Treatment of cancer

David Cutter and Martin Scott-Brown

Introduction

The variety of conditions that are considered to be 'cancer' is extremely wide, with marked variation in the management approach from disease to disease. A common feature in the management of malignant conditions, however, is the involvement of a wide range of medical professionals at different stages of the patient pathway. This commonly includes physicians, surgeons, radiologists, pathologists, medical oncologists, radiation oncologists, and specialist nurses, as well as a plethora of other allied disciplines. As such, a practice that has been widely adopted is to work as a multidisciplinary team (MDT), with regular meetings to decide the appropriate treatment for each patient with a cancer diagnosis, on an individual and case-by-case basis.

The main treatment modalities for the treatment of cancer are surgery, radiotherapy, and chemotherapy. While these are often combined to form a multimodality therapy, they are all, in isolation, potentially radical (curative) therapies for certain conditions. For example, surgery (in the case of a Stage I colon adenocarcinoma), radiotherapy (in the case of early laryngeal squamous cell carcinoma), and chemotherapy (in the case of acute lymphoblastic leukaemia) are all curative as single-modality treatments. It is commonly the case, however, for a patient to require more than one mode of therapy to achieve the best outcome, for example a combination of surgery, chemotherapy, and radiotherapy for early breast cancer. It can also be the case that two or more different management strategies are thought to give equivalent oncological results, for example surgery or radiotherapy for early prostate cancer. In this situation, the MDT and the patient need to decide on the 'best' management plan for the individual, based on their personal and professional opinions and on the differing toxicity profiles of the alternate treatments.

Surgery

Curative surgery

Surgery is the longest established therapy for cancer and remains the mainstay of radical treatment for most solid tumours. The aim of curative surgery is the complete macroscopic and, as much as possible, microscopic excision of all malignant tissue. The accepted definition of adequate surgical margins varies significantly between cancer types, and also depends on other factors such as tumour size and histological grade/type. The extent of the resection must be balanced against the likely impairment of function and the risks of surgical complications. A detailed knowledge of the natural history of the cancer types and stages and of the possible alternative therapies is therefore essential in formulating a surgical management plan. Often, multimodality therapy may offer the possibility of less extensive or morbid surgery.

Curative surgery is best performed by specialist oncological surgeons who perform a certain number of site-specialized cancer operations each year. The advantage of specific surgical methods and exacting technique has been proven. For example, in rectal cancer the gold-standard operation of 'total mesorectal excision' has been demonstrated to have reduced local recurrence rates when compared with prior surgical techniques. Oncologically adequate primary surgery is a vital part of achieving local cancer control and long-term survival.

Many cancer types metastasize via the lymphatic system. The en bloc resection of regional lymph nodes forms part of the primary treatment for some cancer types. In addition, lymph node dissection provides important staging information and is useful for guiding further therapy. There is, however, considerable controversy over

the extent of regional surgery that is appropriate for different cancer sites and types, either where alternative therapy exists (e.g. lymphatic radiotherapy for breast cancer) or where there is uncertainty over the therapeutic benefit (e.g. melanoma).

Cytoreductive surgery

In certain cancers, although all gross disease may not be technically resectable, there is therapeutic value in removing as much disease as possible prior to receiving further therapy. A good example of this is ovarian cancer, where 'maximal cytoreduction', such that there is <2 cm³ of residual disease remaining after surgery, has been demonstrated to improve median survival when performed in combination with chemotherapy.

Surgery for metastatic disease

Solid metastatic cancers are not always incurable and, in certain circumstances, surgery may be used with curative intent for the treatment of limited, and technically resectable, metastatic disease. The most common example of this is the resection of liver metastases from colorectal cancer. For the highly selected minority who are suitable for this treatment, 5-year overall survival rates in contemporary series now exceed 50%. Unfortunately, the majority are not suitable, due to extra-hepatic disease or the extent or location of their liver disease. Surgical resection of isolated or limited lung and brain metastases may also be appropriate on a case-by-case basis. More favourable prognostic factors for these patients include a long disease-free interval, single or few metastases, and smaller bulk of disease.

Palliative surgery

While surgery is less commonly used as a palliative therapy for cancer, there are specific circumstances when it is invaluable for symptom control. Examples include:

- relief of bowel obstruction (or resection for bleeding/perforation)
- palliative loco-regional resection (e.g. to prevent unpleasant local symptoms from a fungating tumour)
- fixation of pathological fractures
- surgical relief of malignant spinal cord compression (demonstrated to be superior to radiotherapy alone in specific circumstances)

The surgeon must know the patient's prognosis and alternative therapeutic options in order to balance the potential benefits, in terms of symptom control and quality of life, against the potential disadvantages and complications of an invasive procedure. It is essential that there is collaboration between surgeons, oncologists, palliative care specialists, and (in some instances) interventional radiologists in these circumstances to decide the best course of management.

Prophylactic surgery

There are some genetic conditions that lead to an extremely high lifetime risk of developing certain types of cancer, for example BRCA mutations leading to breast cancer and familial adenomatous polyposis leading to colon cancer. Prophylactic surgery is a treatment option in these cases, following careful education and counselling about the potential advantages and disadvantages of this approach.

Radiotherapy

Radical and adjuvant radiotherapy

Radiotherapy is the main alternative to surgery as a radical therapy for malignant conditions, either as a single modality or when combined

with concurrent chemotherapy. It has replaced, or is an alternative to, surgery for the radical treatment of a variety of cancers, including head and neck cancers, cervical cancer, anal cancer, non-melanomatous skin cancers, bladder cancer, and prostate cancer. Radiotherapy is an effective therapy for lymphoma and germ cell tumours and has been used extensively for these conditions.

Radiotherapy is also used as an adjuvant therapy to eradicate any residual microscopic disease and improve local disease control rates and in some cases, therefore, survival. This is used most commonly for breast cancer, but also for sarcomas, endometrial cancer, and head and neck cancers. Occasionally, radiotherapy is administered neo-adjuvantly (i.e. prior to surgery) to 'down stage' tumours, improve operability, and increase local disease control. The most common example of this is neo-adjuvant chemoradiotherapy for locally advanced rectal cancer.

The commonest form of radiotherapy is external beam radiotherapy, most frequently administered as photons from a linear accelerator. Due to the radiobiology of late toxicity of the normal tissues that are unavoidably irradiated during a radical course of treatment, external beam radiotherapy is usually fractionated (i.e. given in a smaller dose daily over 4–7 weeks) rather than administered as a single treatment. Occasionally, though, external beam radiotherapy is administered as a single large fraction (stereotactic radiosurgery) or in a very few fractions (stereotactic radiotherapy). The radiation dose for a radical treatment is usually in the range of 50–70 Gy, although smaller doses of 40 Gy or less are required for seminomas and lymphomas.

Other commonly used forms of radiotherapy include brachytherapy, which is the placement of radioactive sources at the site for treatment (e.g. intra-prostatic implantation of iodine-125 seeds for localized prostate cancer) and radioisotope therapy (e.g. the use of orally administered iodine-131 for the treatment of differentiated thyroid cancer).

Palliative radiotherapy

Radiotherapy is an effective palliative treatment for symptom control in advanced malignancy. Common uses include:

- relief of pain (especially bone pain, but also from other sites)
- control of bleeding (e.g. haematuria, haemoptysis, PR or PV bleeding)
- treatment for obstruction of hollow organs (e.g. bronchus, oesophagus, or rectum)
- treatment for malignant spinal cord compression
- treatment for superior vena cava obstruction
- treatment for brain and/or leptomeningeal metastases
- treatment of other symptomatic sites (e.g. fungating tumours, skin metastases, nodal disease)

Due to the differing aims of palliative radiotherapy, for convenience, such treatments are often administered as fewer and individually larger fractions, to a lower total dose. For example, a single 8 Gy fraction is commonly used for bone pain, and 20–36 Gy in 5–12 treatments in other circumstances. Occasionally, higher radiotherapy doses are appropriate to attempt to maintain local disease control for as long as possible and hopefully prevent unpleasant symptoms from developing if the prognosis and clinical situation suggest this may be a potential problem. Radioisotopes are also used as a palliative treatment (e.g. strontium for widespread bone pain).

Cytotoxic chemotherapy and endocrine therapy

Radical and adjuvant chemotherapy

In terms of radical therapy, cytotoxic chemotherapy is the third most important modality of treatment and is only curative in isolation for haematological malignancies and germ cell tumours which are exquisitely chemosensitive.

In terms of numbers, cytotoxic chemotherapy plays a much more significant role as an adjuvant therapy for solid tumours to reduce the risk of recurrent disease following primary therapy (usually surgery). The best examples of this are adjuvant chemotherapy for breast cancer and colon cancer.

Endocrine therapy in the form of tamoxifen and, more recently, aromatase inhibitors also plays an important role in the adjuvant therapy of hormone-responsive breast cancers, reducing recurrence rates and improving overall survival.

Palliative chemotherapy

Cytotoxic chemotherapy, as a systemic treatment, has the theoretical advantage of being able to treat all sites of metastatic disease simultaneously and has an established role in the management of advanced malignancy. Chemotherapy has contributed significantly towards improved survival for some disease types; for example, the median survival of patients with metastatic colorectal cancer has improved from 5–6 months, without treatment, to 20–24 months with modern chemotherapy. For other sites, however, the benefits are less marked; for example, palliative chemotherapy for advanced pancreatic cancer improves median survival from 2–3 months to 5–6 months, albeit with some associated benefits in terms of quality of life.

Endocrine therapies are also commonly used as palliative treatments for hormone-responsive advanced breast cancer and prostate cancer, producing significant clinical benefits without the toxicity often associated with cytotoxic chemotherapy.

Newer therapies

Surgical advances and other local therapies

Conventional surgical techniques are constantly evolving with the development of new technology, for example minimally invasive surgery, with the aim of reducing surgical morbidity while maintaining or improving oncological outcomes. A number of other local cancer therapies are also in use and under investigation. These include cryotherapy, most commonly used for locally recurrent prostate cancer, and radiofrequency ablation.

Advances in radiotherapy

While the basic principle behind radiotherapy remains the same today as always, technological advances in the delivery of radiotherapy are allowing improvements in the therapeutic ratio for various malignancies. Intensity-modulated radiotherapy, for example, allows the delivery of more complicated distributions of radiation dose (including concave volumes) to the intended target, while avoiding high doses to adjacent organs and thereby reducing toxicity. This ability has been utilized in prostate cancer to reduce rectal and urinary toxicity and in head and neck cancer to reduce xerostomia from salivary gland irradiation, while maintaining efficacy. A variety of techniques using both conventional linear accelerators and alternative equipment (e.g. tomotherapy and Cyberknife systems) have been developed. Progress in the imaging techniques associated with radiotherapy will also allow improved accuracy of target definition and compensation for organ movement (e.g. with respiration) to maximize the radiotherapy dose to the tumour while minimizing the exposure of normal tissues.

The vast majority of external beam radiotherapy is currently administered with photon beams (X-rays). There is a developing interest in replacing photons with protons and perhaps even heavier charged particles to take advantage of specific physical characteristics of their depth dose curves, allowing the delivery of a high dose of radiation to a tightly defined volume while sparing adjacent structures. In addition to having these dosimetric advantages, certain charged particle beams, such as carbon ions, also possess some biologic advantages in terms of tumour kill potential. The equipment, expertise, and quality control required to perform these therapies is extremely expensive and, at present, particle therapy is mainly utilized for research purposes and some very specific indications, for example paediatric tumours and skull base chordomas and is unlikely to enter mainstream practice, at least in the UK, for the foreseeable future.

Targeting of radioisotopes allows radiotherapy to be administered systemically. The natural avidity of thyroid tissue for iodine has allowed the use of ¹³¹I as a 'targeted' therapy for over 50 years. With advances in modern cellular biology, it is now possible to design conjugates that direct radioisotopes to particular cellular targets. An example of such a targeted radiopharmaceutical that

has proven effective is ⁹⁰Y-ibritumomab tiuxetan for non-Hodgkin's lymphoma, and further agents are in preclinical development and early clinical trials.

'Targeted' drug therapies

Over the last decade or so, new generations of non-conventional anticancer drug therapies have emerged from development into clinical practice and are now an increasingly important part of modern cancer treatment. They are often developed with the intent of 'targeting' a specific cellular mechanism or pathway that is known to be important in the mechanisms of cancer. The two main types are the monoclonal antibody therapies and 'small molecule' therapies.

The most widely used monoclonal antibody therapies are trastuzumab and rituximab. Trastuzumab is a humanized monoclonal antibody that interferes with the HER2/neu receptor. This receptor is overexpressed in a proportion of breast cancers, and overactivity of the related cellular pathways (the PI3K/Akt and MAPK pathways) is implicated in many aspects of cancer progression, for example uncontrolled cell division, invasion, and angiogenesis. Adjuvant trastuzumab given for HER2-positive early breast cancer (20%–30% of cases) has been shown to improve both disease-free and overall survival in large randomized trials. Trastuzumab is also used as a palliative treatment for HER2-positive metastatic breast cancer, both as monotherapy and in combination with conventional chemotherapy, where it has been proven to improve response rates, compared to chemotherapy given alone. Rituximab is a chimeric monoclonal antibody that binds to the CD20 protein, which is widely expressed on B-lymphocytes. The exact mode of action is unknown but one mechanism involves the induction of apoptosis in CD20-positive cells, and rituximab is widely used in the treatment of B-cell non-Hodgkin's lymphoma, having been shown to improve results over conventional cytotoxic chemotherapy alone in various forms of the disease. Other examples of monoclonal antibodies used for cancer therapy are cetuximab, which targets the epidermal growth factor receptor; bevacizumab, which targets vascular endothelial growth factor A; and alemtuzumab, which targets CD52.

The majority of the currently used 'targeted small molecule' therapies are directed at a large group of tyrosine kinase (TK) enzymes. The first example used in clinical practice, imatinib, has proven extremely successful in the treatment of chronic myeloid leukaemia (where the target is the TK domain of the pathogenic bcr–abl fusion protein) and gastrointestinal stromal tumours (where the target is the TK c-kit). Other examples of TK inhibitors include the 'multitarget' inhibitors sorafenib and sunitinib, which have shown efficacy in metastatic renal cell carcinoma and hepatocellular carcinoma, diseases where effective therapies were previously lacking.

Research into new systemic therapies is ongoing, with new agents (e.g. mTOR and proteasome inhibitors) under active investigation. As we gain a greater understanding of the underlying cellular basis of cancer, further targets and associated therapies will undoubtedly be developed and added to the therapeutic options available for a variety of cancers.

326 Prostate cancer

Daniel Ajzensztejn

Definition of the disease

Prostate cancer is the commonest male malignancy, with approximately 35 000 new cases in the UK annually, equating to a lifetime risk of 1 in 10. When diagnosed early, it has a high chance of cure with surgery, external beam radiotherapy, or brachytherapy. Even for metastatic disease, the prognosis is usually several years.

Aetiology of the disease

The mechanism of transformation from normal prostate cells to cancer is poorly understood but appears to have a hormonal basis, with androgen stimulation playing an important role in the pathogenesis. While in most cases there is no clear aetiology, in up to 5% of cases there is a recognizable pattern of inheritance, some of which is attributable to mutations of the BRCA1 tumour suppressor gene.

Approximately 75% of prostate cancers arise in the peripheral zone of the gland, with the remainder arising in the central and transitional zones. Many prostate cancers are multifocal, arising synchronously within different parts of the prostate.

Histologically, over 95% of prostate cancers are adenocarcinomas, derived from prostatic acinar cells.

Typical symptoms of the disease, and less common symptoms

The disease generally presents in one of three ways:

- asymptotically
- with local symptoms
- with symptoms of metastatic disease

Asymptomatic prostate cancer

Prostate cancer is often diagnosed in asymptomatic individuals on the basis of an elevated level of serum prostate-specific antigen (PSA) or an abnormal-feeling prostate on digital rectal examination (DRE). Alternatively, it may be discovered as the result of an unexpected histological finding following trans-urethral resection of the prostate (TURP) for benign prostatic hypertrophy (BPH).

Prostate cancer with local symptoms

Prostate cancer can cause local symptoms which often initially mimic those of BPH: urinary frequency, poor stream, urgency, hesitancy, incomplete emptying, and nocturia. Rarer but recognized symptoms include incontinence, impotence, haematuria, and haematospermia, all of which are suggestive of more locally advanced disease.

Prostate cancer with symptoms of metastatic disease

Only 5% of patients have metastatic disease at presentation. The disease spreads mainly by the haematogenous route. It has a predilection for bones, particularly the axial skeleton. Bone metastases are usually osteoblastic, although up to 20% are osteoclastic. Sites of bony involvement include, in decreasing order of frequency, the lumbar spine, the proximal femur, the pelvis, the thoracic spine, the ribs, the sternum, and the skull base (which typically presents with cranial nerve palsies). Compared to the case with other malignancies, the spread of prostate cancer to the liver and the lungs is a relatively rare and late event.

Demographics of the disease

Like the prostate gland from which it arises, prostate cancer is exclusively a male disease. The risk of developing the disease increases with age. The disease is rare in those below the age of 40, and only 15% of patients are diagnosed below the age of 65. Post-mortem studies in men dying from other causes show that, by the age of 80, 70% of men will have at least microscopic evidence of prostate cancer.

Natural history, and complications of the disease

Without treatment, the natural history of the disease is variable. Prostate cancer often behaves very indolently. Given that many patients who develop the disease are elderly, it is not difficult to see why more prostate cancer patients die of other causes than from their cancer. In some patients, however, the disease can behave in a more aggressive manner. Staging investigations which can help predict the behaviour of a given cancer are discussed in 'Prognosis and how to estimate it'.

Approach to diagnosing the disease

DRE

The anatomy of the prostate allows the peripheral zone, where the majority of prostate cancers arise, to be palpated on rectal examination. A DRE may reveal a hard, irregular gland, firm nodules, or induration and can detect approximately 55% of prostate cancers.

Serum PSA

PSA, which is expressed by both normal and malignant prostate cells, has become increasingly important in the screening and diagnosing of prostate cancers since the late 1980s. PSA can also be elevated in benign conditions, including BPH, prostatitis, and urinary retention, or following prostate biopsy (see also Table 326.1 and 'Serum PSA testing').

Referral guidelines

The National Institute for Health and Care Excellence (NICE) advise urgent referral for any of the following:

- hard, irregular prostate on DRE
- normal-feeling prostate but rising/raised age-specific PSA, with or without lower urinary tract symptoms
- symptoms and high PSA levels

Other diagnoses that should be considered

BPH is a common cause of urinary symptoms such as urinary frequency, poor stream, urgency, hesitancy, incomplete emptying, and

Table 326.1 Age-specific cut-off PSA measurements

Age	PSA (ng/ml)
50–59	> 3.0
60–69	> 4.0
70–79	> 5.0

Note: No age-specific reference ranges exist for men over 80.

Reproduced with permission of NHS Cancer Screening Programme © 2009.

nocturia. It is frequently associated with mild PSA elevation, which can instigate investigation to exclude a prostate cancer.

'Gold-standard' diagnostic test

Serum PSA testing

PSA is a highly sensitive test but lacks specificity. Levels above 10 correlate with presence of prostate cancer in up to two-thirds of cases. PSA levels between 4 and 10 prove to be associated with cancer in about one-quarter of cases. While a PSA level less than 4 is reassuring, a percentage of patients with prostate cancer do have PSA results in this range. The specificity of the test can be increased by using an age-specific PSA table (see Table 326.1) or by combining the test with other investigations.

Trans-rectal ultrasound and biopsy

Trans-rectal ultrasound (TRUS) allows visualization of the prostate gland and enables biopsies to be taken. On TRUS, cancers appear hypoechoic. The whole gland should be sampled, with at least 12 biopsies taken. In addition to its diagnostic value, TRUS is also useful for assessing the volume of the prostate and so can assist in treatment choice.

Gleason score

The Gleason score is a histological grade based on the Gleason grade, which allocates tumours a value between 1 and 5, based on the glandular architecture. A Gleason grade of 1 represents a near-normal glandular pattern, while a grade of 5 represents the more aggressive end of the spectrum, with no clear glandular pattern.

The Gleason score is the sum of two Gleason grades: the predominant pattern and the second most common pattern. A typical score would be expressed, for example, as 'Gleason 3 + 3 = 6', 'Gleason 4 + 3 = 7', or 'Gleason 4 + 5 = 9'.

Staging

Prostate cancer can be staged using the TNM system (available online at <http://cancerstaging.org/references-tools/quickreferences/Documents/ProstateSmall.pdf>). Additionally, prostate cancer can be classified according to the following three categories:

- localized prostate cancer which is completely contained within the prostate (T1 or T2), with no metastatic involvement of regional lymph nodes (N0), or distant sites (M0)
- locally advanced prostate cancer which extends through the prostatic capsule, with extra-capsular extension or invasion of one or both seminal vesicles (T3), invasion of adjacent structures other than seminal vesicles (T4), or involvement of regional lymph nodes (N1), but no distant metastases (M0)
- metastatic prostate cancer which has spread beyond regional lymph nodes, with involvement either of non-regional lymph nodes (M1a), bone (M1b), or other sites with or without associated bone disease (M1c)

Risk stratification

Based on the PSA level, Gleason score, and T stage, patients can be stratified into three categories according to their risk of disease recurrence after definitive local treatment. This risk stratification is also helpful in guiding both imaging investigations and in formulating recommendations for treatment. The three categories are shown in Table 326.2.

	PSA level (ng/ml)		Gleason score		T staging
Low risk	<10	and	≤6	and	T1–T2a
Intermediate risk	10–20	or	7	or	T2b
High risk	>20	or	8–10	or	T2c, T3, or T4

Adapted from NICE Guidance 2008.

Multiparametric MRI pelvis

When radical treatment is being considered, it is important to know if the tumour is confined within the prostate (T2 disease) or shows evidence of having breached the prostatic capsule (T3 disease). This is most accurately assessed on multiparametric MRI. It is also helpful in identifying seminal vesicle invasion and enlarged local lymph nodes.

Acceptable diagnostic alternatives to the gold standard

Prostate cancer is not uncommonly an incidental finding found at a review of histology performed after a TURP procedure for presumed BPH. For this reason, histological examination should be performed on all tissue removed at TURP.

When an MRI scan of the prostate is not possible or contraindicated, local disease can be staged on CT or ultrasound, although both are regarded as inferior to MRI.

Other relevant investigations

Nuclear medicine bone scan

A nuclear medicine bone scan is used to determine the presence and location of skeletal metastases. A bone scan should be performed in all patients with intermediate or high-risk disease (see Table 326.2). In the absence of bone pain, a bone scan is not routinely indicated in patients with low-risk disease.

Axial MRI

An axial MRI can be used to exclude skeletal metastasis, as an alternative to a nuclear medicine bone scan or to further investigate indeterminate lesions seen on a bone scan. It is able to detect small axial bone metastases not visible on a bone scan.

Prognosis and how to estimate it

The prognosis of a man diagnosed with prostate cancer varies according to his stage, Gleason grade, and PSA level, as shown in Table 326.2 (also see 'Risk stratification'). Age and comorbidities are, of course, independent factors, which will affect the patient's chance of being alive 5–10 years after being diagnosed.

In a man with low-risk disease, there is a very good chance of the disease being cured with any of the radical treatments discussed in 'Treatment and its effectiveness'. For men with high-risk disease, while long-term cure is still possible, there is a higher likelihood that the cancer will either progress or spread. Partin tables, which take account of the variables in Table 326.2, along with more detailed online nomograms can be used to estimate individual patient outcomes.

Treatment and its effectiveness

Prevention

There is currently no treatment licensed for the prevention of prostate cancer. The recent Phase 3 Prostate Cancer Prevention Trial randomized 18 882 men over 55 with normal DRE and a PSA level under 3 ng/ml to receive either 7 years of finasteride or placebo. Finasteride is an anti-androgen which inhibits the enzyme 5-alpha reductase, thereby blocking the metabolism of testosterone to the more potent androgen, dihydrotestosterone. Despite the not-insignificant toxicity profile that includes impotence, loss of libido, and ejaculatory difficulties, the trial did demonstrate an impressive 24.8% reduction in the prevalence of prostate cancer in the finasteride arm of the study. Of note, however, is that, of those men who did go on to develop cancer, there was a higher proportion of high-grade cancers in the finasteride arm.

Screening

The existence of minimally invasive and cheap initial screening in the form of DRE and PSA testing makes screening for prostate cancer an attractive possibility. Numerous studies have shown that, for

patients with a PSA level more than 4 ng/ml, there is a 1:3 chance of detecting prostate cancer at biopsy. Using this cut-off in screening would pick up nearly 70% of prostate cancers. While strong evidence exists that prostate cancer screening is effective in diagnosing more cancers, controversy remains over what impact, if any, detecting more prostate cancers would have on the more important endpoint of improving overall survival. Two large screening trials set up to address this question have recently reported conflicting outcomes. For the present, therefore, there are no plans to introduce a national PSA screening programme in this country, and men should be encouraged to discuss the pros and cons of individual screening with their family doctors.

Treatment of early stage prostate cancer

Early stage prostate cancer, where the disease is confined to the prostate gland, is potentially curable. Radical prostatectomy, radical radiotherapy, and brachytherapy, along with active surveillance, all have a role in the curative treatment of prostate cancer (Table 326.3). There are no randomized trials comparing these treatments head to head; in the absence of these, side effect profiles play an important role in clinician recommendations and patient choice.

Watchful waiting

While so-called watchful waiting should not be regarded as a curative treatment, it is appropriate for some patients. Watchful waiting is the conscious decision not to treat until patients develop symptoms, at which point they are usually treated with hormone therapy. It is particularly suitable for patients with a short life expectancy, such as the elderly or those with significant comorbidities, as these patients are unlikely to die from prostate cancer.

Active surveillance

Active surveillance is a programme of serial DRE, PSA testing, and TRUS-guided biopsies which allow the disease to be reassessed at regular intervals, with a view to deciding if and when treatment becomes necessary. It should be considered in patients who have low-grade tumours and are fit enough to undergo a radical treatment in the event of disease progression. This approach can delay and, in some cases, avoid altogether the risks and side effects of a radical treatment.

Radical prostatectomy

Radical prostatectomy involves the complete resection of the prostate along with the seminal vesicles. Various surgical techniques for this exist, including open retropubic or perineal approaches and laparoscopic or robotically assisted techniques. Surgery is usually reserved for medically fit men who are under 65–70 years old and have T1 or T2 node-negative disease, a low-to-moderate Gleason score, and a PSA level <10, but it can also be used in men with higher-risk disease. In appropriately selected patients, mortality is less than 1%, but major morbidity may be as high as 10%. Approximately 10%–40% of patients will have a degree of urinary incontinence, and up to 60% will have impotence following surgery.

Radical radiotherapy (external beam radiotherapy)

Current NICE guidelines recommend that patients undergoing radical radiotherapy for prostate cancer receive a minimum dose of 74 Gy in no more than 2 Gy per fraction. Patients undergo a 15-minute treatment daily for up to 7.5 weeks. Recent trial evidence suggests shorter regimes with a higher dose per fraction are equally efficacious, and many UK hospitals are now adopting treatment with 60 Gy in 20 fractions over 4 weeks as the current standard of care. There is ongoing research aimed at reducing the number of treatments even further using stereotactic body radiotherapy. Side effects of radiotherapy can be divided into acute side effects (predominantly urinary symptoms, rectal discomfort, bowel symptoms, and fatigue), which generally settle within a few weeks of finishing the treatment, and long-term side effects, which are frequently permanent. Impotence occurs less frequently than following surgery but still affects up to 30%–60% of patients. Other long-term side effects include proctitis (which occurs in approximately 5% of patients), incontinence (which occurs in less than 5% of patients), and long-term changes in bowel habit. Unlike surgery, mortality is not increased by radiotherapy, so there is no age cut-off; however, there is a 2%–3% risk of severe toxicity. In patients with intermittent or high-risk disease, hormonal therapy is usually given in combination with radiotherapy. Pelvic radiotherapy can be considered for patients with a high risk of pelvic lymph node involvement.

Brachytherapy

Brachytherapy is a form of radiotherapy in which the radiation is delivered directly to the prostate using radioactive sources. Two different techniques are used: permanent implantation of radioactive seeds (low-dose-rate brachytherapy) or temporary implantation of radioactive wires (high-dose-rate brachytherapy). Brachytherapy is particularly suitable for men with low-risk disease and relatively small prostate glands and is usually not advised in men with significant obstructive lower urinary tract symptoms or those who have previously undergone TURP. Brachytherapy has a relatively favourable side effect profile, causing lower rates of impotence and incontinence than surgery or external beam radiotherapy but higher rates of obstructive and irritative urinary symptoms. In men with intermediate or high-risk disease, combined treatment with high-dose-rate brachytherapy and external beam radiotherapy can be considered.

Cryotherapy and high-intensity focused ultrasound

Cryotherapy and high-intensity focused ultrasound are new techniques that aim to eradicate prostate cancer by freezing or heating the gland, respectively. They are not currently recommended outside the context of clinical trials, as there is an inadequate amount of long-term outcome data.

Treatment of advanced prostate cancer

Advanced or metastatic disease is, by definition, incurable, and the aim of treatment is therefore to prolong survival and relieve symptoms. Even in this setting, the disease may follow a relatively indolent

Table 326.3 Summary of treatment management options for men with localized prostate cancer

course in some patients. In this section, some of the more commonly used treatments for advanced prostate cancer will be discussed. Each has slightly different indications; therefore, not all drugs will be suitable for every patient. The sequencing of the drugs is individualized based on patient and disease characteristics.

Hormone therapy

Prostate cancer growth is dependent on the presence of testosterone. Therefore, androgen deprivation therapy (ADT) is one approach that can be used for the treatment of men with metastatic prostate cancer.

First-line ADT can be achieved surgically, through bilateral orchiectomy, or medically, by use of subcutaneously administered luteinizing hormone-releasing hormone agonists (LHRHa). These drugs stimulate the production of testosterone in a non-pulsatile (non-physiological) manner, resulting in a disruption of the endogenous hormonal feedback systems and the subsequent downregulation of testosterone production. Anti-androgen tablets should always be started 2 weeks before commencing LHRHa therapy and continued for a further 2 weeks after starting, to prevent transient 'tumour flare', which is caused by an initial increase in testosterone levels during the early days of treatment. Monitoring response to therapy is usually possible by measuring serum PSA, which often falls to undetectable levels. Recently, a luteinizing hormone-releasing hormone antagonist called degarelix has been introduced; it directly blocks the pituitary axis, thus avoiding the initial stimulation of androgen production and negating the need for initial anti-androgens.

If serial PSA testing indicates that the disease appears to be escaping biochemical control, several additional lines of hormonal therapies exist which interfere with various aspects of testosterone metabolism and actions on the tumour:

- anti-androgen tablets can be added to ADT to achieve so-called complete androgen blockade; these drugs block androgen receptors on the cancer cells
- gonadotrophin-releasing hormone antagonists block the release of luteinizing hormone from the pituitary, thereby suppressing testosterone release from the testes
- abiraterone inhibits formation of testosterone by blocking the enzyme CYP17A1; as cortisol production is also inhibited, the drug is therefore given together with prednisolone
- enzalutamide is an inhibitor of androgen receptor signalling

Other hormone therapies that can be used later in the disease course include oestrogens, progestogens, and corticosteroids.

Chemotherapy

Chemotherapy is approved by NICE for the treatment of hormone-refractory metastatic prostate cancer. Docetaxel is generally considered to be the first-line treatment for medically fit patients with

metastatic disease. Side effects include tiredness, nausea, vomiting, hair loss, and bone marrow suppression (along with the accompanying risk of neutropenic sepsis).

Palliative radiotherapy

Radiotherapy plays an important role in the management of bone metastases. Pain caused by metastases usually responds very well even to a single fraction of radiotherapy. Spinal cord compression not suitable for spinal surgery can be treated with a short course of radiotherapy (1–5 days of treatment). Radiotherapy is also indicated following surgical fixation of pathological fractures or spinal surgery.

Bisphosphonates and denosumab

Bisphosphonates and denosumab may reduce the incidence of skeletal events, although evidence for this is lacking and their use in this context is not recommended by NICE. They have a role in the treatment of osteoporosis, which is a long-term side effect of androgen deprivation, and in the control of pain associated with metastatic bone disease.

Bone-seeking radioisotopes

Administration of bone-seeking radioisotopes can be helpful in a subset of patients, to control widespread symptomatic osteoblastic bone disease when the disease no longer responds to hormonal manipulation. The use of radium-223 in this context is associated with a small increase in life expectancy.

Immunotherapy

Sipuleucel-T is a personalized cell-based cancer vaccine licensed for the treatment of prostate cancer. It works by programming the immune system to seek out cancer cells expressing prostate acid phosphatase, which is a tissue antigen that is expressed by most prostate cancer cells, irrespective of where they are in the patient. It is prepared specifically for each patient and is thus costly, but it has been shown to improve 3-year survival in patients with metastatic, castration-resistant prostate cancer by 10% compared to placebo (31.7% vs 21.7%) and prolongs mean survival by over 4 months. There is ongoing research using immune checkpoint inhibitors in metastatic prostate cancer.

327 Breast cancer

Daniel Ajzensztejn

Definition of the disease

Breast cancer is the commonest female cancer, with a lifetime risk of approximately 1 in 9. There are approximately 40 000 new cases and 11 000 deaths from the disease in England and Wales each year.

Aetiology of the disease

The aetiology of breast cancer is complex, with hormonal, genetic, and modifiable lifestyle factors all involved in developing the disease.

Hormonal risk factors include early menarche, late menopause, usage of hormone replacement therapy, late age at first pregnancy, and nulliparity.

Genetic factors account for up to 10% of breast cancers. Patients with mutations in the BRCA1 tumour suppressor gene have an approximately 50% lifetime risk of developing breast cancer and account for approximately 1% of all breast cancer diagnoses. Carriers also have an increased risk of developing ovarian cancer. BRCA2 tumour suppressor gene mutations account for a further 1% of breast cancers, and carriers have a lifetime risk of approximately 75% of developing breast cancer. Carriers also have an increased risk of prostate cancer, pancreatic cancer, bladder cancer, and non-Hodgkin's lymphoma. Li-Fraumeni syndrome is caused by a germline p53 mutation; carriers of this mutation have a 50% lifetime risk of breast cancer and other malignancies. Several other genetic syndromes have been linked to an increased incidence of breast cancer. There are also families with an increased risk of developing the disease but where the genetic basis of this risk has not yet been fully established.

Modifiable lifestyle factors are also believed to play a role in the development of breast cancer. Obesity results in increased circulating levels of oestrogen, which increases the risk of breast cancer. Healthy diets which are low in alcohol and fats have been suggested to reduce the risk of developing the disease.

Typical symptoms of the disease, and less common symptoms

Breast cancer generally presents in one of three ways:

- asymptotically
- with locoregional symptoms
- as metastatic disease

Asymptomatic breast cancer

The UK, like many countries, has a national mammographic screening programme, so many breast cancers are picked up prior to onset of symptoms. In addition, screening is able to detect ductal carcinoma in situ (DCIS), a pre-malignant condition which, without treatment, progresses to invasive cancer in up to 50% of cases.

Breast cancer with locoregional symptoms

Locoregional symptoms of breast cancer include:

- lumps
- skin/nipple changes
- lymphadenopathy

Lumps

While most breast lumps are not cancerous, concerning features include lumps which are painless, solitary, unilateral, or hard. Half of all breast cancers arise within the upper outer quadrant of the breast.

Skin/nipple changes

Skin redness, dimpling, change in contour, 'peau d'orange', ulceration, nipple inversion, and nipple discharge may all be the first presentations of breast cancer.

Lymphadenopathy

Although relatively uncommon, axillary lymphadenopathy may be the presenting symptom of breast cancer. Usually, an ipsilateral breast tumour will be found on either examination or imaging. See also see the referral guidelines in 'Approach to diagnosing the disease'.

Metastatic breast cancer

The first presentation of breast cancer may be with metastatic spread. Common sites of spread include the bones, the liver, the lungs, and the brain.

Demographics of the disease

The risk of developing breast cancer increases with age. At age 25, the disease affects approximately 1 in 20 000 women. By the age of 45, the risk has risen to just under 1 in 100. By the time a woman reaches age 85, her lifetime risk of having developed the disease is 1 in 9. The disease can develop in men, but this is relatively rare, accounting for less than 1% of all breast cancer diagnoses.

Natural history, and complications of the disease

Breast cancer is an adenocarcinoma which arises from the glandular tissue of the breast. The disease can be further subdivided histologically. Approximately 75% of breast adenocarcinomas are ductal. Lobular carcinomas account for a further 10%, with medullary, tubular, and several less common subtypes accounting for the remainder.

DCIS is a pre-malignant condition which, without treatment, progresses to invasive ductal carcinoma in up to 50% of cases. Lobular carcinoma in situ (LCIS) is not a true pre-malignant condition. Its presence is, however, indicative of unstable breast tissue, and a finding of LCIS triples a person's lifetime risk of developing breast cancer in either breast (usually, ductal adenocarcinoma).

Invasive breast cancer normally spreads to the axillary lymph nodes in a stepwise progression from the first level through to the third-level axillary nodes. Knowledge of this natural history has revolutionized axillary surgery in recent years through the introduction of sentinel node biopsies (see 'Sentinel node biopsy' in 'Treatment and its effectiveness'). The supraclavicular and internal mammary lymph nodes may also be involved.

Metastatic disease is rare in the absence of node involvement. As mentioned in 'Metastatic breast cancer', common sites of spread are the bones, the liver, the lungs, and the brain.

Approach to diagnosing the disease

NICE guidelines advise urgent referral (within 2 weeks) following an abnormal screening mammogram (see 'Screening') or for any patient who is over the age of 30 and presents with any of the following breast signs or symptoms: a discrete lump; ulceration; a skin nodule; skin distortion; nipple eczema; recent nipple retraction or distortion; and unilateral nipple discharge. Other breast symptoms for which referral is advised (although not necessarily urgently) include a discrete lump in women under the age of 30; asymmetrical

nodularity that persists at review after menstruation; an abscess; a persistent refilling or recurrent cyst; intractable pain; and bilateral nipple discharge.

All such patients are seen by a clinician; their history is taken and they then undergo triple assessment, which comprises:

- clinical examination
- imaging (bilateral mammography and ultrasound)
- histology: (assessed on core biopsy)

The assessing clinicians will allocate each a score between 1 and 5, and these scores will be used to recommend further investigation and treatment through multidisciplinary team discussions.

In patients with confirmed breast cancer, blood tests, including a full blood count, liver function tests, and calcium levels, should be performed. Further investigations may include imaging with CT thorax and abdomen along with an isotope bone scan or an MRI of the marrow (the image modality of choice varies according to local protocol). Decisions as to which patients should have such imaging routinely are guided by the risk of finding metastatic disease. In patients with T1 or T2 tumours who have a risk in the order of 2% for having metastatic disease, some clinicians would not routinely perform additional staging investigations. In contrast, patients with T3 or T4 tumours have approximately ten times this risk of metastatic disease, and further staging investigations are routine.

Additional investigations may occasionally be indicated; for example, where full blood count is suggestive of bone marrow involvement, then bone marrow aspiration and trephine should be considered, to exclude metastatic bone marrow infiltration.

The anatomical extent of the cancer is staged using the TNM staging system, which is available online at <http://cancerstaging.org/references-tools/quickreferences/Documents/BreastMedium.pdf>.

Other diagnoses that should be considered

The majority (90%) of referrals to triple assessment clinics turn out to be related to benign breast disorders and these are therefore the main differentials.

Benign breast disorders that may present similarly to breast cancers include fibrocystic disease, fibroadenomas, intra-ductal papilloma, lipoma, fat necrosis (traumatic), and mastitis.

'Gold-standard' diagnostic test

The triple assessment discussed in 'Approach to diagnosing the disease' is considered the gold standard for the investigation and diagnosis of breast cancer.

Acceptable diagnostic alternatives to the gold standard

Most women enter the national mammographic screening programme at the age of 50 (see 'Screening'). For women at high risk of developing breast cancer, there is NICE guidance for the use of annual breast MRI rather than mammographic screening, with the screening commencing at age 30 (or at age 20 in patients with Li-Fraumeni syndrome).

Other relevant investigations

The oestrogen receptor status of breast cancer cells, as assessed histologically, is used to predict the likely response to hormonal therapies such as tamoxifen and aromatase inhibitors. The progesterone receptor status is also assessed in some centres, although its routine use is not recommended by NICE. HER2 testing by immunohistochemistry and/or fluorescence in situ hybridization should also be performed. Overexpression of the HER2 receptor is associated with a worse prognosis, but also opens additional treatment options such as trastuzumab, a monoclonal antibody that targets the receptor.

In the metastatic setting, tumour markers such as CA 15-3 can be measured at baseline and, if found to be elevated, may be used to assess response to treatment, in addition to radiological methods.

Prognosis and how to estimate it

The prognosis of breast cancer is related to its anatomical extent, as well as other factors. Regional lymph node involvement is the most important prognostic factor in early breast cancer. Other poor prognostic factors include large tumour size, high tumour grade, negative receptor status (oestrogen receptor and/or HER2), and young patient age. Patients with favourable prognostic cancers have a predicted 10-year survival of approximately 95%. Those with poor prognosis cancers have a predicted 10-year survival closer to 20%.

In metastatic breast cancer, even with treatment, the median survival is only 2–3 years. However, there is considerable patient-to-patient variation, with approximately 15% of patients living more than 5 years.

Treatment and its effectiveness

Prevention

Most of the work on prevention of breast cancer has concentrated on women at high risk of developing the disease. In this patient population, there is evidence that selective oestrogen receptor modulators (tamoxifen and raloxifene) reduce the incidence of breast cancer. Their use, however, has not been shown to have an impact on cancer mortality. Risk-reductive surgical techniques such as bilateral oophorectomies and prophylactic mastectomies with or without nipple sparing also have a proven role in high-risk patients.

For the wider female population, while there is some evidence from the MORE osteoporosis prevention trial that raloxifene reduces breast cancer incidence, questions remain as to how long women would need to take the drug and at what age they should start. There are also concerns over the long-term safety of taking such medications. Current advice is therefore to reduce the modifiable risk factors discussed in 'Aetiology of the disease'.

Screening

A breast screening programme was introduced in the UK in 1988. Women between the ages of 50 and 70 are invited for mammograms every 3 years. Beyond this age, women can request mammograms every 3 years but are not invited routinely. The aim of mammographic screening programmes is to detect both preinvasive carcinoma in situ (see 'Natural history, and complications of the disease') and early breast cancers. Such programmes are estimated to reduce breast cancer mortality by approximately 20%. It has been recently recognized that screening also results in the diagnosis and treatment of some cancers that would not have caused problems during a woman's lifetime had the screening not been performed. It is estimated that this over-diagnosis will affect approximately 1% of women screened from age 50–70.

Treatment of early stage breast cancer

Early stage breast cancer is defined as disease confined to the breast and the regional lymph nodes at the time of diagnosis, and accounts for approximately 95% of breast cancer diagnoses. Treatment of early stage breast cancer is aimed at removing macroscopic cancer with surgery, treating local microscopic disease spread with radiotherapy, and treating systemic microscopic disease with systemic therapies such as hormones, chemotherapy, and targeted therapies.

Surgery for early stage breast cancer

Surgical options for early stage breast cancer include:

- mastectomy
- breast-conserving surgery
- axillary node clearance
- sentinel node biopsy

Mastectomy

Historically, the surgery of choice for treatment of breast cancer was modified radical mastectomy. This procedure involves removal of the entire breast, including the nipple and areola complex.

Breast-conserving surgery

Clinical outcomes similar to those obtained with mastectomy can be achieved by combining wide local excision of the tumour with

radiotherapy. For the majority of patients, this approach has become standard care.

Axillary node clearance

Axillary node clearance involves the dissection of first-, second-, and third-level axillary nodes. Despite being associated with complications such as axillary pain, numbness, reduced arm movement, and the development of lymphoedema, this surgery was considered the standard of care for axillary surgery until recently.

Sentinel node biopsy

Sentinel node biopsy involves identifying the first node in the regional lymphatic basin to which the tumour drains. The sentinel node is most reliably identified by using two separate localizing techniques in combination. Peritumoural injection of blue dye and of a radioisotope can together locate the sentinel node with 95% sensitivity. Axillary node clearance is subsequently performed only where the sentinel node is found to be involved with the tumour.

Radiotherapy for early stage breast cancer

Following breast-conserving surgery, radiotherapy to the conserved breast approximately halves the risk of the disease recurring and reduces the risk of dying from the disease by about a sixth. There are several widely used radiotherapy schedules. The gold standard against which they are compared remains 50 Gy in 25 fractions, with daily treatment Monday–Friday over a 5-week period. This may be followed by a further boost to the tumour bed. The START trial has demonstrated that similar outcomes can be achieved with shorter or less intense regimens (e.g. 40 Gy in 15 fractions over 3 weeks), and these are also widely used.

Adjuvant systemic therapies for early stage breast cancer

Adjuvant systemic therapies for early stage breast cancer include:

- adjuvant hormone therapy
- adjuvant chemotherapy

Adjuvant hormone therapy for early stage breast cancer

Approximately 70% of breast cancers demonstrate oestrogen receptor positivity. Clinical trials in the 1980s revolutionized breast cancer management by showing that the addition of 5 years of tamoxifen to standard treatment in this group of patients was able to reduce rates of local recurrence by approximately 50%, and mortality by about a third. More recent trials have shown 10 years of tamoxifen to be superior to 5 years and this is now the standard treatment in oestrogen-receptor-positive premenopausal women. In postmenopausal women, particularly those with higher-risk node-positive disease, aromatase inhibitors offer some additional benefit compared to tamoxifen.

Adjuvant chemotherapy for early stage breast cancer

There are many chemotherapy regimens used to treat breast cancer. The most common in the United Kingdom is FEC (for fluorouracil, epirubicin, and cyclophosphamide). In patients with node-positive disease, NICE recommends that docetaxel should also be used as part of their adjuvant therapy. Common side effects of such agents include tiredness, reversible alopecia, nausea, and vomiting. Less common, but serious, side effects include neutropenic sepsis, which requires IV antibiotics for several days until white blood cell counts normalize. Chemotherapy is associated with an approximately 1% mortality, which is largely attributed to neutropenic sepsis. As a result, all patients commencing chemotherapy are given instructions to immediately contact an acute oncology service in the event of elevated temperature, rigours, or other signs of infection.

Adjuvant targeted therapies for early stage breast cancer

Approximately 15% of early breast cancers express high levels of the HER2 receptor. Historically, this phenotype has been associated with a much poorer prognosis. The humanized monoclonal antibody trastuzumab targets this receptor. When the drug is given every 3 weeks for a year to patients with HER2 positive cancers, the risk of relapse is halved, leading to an approximate 30% reduction in mortality. While trastuzumab is generally well tolerated, with few side

effects, there is a small but significant risk of reversible cardiotoxicity, which is usually asymptomatic and responds to cessation of the drug and treatment with an angiotensin-converting enzyme inhibitor. For this reason, all patients are monitored with echocardiograms every 3 months for the duration of their treatment.

Neoadjuvant Therapy

Systemic treatments for breast cancer can also be delivered prior to surgery. This can include chemotherapy alone or in combination with therapies such as trastuzumab and pertuzumab.

Clinical trials for treatment in early stage breast cancer

The UK National Cancer Research Network (NCRN) was set up in 2001 to provide the NHS with an infrastructure to support high-quality cancer clinical studies to improve the speed, quality, and integration of research resulting in improved patient care. Patients may be offered information about suitable clinical trials as part of their treatment.

Treatment of advanced (metastatic) breast cancer

A multimodality approach is just as important in the treatment of metastatic breast cancer as it is for the treatment of early stage breast cancer.

Palliative systemic therapies for advanced breast cancer

Palliative systemic therapies for advanced breast cancer include:

- hormone therapy
- chemotherapy
- bone directed therapy
- HER2 directed therapy

Hormone therapy for advanced ER positive breast cancer

For the majority of patients with oestrogen-receptor-positive metastatic disease, hormone therapy should be used as first-line palliative therapy. Several different hormone treatments are available, and disease that progresses on one may respond to another. The main advantage of hormone therapies is that most are taken in tablet form and have few side effects, compared to chemotherapy. The main disadvantage is time to onset of action, which may be several months. Thus, hormone therapy may be unsuitable for patients with rapidly progressing disease, particularly liver metastases. Several classes of hormone therapy are available, including selective oestrogen receptor modulators (e.g. tamoxifen), non-steroidal aromatase inhibitors (e.g. anastrozole and letrozole), steroidal aromatase inhibitors (e.g. exemestane), and oestrogen receptor antagonists (e.g. fulvestrant). Selective cyclin-dependent kinase 4 and 6 (CDK4/6) inhibitors are a new class of drug showing promising results in this subset of patients. Older treatments such as sex steroid therapies (e.g. diethylstilbestrol), androgens, and progestogens (e.g. megestrol, medoxyprogesterone) and oestrogen-deprivation therapies (oophorectomy, ovarian irradiation, or the use of analogues of gonadotropin-releasing hormone) still have a role in clinical practice.

Chemotherapy for advanced breast cancer

Chemotherapy is useful in patients with oestrogen-receptor-negative disease or in those for whom hormone therapy is not suitable. NICE guidelines recommend that patients requiring chemotherapy and who have not previously been treated with an anthracycline-containing regimen such as FEC should receive it first line. Second-line chemotherapy should be with single-agent docetaxel. Other chemotherapy regimens such as single-agent capecitabine or vinorelbine can be used as third- or fourth-line treatments.

Bone directed therapy for advanced breast cancer

For patients with bone metastases, denosumab and bisphosphonates have dramatically altered the course of their disease. These drugs have a proven role in preventing or delaying skeletal complications such as pathological fractures and spinal cord compression, as well as the need for radiotherapy and surgery. Bisphosphonates are also useful in managing the hypercalcaemia of malignancy.

HER2 directed therapy for advanced HER2 positive breast cancer

Targeted drugs such as trastuzumab, ado-trastuzumab emtansine, lapatinib, and pertuzumab have all been demonstrated to prolong survival in patients with metastatic HER2-positive disease.

Surgery for advanced breast cancer

Surgery plays an important role in the management of metastatic breast cancer in carefully selected patients with oligometastatic disease. Indications include resection of brain or lung metastases, and spinal surgery for cord compression.

Radiotherapy for advanced breast cancer

Radiotherapy has several important roles in the management of metastatic breast cancer. Bone pain from metastatic deposits often responds very well to even single-fraction radiotherapy treatments. Radiotherapy can also be used to reduce the risk of developing a fracture and for the treatment of cord compression or brain metastases not suitable for surgery (or following recovery from surgery). In addition, radiotherapy can be used to control advanced local disease within the breast and axilla. Specialized radiotherapy techniques such as stereotactic radiosurgery can also have a role in the management of oligometastatic disease.

Clinical trials for treatment in advanced breast cancer

Breast cancer is an area of extensive research, and patients with advanced disease may be offered information about newer targeted treatments and/or chemotherapy drugs as part of the NCRN portfolio of clinical trials.

328 Ovarian and testicular cancer

Hannah Chapman and Christine Elwell

Ovarian cancer

Definition of ovarian cancer

Ovarian cancer is the fifth most common cancer in females in the UK. In 2008, there were approximately 4000 deaths from ovarian cancer. Ninety per cent of all ovarian cancers are of epithelial origin. Germ cell and sex cord–stromal cell tumours also occur. Primary peritoneal and fallopian tube carcinomas behave clinically like ovarian carcinomas.

Aetiology of ovarian cancer

Risk factors for ovarian cancer include:

- nulliparity
- early menarche
- late menopause
- family history
- α BRCA1 or BRCA2 mutation
- Lynch II syndrome (hereditary non-polyposis colorectal cancer)

Typical symptoms of ovarian cancer, and less common symptoms

Ovarian cancer is frequently asymptomatic. Ultrasound and a CA-125 test can detect ovarian cancer in asymptomatic women. A randomized controlled trial to assess the impact of screening on mortality is in progress. Advanced disease is associated with abdominal bloating, abdominal pain, anorexia, and weight loss. Dyspnoea can occur due to pleural effusion. Sex cord–stromal tumours can cause paraneoplastic syndromes by secreting sex hormones.

Demographics of ovarian cancer

For ovarian cancer, the average age at diagnosis is 59 years. However, the highest incidence is in women between 80 and 84 years.

Natural history of ovarian cancer, and complications of the disease

The majority of patients with ovarian cancer present with advanced disease. Transcoelomic spread to the peritoneum and pleura is common, leading to ascites and pleural effusion, respectively. Omental or serosal deposits can cause bowel obstruction. Lymph node and haematogenous metastases also occur.

Approach to diagnosing ovarian cancer

The presence of an adnexal mass seen on imaging raises the suspicion of ovarian cancer. Diagnosis can only be confirmed pathologically (e.g. cytology of ascitic fluid, or pathological specimen of the ovaries).

Other diagnoses that should be considered aside from ovarian cancer

Other diagnoses that should be considered aside from ovarian cancer include benign ovarian cysts, which are common, particularly in menstruating women. Other differential diagnoses include:

- bowel cancer
- pelvic inflammatory disease
- hydrosalpinx
- uterine cancer
- uterine fibroids

'Gold-standard' diagnostic test for ovarian cancer

Laparotomy is the gold-standard test for the diagnosis and staging of ovarian cancer.

Acceptable diagnostic alternatives to the gold-standard test for ovarian cancer

A patient with a suggestive clinical history and a CA-125 level >2000 should be regarded as having ovarian cancer until proven otherwise. If a patient is not fit for surgery, ascitic fluid cytology can be diagnostic. Pelvic ultrasound or MRI may be helpful.

Other relevant investigations for ovarian cancer

CA-125 is raised in 90% of women with ovarian cancer. However, it can also be raised due to endometriosis, uterine fibroids, benign ovarian tumours, or other cancers. It is most useful as a surrogate for response to treatment. Measure beta-human chorionic gonadotropin, alpha-fetoprotein, and lactate dehydrogenase if you suspect a germ cell tumour.

Prognosis of ovarian cancer, and how to estimate it

For ovarian cancer, the overall 5-year survival is approximately 40%. Poor prognostic factors include:

- Stage III/IV disease
- clear cell type
- a high-grade tumour
- a residual tumour >3 cm in diameter after surgery

Treatment of ovarian cancer, and its effectiveness

For ovarian cancer, total abdominal hysterectomy, bilateral salpingo-oophorectomy, and omentectomy are the mainstays of treatment. Adjuvant chemotherapy is usually indicated. In advanced disease, primary chemotherapy can be given prior to interval debulking surgery. Chemotherapy or hormone therapy is used to treat metastatic or recurrent disease.

Testicular cancer

Definition of testicular cancer

Testicular cancer is a rare disease: there were 2138 new cases of testicular cancer diagnosed in 2008 in the UK, and only 70 deaths. Ninety-five per cent of testicular cancers are germ cell tumours. Stromal cell tumours and lymphomas make up the remaining 5%. Germ cell tumours can be either seminomas or non-seminomas. Non-seminomas are subtyped according to the WHO classification system.

Aetiology of testicular cancer

In testicular cancer, germ cell tumours arise from a carcinoma in situ. Having an undescended testis increases the risk of testicular cancer by tenfold. The risk is also increased in the contralateral testis. If orchidopexy is performed before 2 years of age, the risk is partially normalized. The incidence of testicular cancer is higher in first-degree relatives of men with testicular cancer. Other risk factors include infertility, Down's syndrome, and Klinefelter syndrome.

Typical symptoms of testicular cancer, and less common symptoms

Patients with testicular cancer typically present with a painless testicular mass. Rarely, an extremely high level of beta-human chorionic gonadotropin causes gynaecomastia and/or hyperthyroidism (because beta-human chorionic gonadotropin has a subunit in common with thyroid-stimulating hormone). Metastatic pulmonary disease may cause dyspnoea and haemoptysis.

Demographics of testicular cancer

Testicular cancer is more common in Caucasian men than in African or Asian men. The peak incidence is at 25–34 years of age. Seminomatous tumours present on average 10 years later than non-seminomatous tumours.

Natural history of testicular cancer, and complications of the disease

Testicular cancer is highly curable, even in the presence of metastases. Local spread commonly involves the rete testis. The pattern of lymphatic spread is predictable, particularly for seminomatous tumours. The lung is the most common site for distant metastases. Late complications of treatment occur, including secondary malignancies.

Approach to diagnosing testicular cancer

A testicular mass needs prompt investigation. Biopsy should be avoided due to the risk of bleeding and tumour seeding. Patients should proceed to surgery if a mass is clinically suspicious.

Other diagnoses that should be considered aside from testicular cancer

Other diagnoses that should be considered aside from testicular cancer include:

- epididymitis
- epididymal cyst
- hydrocele
- varicocele
- spermatocele
- metastasis of other cancers
- orchitis

'Gold-standard' diagnostic test for testicular cancer

For testicular cancer, testicular ultrasound is the gold-standard investigation, followed by orchidectomy.

Acceptable diagnostic alternatives to the gold-standard test for testicular cancer

When diagnosing testicular cancer, it is rarely relevant to have any test other than testicular ultrasound followed by orchidectomy.

Other relevant investigations for testicular cancer

In testicular cancer, tumour markers are prognostic and are surrogate markers for response to treatment. Beta-human chorionic gonadotropin is secreted by both seminomas and non-seminomas. Alpha-fetoprotein is secreted by embryonal or yolk sac elements in non-seminomas. Lactate dehydrogenase is a non-specific, prognostic marker in testicular cancer. Staging investigations include CT chest, abdomen, and pelvis.

Prognosis of testicular cancer, and how to estimate it

For testicular cancer, the prognosis is good, with a 5-year survival rate of 98%. Non-pulmonary visceral metastases and very high tumour markers at diagnosis are associated with a worse prognosis.

Treatment of testicular cancer, and its effectiveness

For testicular cancer, radical orchidectomy is the primary treatment. Adjuvant chemotherapy or radiotherapy reduces the risk of recurrence. Metastatic and recurrent disease is treated with chemotherapy. Testicular cancers, particularly seminomas, are highly chemosensitive.

329 Symptom control in cancer

Martin Scott-Brown

Introduction

Treatment in cancer is aimed at improving survival (curing where possible) and/or improving symptoms. Symptoms may be caused by the cancer itself (primary tumour, metastases, or paraneoplastic phenomenon) or by the treatments patients undergo to treat the cancer (surgery, radiotherapy, chemotherapy, hormone therapy, and biological therapy). Therefore, symptom control is one of the key roles of oncologists as they treat cancer patients.

The most important part of symptom control in cancer patients is to elucidate the underlying cause of the symptom. Symptom control is most effective when the underlying cause is targeted; for example, shoulder pain may be treated most effectively by local radiotherapy if it is due to a bone metastasis in the humeral head, by dexamethasone if it is referred pain due to diaphragmatic irritation from hepatomegaly, and by amitriptyline or gabapentin if it is neuropathic pain due to cervical nerve root irritation.

Covering all symptom control in cancer patients is beyond the remit of this chapter; however, we will cover the control of pain and nausea and vomiting, as these are very common symptoms in cancer patients.

Pain in the cancer patient

Three-quarters of cancer patients experience pain at some point in their illness. Acute, severe pain can produce fear and anxiety for the patient and their carers. Chronic pain is extremely debilitating, is associated with depression, and impairs a patient's ability to cope with ongoing treatment. Multiple, concurrent pains are common, particularly in advanced cancer, and it is important to consider the cause and appropriate management of each pain separately.

History taking for pain in the cancer patient

The history should include the number and location of pain sites, the character of the pain (e.g. nociceptive or neuropathic, constant or episodic, with triggering or relieving factors), and its response to analgesics. Also, ascertain the impact of the pain on the patient.

Examination for pain in the cancer patient

During the examination, examine painful areas gently and carefully, to avoid exacerbating pain. Ascertain whether the pain is due to masses or organomegaly, whether the pain arises from soft tissue or bone, and whether there are associated sensory changes which may suggest a neuropathic element.

Causes of pain in the cancer patient

Pain is often caused by the tumour/metastases compressing normal structures. Bone metastases can be painful but will also result in neuropathic pain if they are compressing nerves. Intracranial disease can cause raised intracranial pressure resulting in headache. Liver metastases become painful once they cause stretching of the liver capsule. Primary bowel tumours or peritoneal disease can cause pain secondary to bowel obstruction. Cancer also predisposes patients to pulmonary embolism, which can present with pleuritic chest pain, so we must not overlook non-malignant causes of pain that may be present in the cancer patient.

General principles of pain management in the cancer patient

It is vital to ensure that reversible causes of pain are excluded and treated (e.g. constipation or infection). If the underlying cause has

been identified, consider whether this can be helped by disease-modifying treatment (e.g. radiotherapy, chemotherapy, hormone therapy, or surgery).

Ensure the patient has adequate analgesia and understands how best to use it. Give regular analgesics to maintain an analgesic effect. Always have additional analgesia written up for pain that breaks through the regular analgesic regimen ('breakthrough pain'). Add additional analgesics one at a time, so that you are able to assess the efficacy of each drug. Ineffective drugs or those that are no longer making a significant contribution to analgesia should be stopped. Titrate opioids to effect or tolerance before adding in additional drugs, to avoid unnecessarily complicated regimes. In difficult cancer pain, combinations are often necessary to achieve adequate analgesia with minimum side effects. Consider referral to the palliative care or pain team.

The WHO analgesic ladder (see Table 329.1) provides a systematic approach to pain management in cancer.

An adjuvant is a drug (e.g. corticosteroids, tricyclic antidepressants, anticonvulsants) which is not analgesic in its prime function but has analgesic actions in particular kinds of pain. It may be appropriate at any stage of the ladder. In practice, however, this recommendation is a guideline, and the choice of analgesic should be determined by the cause and nature of the pain and the significance of potential adverse effects for a particular patient.

Management of specific pains in the cancer patient

Neuropathic pain is associated with nerve compression or injury. It usually responds to standard analgesics; however, there may be a ceiling of unacceptable side effects with opioids before complete analgesia is achieved, so adjuvants may be necessary (e.g. dexamethasone, amitriptyline, gabapentin); in difficult neuropathic pain, consider referral to the pain team.

Bone pain may be usefully treated with radiotherapy, bisphosphonates, hormonal therapy, or radioisotopes. Vertebroplasty or surgical fixation may also be beneficial.

Liver metastases stretching the liver capsule may cause intense right upper quadrant pain that may be exacerbated by inspiration; there may also be a palpable, tender liver. This pain may respond to NSAIDs and opioids, but a corticosteroid may be highly effective as an adjuvant and reduce the need for opioids.

Nausea and vomiting in the cancer patient

Nausea and vomiting is very common in cancer patients (up to 50%), especially in those receiving chemotherapy (70%–80%). Nausea and vomiting contributes significantly to the morbidity of cancer and its treatment. It is important to determine the underlying causes of the vomiting, as this guides treatment. In many cases, the causes for vomiting are multifactorial, so this requires an understanding of the sites

Table 329.1 The WHO analgesic ladder

Step 1	Non-opioid (e.g. paracetamol, ibuprofen) ± adjuvants
Step 2	Opioid for mild to moderate pain (e.g. codeine, tramadol) + non-opioid ± adjuvants
Step 3	Opioid for moderate to severe pain (e.g. morphine) + non-opioid ± adjuvants

of action of the anti-emetics and a logical approach to their use to achieve control of this distressing symptom (see Table 329.2).

Chemical/metabolic nausea is often continuous and is not relieved by vomiting. Causes include chemotherapy and abdominal or cranial radiotherapy, uraemia, hypercalcaemia, and drugs (e.g. opioids or antibiotics).

Gastric stasis/bowel obstruction is usually associated with abdominal distension (particularly after eating), and intermittent nausea which is relieved by vomiting. It can be caused by drugs (e.g. opioids or anticholinergic drugs), gastrointestinal tumours, peritoneal carcinomatosis, or adhesions secondary to previous abdominal surgery.

The nausea associated with raised intracranial pressure is commonly worse in the morning, with headache and, occasionally, neurological signs.

Vestibular disease or base of skull pathology usually results in nausea exacerbated by movement.

History taking for nausea and vomiting in the cancer patient

A detailed history will often elucidate the cause of nausea. Important points include:

- Is nausea or vomiting the major symptom?
- Is the nausea relieved by vomiting?

- Has the patient recently received chemotherapy or radiotherapy or recently commenced on a new drug?
- Are there other associated symptoms (e.g. colicky abdominal pain, headache, vertigo)?

Examination for nausea and vomiting in the cancer patient

The examination should assess both the impact of vomiting (e.g. hypovolaemia) as well as the cause of the nausea/vomiting (e.g. look for organomegaly, abdominal distension, bowel sounds; perform both a neurological examination and fundoscopy).

Investigation for nausea and vomiting in the cancer patient

A systematic approach to investigations is useful, as these can often help to elucidate the cause, including blood tests (e.g. urea and electrolytes, calcium level, bilirubin level) and imaging (e.g. abdominal X-ray, CT brain, CT abdomen, contrast swallow/meal).

Management of nausea and vomiting in the cancer patient

Most patients with nausea and vomiting can be managed as outpatients, as long as the patient has an adequate oral intake to maintain

hydration status, is not hypotensive, and does not have an electrolyte imbalance.

If the patient is severely dehydrated (e.g. hypotensive or tachycardic), drowsy, or confused, start IV rehydration and perform blood tests immediately. If the patient is oliguric, give IV fluids and insert a urinary catheter to monitor urinary output (aim for an output >0.5 ml/kg per hour).

If the patient is distressed by severe nausea and/or vomiting, consider giving a broad-spectrum anti-emetic such as cyclizine 50 mg subcutaneously or intravenously, prior to further assessment. In persistent vomiting, absorption by oral route may be poor, so give essential medication by subcutaneous or IV routes.

Review current medications and consider stopping drugs which may be causative, but do not stop opioids if the patient has been in pain but add an anti-emetic. Treat correctable causes (e.g. hypercalcaemia, raised intracranial pressure, uraemia, gastritis, constipation).

Anti-emetics should be given on a regular basis, with the dose adjusted as needed. If oral absorption is poor because of continuous vomiting, give the anti-emetic subcutaneously, intravenously, or per rectum. If there is little response to the first anti-emetic after 24

hours, then optimize the dose, taking account of the doses required. If there is still no response, change to an alternative anti-emetic with a different receptor profile. Finally, add in a second anti-emetic with a different receptor profile.

Antimuscarinic drugs (e.g. cyclizine) block the cholinergic pathway through which prokinetic drugs (e.g. metoclopramide, domperidone) act. Although the central effects of metoclopramide are not inhibited by cyclizine, a combination of cyclizine and metoclopramide is best avoided.

If nausea/vomiting remains difficult to control, seek advice from the palliative care team.

330 Dying from cancer

Martin Scott-Brown

Introduction

For many patients, dying from cancer has been an ever-present reality from the time they were diagnosed with incurable recurrent or metastatic cancer. Treatment may have delayed the inevitable, but there does come a point where aggressive management no longer improves the prognosis or can only prolong life that is of such a poor quality that it is not valued by the patient. It sometimes is easier to continue with treatment than to take the time with the patient to discuss the reasons why further treatment is not appropriate. For patients with advanced cancer and whose condition is deteriorating, the following questions should be considered before initiating treatment aimed at prolonging life:

- Is this the final stage of a progressive deterioration or an acute event? Are the causes of this deterioration reversible? The ICU is usually not appropriate for patients with advanced cancer.
- Are there any further oncological treatments that may improve the prognosis?
- What is the patient's perception of their quality of life? Is there a realistic chance of return to a quality of life that will be of value to the patient?
- Is the patient dying?

Treatment of correctable causes (e.g. obstructive uropathy, chest infection) may still not be in the patient's best interest if they recover only to face a period of further deterioration and distressing symptoms before they die. However, patients and their families must be included in discussions as to the level of further intervention and the reasons for stopping active treatment.

The diagnosis of dying

It is not always easy to 'diagnose' those patients who are dying, and the diagnosis of dying is a skill often obtained only through experience. It is important to make the diagnosis, as it then avoids inappropriate treatment and unnecessary investigations. The following can be helpful indicators in the context of advanced cancer:

- the patient is profoundly weak and bed bound
- the patient is semi-comatose
- the patient is unable to take oral medication
- the patient is unable to take more than sips of water

Management of the dying patient

The priorities at this stage are:

- good symptom control
- clear, sensitive communication with the patient and their family

As oncologists, we know that many of our patients will die from their cancers. Our treatments may not prevent their death; however, our expertise must be used to enable them to die with their symptoms controlled.

General management

Initiate the hospital's care pathway for dying patients. Previously, the Liverpool care pathway was widely used; following certain criticisms (mainly around patient and relative communication), updated pathways largely based on the Liverpool care pathway but not using the name are used by many hospitals

Document the 'do not attempt cardiopulmonary resuscitation' decision. Involve the hospital palliative care team if there are:

- difficult symptom control issues
- difficult communication issues with the patient or family

Avoid investigations that are not going to alter management (e.g. blood tests). Stop inappropriate nursing interventions (e.g. monitoring vital signs). Stop medication that will have no impact on the patient's symptoms. If possible, convert essential medication to the subcutaneous (SC) route (using a syringe driver if necessary). Consider a urinary catheter.

Communication

Wherever possible, enable the patient to discuss their prognosis and ongoing plan of care. Involve the family in all discussions (with the patient's permission). Offer the input of the hospital chaplaincy team or representative of his or her own faith. Patients and families will often ask, 'How long?' This is very difficult to answer; however, the following is a good rule of thumb:

- if the patient is deteriorating every week, the prognosis is probably 'weeks'
- if the patient is deteriorating every day, the prognosis is probably 'days'
- if the patient is deteriorating every hour, the prognosis is probably 'hours'

Patients who are in their last 'hours' usually develop a deepening coma, variable respiratory pattern, and poor peripheral circulation.

Symptom control

Pain

As long as the patient is responsive, pain can be assessed in the usual way. Once they become unresponsive, you have to rely on non-verbal cues (e.g. grimacing, groaning, and muscle tension in areas of pain). Family members will often report perceptions that the patient is in pain. If there is any doubt, give a breakthrough dose of SC morphine and monitor the apparent level of distress. If the patient is unable to take oral medication, convert regular per oral opioids to an SC infusion of diamorphine. The opioid level may need to be reduced if the patient is dying of renal failure. Patients may develop a generalized musculoskeletal pain when they are bed bound and dying. This usually responds well to low-dose diamorphine SC 10–20 mg per 24 hours. If a patient has been on oral NSAIDs, these can be converted to tenoxicam SC 20 mg once daily or diclofenac per rectum 50 mg twice daily; alternatively, the dose of opioid can be increased to compensate. If the patient is using co-analgesics such as tricyclic antidepressants or anticonvulsants, the opioid levels may need to be increased once the levels of these drugs have been significantly reduced.

Breathlessness

Many patients fear dying with severe breathlessness. Reassure patients that breathlessness can be relieved, although, occasionally, patients may have to be sedated to achieve adequate relief. Slowly progressive breathlessness can be managed with a SC infusion of morphine (10–20 mg per 24 hours) plus midazolam (10–20 mg per 24 hours). This can be titrated up to achieve the desired effect. Patients who are dying consequent to rapidly deteriorating respiratory function are in severe distress and need urgent attention. Sedation is usually the only way to provide relief, and midazolam needs to be titrated rapidly (up to 60 mg per 24 hours)

Vomiting

The control of nausea and vomiting is no different in the terminal phase; however, medication should be given via the SC route.

Restlessness and agitation

In the terminal phase of cancer, there are many potential causes of restlessness, agitation, and cognitive failure (including renal failure, opioid toxicity, and cerebral metastases). It is not usually possible to identify a single cause, but it is worth excluding urinary retention and considering a reduction in opioids if the patient is not in pain and there are signs of opioid toxicity. Attention to the patient's surroundings is important, with familiar faces and a peaceful, quiet environment. Appropriate drugs can also be helpful to gain control of the symptoms (e.g. midazolam, haloperidol, and levomepromazine). Seek specialist palliative care advice when agitation does not settle.

Upper respiratory tract secretions ('death rattle')

Upper respiratory tract secretions (the 'death rattle') can be reduced using anti-cholinergic drugs (e.g. hyoscine butylbromide 20 mg SC, followed by 40–80 mg per 24 hours by SC infusion), but they are usually difficult to control completely. Reassure the family that, if the patient is unconscious, they will not be distressed by the secretions. Early treatment often achieves better control. Repositioning the patient on their side may be helpful. Avoid suction except in severe cases.

Nutrition and hydration

If nutrition and hydration need to be given by a non-oral route, then, under UK law, they constitute medical treatments rather than basic

human rights. For patients and families, however, they remain deeply symbolic of survival, and this area often needs very sensitive communication. If the patient is still responsive and competent, then their wishes are paramount. At this stage, comfort is the primary goal and this can usually be achieved without recourse to artificial nutrition or hydration, as it is normal for patients who are dying to lose interest in food and fluid. Symptoms of thirst can usually be alleviated by sips of water from a cup or sponge and good mouth care. If patients remain symptomatically thirsty in spite of these measures, then IV or SC fluids can be considered (1–2 l per 24 hours). If the family cannot accept that parenteral fluids are not necessary, then it may be appropriate to continue them rather than provoke conflict and risk a complicated bereavement.

PART 17

Dietary, lifestyle, and environmental factors affecting health

331 Normal nutritional function

Michelle Ellinson and Tommy Rampling

Introduction

Normal nutritional function requires a healthy diet. Healthy eating incorporates a variety of nutrients that are essential for energy expenditure, prevention of disease, and maintenance of normal physiological function. An unhealthy diet can result in malnutrition, and this contributes to illness and death throughout the world. The core principle of healthy eating is obtaining an adequate balance, and the diseases resulting from overnourishment differ greatly from those resulting from undernourishment.

In resource-limited settings diets tend to rely heavily on staple crops, and can be very seasonal. Energy sources are predominantly cereals, whereas meat and fish are limited. Malnutrition tends to occur from a lack of essential nutrients, leading to conditions such as vitamin deficiencies, kwashiorkor, and iodine deficiency syndromes. In high-resource settings, people have more freedom to choose what they eat. Thus, diets tend to be high in fat and dense in energy. Obesity, diabetes, coronary heart disease, cancer, and hypertension are major contributors to morbidity and mortality.

A healthy diet should contain adequate proportions of carbohydrates, fats, proteins, vitamins, and trace elements. The intake of these constituents is sporadic, with meals constituting major boluses of potential energy. Energy expenditure, conversely, is continuous. The human body has, therefore, developed complex mechanisms directing nutrients into storage when in excess, and mobilizing these stores as they are needed, and it is essential that sufficient energy is always available to maintain the basal metabolic rate, which is the amount of energy expended while at rest in a neutrally temperate environment. This energy is sufficient only for the functioning of the vital organs, such as the heart, the lungs, the liver, the kidneys, and the CNS.

Carbohydrates

Carbohydrates are monomers, dimers, and polymers of saccharide molecules, and can be classified as such. Monosaccharides, such as glucose and fructose, and disaccharides, such as sucrose, lactose, and maltose, are termed 'simple sugars'. Oligosaccharides contain between three and ten monosaccharide units, and polysaccharides contain more than ten units. Starch is a polysaccharide complex carbohydrate that is found mainly in plants and should be part of the staple diet. There are various types of starch, depending on the linkage and hydrolysis of the units, and the resistance of the starch to digestion within the intestine. Foods such as white bread and potatoes contain starch that is rapidly digested in the small intestine, whereas foods such as beans, peas, lentils, and pasta take longer to be digested in the small intestine, thus producing a lower glycaemic response in the blood. Resistant starches are foods that are not digested in the small intestine, and instead become fermented in the large intestine by the bacteria. Dietary fibre, which contains non-starch polysaccharides, is an example of a resistant starch and is essential for maintenance of a healthy large bowel, lowering of cholesterol, increasing bowel motility, and reduction in constipation. Foods that are a good source of fibre include fruits, vegetables, and cereals.

After a meal, the body goes into the absorptive state, and the liver, the adipose tissue, the skeletal muscles, and the brain utilize the glucose. The liver retains up to 60% of the glucose via the hepatic portal system and converts it to glycogen. In addition, pyruvate carboxylase is downregulated, so there is decreased gluconeogenesis. Insulin levels increase as there is increased production by the beta cells in the islets of Langerhans in the pancreas. Once insulin is in circulation, there are insulin receptors on the cell membrane which

cause migration of glucose transporters (e.g. GLUT4) towards the cell membrane to allow uptake of glucose by the cell. Glucose stimulates the release of insulin and therefore decreases the release of glucagon. An increase in insulin also results from an increase in the amino acid arginine, and the hormone secretin, which is released within the gastrointestinal tract. The adipose tissue undergoes an influx of glucose into the adipocytes, where glucose is phosphorylated to create glucose-6-phosphate. Skeletal muscle also absorbs the glucose, which is stored as glycogen. In the well-fed state, the brain uses glucose as the primary fuel. The brain is unable to store glycogen and therefore relies on glucose crossing the blood-brain barrier to enter the endothelial cells lining the blood vessels.

It is recommended to have between four and six servings of carbohydrates per day. The energy content of 1 g of carbohydrate is 4 calories, which is relatively low compared to 9 calories per 1 g of fat. Therefore, adding fat to carbohydrates will increase the calorie content of the carbohydrate-containing food.

Proteins

Proteins are macromolecules consisting of chains of amino acids. Proteins have numerous functions in the body: they serve as constituents of cellular membranes, transport molecules, coenzymes, hormones, and immune mediators, as well as maintain pH balance. There are 20 different amino acids from which proteins can be constructed. Of these, nine are essential dietary requirements, as the body is unable to efficiently manufacture them at the rate in which they are utilized. Nitrogen is one of the constituents of the protein molecule, and a positive nitrogen balance occurs when the amount of nitrogen consumed is greater than the amount excreted in urine, faeces, or sweat. Examples of this occurring would be during growth and tissue repair. Negative nitrogen balance occurs when the amount excreted is greater than the amount consumed, as happens, for example, during surgery, illness, or a decrease in protein intake. In 1991, the Department of Health recommended that the intake for protein in healthy adults be 0.75 g/kg of ideal weight per day.

Foods containing high concentrations of protein include meats, fish, dairy products, eggs, beans, nuts, and pulses. A balanced diet should aim for two servings of protein per day, choosing lean meats and low-fat dairy products if aiming to maintain weight within the healthy weight for height range.

Dietary protein is digested in the small intestine and absorbed as peptides and amino acids. On entering the enterocytes of the small intestine, some of the amino acids are preferentially selected and removed for use as oxidative fuel. The amino acids that remain travel via the portal vein to the liver, where further selective oxidation occurs. This accounts for consumption of up to 60% of the incoming amino acids. The liver is also responsible for large volumes of protein synthesis. The amino acid molecules are reformed into useable human protein structures, such as albumin, and most proteins involved in the coagulation pathways.

The liver is also the only significant site of urea synthesis. The individual atoms that make up urea molecules come from carbon dioxide, aspartate, ammonia, and water. It is formed in an anabolic process known as the urea cycle. The function of urea is to serve as a safe vehicle for excreting nitrogen waste, most notably amino acids and ammonia. When amino acids are released from proteolysis in peripheral tissues, they must transport, or transfer their amino nitrogen to the liver. The predominant amino acid carriers of nitrogen, released from proteolysis in muscle and adipose tissue are alanine and glutamine, and hepatic removal of these two far exceeds that of other amino acids.

Transamination of pyruvate and 2-oxoglutarate allows the transfer of amino acids into tissues via gluconeogenesis, producing glucose that can be recycled to the peripheral tissues. Once formed, alanine can be transaminated further to form aspartate for use in the urea cycle.

The other route of entry of nitrogen into the urea cycle is ammonia. Ammonia is a basic metabolic waste product that can raise intracellular pH to toxic levels. Ammonia may be formed in the peripheral tissues by oxidative deamination of glutamate. Defects of the urea cycle, for example in liver dysfunction, can have serious manifestations, such as hepatic encephalopathy. Therefore, although urea is a waste product and its synthesis requires energy, its synthesis is still an essential function of the liver.

Fats

Fats provide the most calories per gram (i.e. 9 calories/g). The majority of the fat molecule is made up of triglycerides. Fat in the diet may be visible, such as butter, or fat on meat/chicken, or invisible, such as hidden sources of fat in cakes and biscuits. The melting point of fat depends on the length and saturation of the fatty acid chain. Monounsaturated fats such as olive oil have one double bond between two carbon atoms; polyunsaturated fats such as fish oils have two or more double bonds within the chain. Fats provide essential fatty acids which the body cannot synthesize, and are derived from two different parent fatty acids known as omega-3 (i.e. alpha-linolenic acid) and omega-6 (i.e. linoleic acid).

Fats in the body have structural and storage capacity. Cellular membranes are made up of a phospholipid outer layer, with the fatty acid chain pointing inwards. Protein molecules that serve as receptors or enzymes are inserted between the layers. Vitamins and cholesterol molecules are also situated on cellular membranes.

Storage fats, also known as lipids, are stored within adipose tissue as an energy reserve. Fatty acids stored in adipose tissue tend to be by-products of the diet rather than fatty acids that have been generated within the body.

Cholesterol is metabolized to form steroids in the adrenal glands, and bile acids in the liver.

The need for specifying the upper limits of dietary intake of total fat can be seen with the correlation of a diet high in saturated

fatty acids with high blood cholesterol and therefore heart disease. Decreasing the total fat in the diet can reduce the concentration of plasma cholesterol and the risk of developing atherosclerosis. There is also a genetic component to high plasma cholesterol concentrations such as familial hypercholesterolaemia. High-fat diets lead to raised plasma cholesterol and obesity. If saturated fatty acids are replaced by unsaturated fatty acids, the total LDL would decrease. In order to decrease cholesterol intake, diets need to be modified so that the diet will contain total fat that contributes to a maximum of 35% of total energy and that saturated fatty acids contribute to a maximum of 10% of total energy. Patients who have suffered a myocardial infarction should be given dietary advice on the 'Mediterranean diet', which is a diet that focuses on a decrease in saturated fat intake and an increase in the consumption of fruit and vegetables and monounsaturated/polyunsaturated fatty acids.

Dietary fats are generally broken down in the small intestine by bile salts, which emulsify the fats. The hormone cholecystokinin, which is released by the duodenum, causes the gall bladder to release bile salts. Pancreatic lipase breaks down the fatty acids as well as cholesteryl esters, resulting in the production of free cholesterol and fatty acids. The free fatty acids and cholesterol then combine with the bile salts to form micelles which are absorbed in the intestine. Steatorrhoea occurs when there is lipid malabsorption, which could result in deficiencies in the fat-soluble vitamins (vitamins A, D, E, and K) as well as the essential fatty acids.

332 Starvation and malnutrition

Satish Keshav and Alexandra Kent

Definition of the disease

Starvation is a state of severe malnutrition due to a reduction in macro- and micronutrient intake. The basis underlying starvation is an imbalance between energy intake and energy expenditure.

Aetiology of the disease

The commonest cause of starvation is lack of available food, usually due to environmental, social, and economic reasons; other causes include:

- anorexia nervosa
- depression and other psychiatric disorders
- coma and disturbance of consciousness
- intestinal failure
- mechanical failure of digestion, including poor dentition and intestinal obstruction

Protein energy malnutrition is usually seen in developing countries; the two forms seen are:

- marasmus: this is caused by inadequate calories, and leads to emaciation
- kwashiorkor: this was originally thought to be caused by protein malabsorption, although it is now thought that it is likely to be caused by deficiency of micronutrients, particularly those with antioxidant function, such as glutathione, vitamin E, and polyunsaturated fatty acids

Typical symptoms of the disease, and less common symptoms

Individuals experiencing starvation undergo catabolism, whereby the body breaks down fat and muscle tissue to provide energy sources for vital organs, such as the heart and brain. Muscle atrophy leads to weakness, and gastrointestinal atrophy reduces hunger. As the patient becomes more starved, they often lose the ability to sense thirst, and so become dehydrated. Movement becomes painful, and patients become fatigued and apathetic. Depression and irritability may occur. Infections are more common, and cause catabolism, hastening death, which eventually ensues.

Marasmus leads to extensive tissue and muscle wasting, often with loose skin folds and drastic loss of adipose tissue. A patient with kwashiorkor is defined by the presence of pedal oedema, and often presents with hepatomegaly, a distended abdomen, dermatoses, anorexia, thin hair, and irritability.

Symptoms related to specific nutrient deficiencies are shown in Table 332.1.

Demographics of the disease

The WHO states that malnutrition is the biggest contributor to child mortality, associated with ~54% of cases of deaths in children in developing countries in 2001. Currently, it is estimated that there are 963 million undernourished people in the world, which reduces to approximately 1 in 7 people, and is equal to the joint populations of the US, Canada, and the European Union. One person dies every second as a result of hunger; this is equal to 4000 every hour, 100 000 each day, and 36 million each year. It is estimated that 684 000 child deaths per year could be prevented worldwide, by increasing access to vitamin A and zinc. In the developed world, studies have suggested

that 40% of hospital inpatients are malnourished, of which 70% of cases are unrecognized.

Natural history, and complications of the disease

Fluid and electrolyte disturbance

As patients become starved or malnourished, they often lose their thirst reflex and so become dehydrated. This puts them at risk of electrolyte disturbance and renal impairment, especially hypokalaemia, hypochloreaemia, metabolic alkalosis, and ketonuria.

Impaired immune system

The weakened body of a starved/malnourished patient is more prone to infection, due to a dysfunctional immune system. This results in a reduced production of IgA, T-cells, cytokines, and complement, as well as a decrease in phagocytosis, amongst other effects.

Infections

In starvation/malnutrition, resultant infections, particularly diarrhoea, worsen nutrient absorption, increase metabolic needs, and can cause anorexia.

Cardiovascular complications

Cardiovascular complications of starvation/malnutrition include orthostatic hypotension, bradycardia, arrhythmias, and heart failure.

Gastrointestinal complications

Starvation/malnutrition can cause constipation, parotid gland hypertrophy, fatty liver, gallstones, and pancreatitis.

Growth retardation

Malnutrition and illnesses associated with starvation can lead to physical and mental growth retardation, and have been shown to have a significant effect on a child's long-term future, including potential future earnings.

Endocrine effects

The endocrine effects of starvation/malnutrition include delayed puberty, amenorrhoea, hypercortisolaemia, low T3 levels, and diabetes insipidus.

Dermatological complications

Patients who are starved/malnourished will have thin, brittle hair, alopecia, and brittle nails. Lanugo hair will grow in an attempt to insulate the body.

Approach to diagnosing the disease

Many patients seen in a hospital setting are at risk of malnutrition. Any patient with signs of starvation should have a full history taken and complete examination assessing for any signs or symptoms of nutritional deficiency. The Malnutrition Universal Screening Tool can help to assess nutritional status. This combines information about the patient's current BMI, unplanned weight loss in the preceding 3–6 months, and the effect of any acute disease state. The overall score reflects the patient's overall risk of malnutrition and can guide therapy.

Table 332.1 Vitamin deficiencies		
Vitamin	Condition	Symptoms/signs
Vitamin A		Night blindness Poor growth
Vitamin B ₁ (thiamine)	Beriberi	Weakness Muscle pain Heart failure Peripheral neuropathy Wernicke's encephalopathy
Vitamin B ₃ (niacin)	Pellagra	Dermatitis Aggression Insomnia Weakness Confusion Diarrhoea Ataxia Glossitis Dementia Dilated cardiomyopathy
Vitamin B ₁₂		Macrocytic anaemia Peripheral demyelination Sleep disturbances Subacute combined degeneration of the spinal cord
Vitamin C	Scurvy	Malaise Lethargy Myalgia Bruising Gum disease Neuropathy
Vitamin D	Osteomalacia (adults) Rickets (children)	Bone pain Increased fractures Dental problems Skeletal deformities (bow legs) Craniotabes Hypocalcaemia Growth disturbance Metaphyseal cartilage hyperplasia
Calcium		Osteoporosis Rickets Tetany
Folate		Macrocytic anaemia Weakness Headaches Irritability
Iodine	Goitre*	Low thyroid hormones Raised thyroid-stimulating hormone
	Cretinism	Mental retardation Stunted growth Deaf-mutism
Iron		Microcytic anaemia
Selenium	Keshan disease Kashin-Beck disease	Myocardial necrosis Atrophy Degeneration and necrosis of cartilage Selenium aids conversion of thyroxine into triiodothyronine, so deficiency can cause signs of hypothyroidism
Zinc		Anorexia Lethargy Diarrhoea Growth and mental retardation Alopecia Dermatitis Neuropathy Anaemia Hepatosplenomegaly Macular degeneration

*May occur with or without cretinism.

Other diagnoses that should be considered

Starvation is due to poor oral intake, and the underlying cause(s) should be ascertained: these include disinterest, poor dentition, an inability to shop or prepare food, or psychiatric causes (e.g. depression, anorexia nervosa).

'Gold-standard' diagnostic test

There is no specific test that can diagnose starvation. The diagnosis is made on a combination of history, examination, and nutritional assessments.

Investigations

Laboratory studies for starvation/malnutrition should include a full blood count, renal function tests, electrolyte levels, liver function tests, albumin levels, a bone profile, haematinics, and levels of vitamin and trace elements (e.g. zinc, selenium). Starved patients will have ketones in their urine. Patients should undergo investigations to detect potential associated infections, such as a chest X-ray, stool culture, blood culture, and so on. An ECG should be performed to assess for small QRS complexes, the QT interval, arrhythmias, and bradycardia. If there is no clear reason for the starvation, such as poor access to food, it is important to perform a psychiatric assessment.

Prognosis and how to estimate it

The prognosis for starvation is variable and difficult to estimate. Approximately 50% of patients with anorexia nervosa will recover fully, ~30% will improve, and ~20% have a relapsing condition. Unfortunately, many elderly patients will have undiagnosed malnutrition and die from concurrent sepsis, with the malnutrition often under-treated.

Ultimately, patients can deteriorate to the point where their physiological mechanism for protein synthesis and handling is redundant. At this point, food and protein replacement is futile, and the patient is facing an inevitable death.

Treatment and its effectiveness

The mainstay of treatment comprises replacing fluid, correcting electrolyte derangements, and providing protein, carbohydrates, and calories. Protein, energy, and nutrient requirement vary according to age, sex, and activity levels, and should be adapted for each patient. This should all be done under the close supervision of nutritional specialists and dietitians. Physicians should identify complications of malnutrition and starvation early and initiate rapid treatment, as delayed treatment can be fatal (see 'Natural history, and complications of the disease'), with infections, dehydration, and circulatory failure being associated with higher mortality.

Doctors should involve the dietetics department in the management of sick patients early in their admission to prevent complications associated with malnutrition and starvation.

333 Vitamin deficiencies

Aminda De Silva, J. A. Saunders, and M. A. Stroud

Definition of the disease

Vitamins are organic compounds required by the body in small amounts to perform specific cellular functions. Nine vitamins (thiamine (vitamin B₁), riboflavin (vitamin B₂), pyridoxine (vitamin B₆), cyanocobalamin (vitamin B₁₂), niacin (nicotinic acid; vitamin B₃), pantothenic acid (vitamin B₅), biotin (vitamin B₇; vitamin H), folic acid (folate; vitamin B₉), and ascorbic acid (vitamin C)) are water soluble, while four (vitamins A, D, E, and K) are fat soluble.

The importance of vitamins was first appreciated through recognition of their clinical deficiency state (e.g. the existence of scurvy was linked to diets low in fresh fruit and vegetables, and this then led to the identification of vitamin C). However, this approach has led to the concept that the primary purpose of a vitamin is to prevent the associated clinical deficiency state and, consequently, unless patients exhibit signs of a specific clinical deficiency state, they are thought to be replete in the corresponding vitamin. This is a misunderstanding. In reality, most vitamins have many different functions which are incompletely understood, and impaired biochemical function and even functional problems affecting metabolic, immunological, or cognitive status can occur with marginal vitamin depletion long before overt clinical deficiency becomes evident. A high index of suspicion is thus essential in all patients who have malnutrition or malabsorption, to ensure that levels that might compromise health, resistance to disease, and recovery from injury or illness are not left untreated.

Aetiology and demographics of the disease

Vitamins cannot be synthesized by humans but are obtained from the diet. Deficiencies of water-soluble vitamins (except vitamin B₁₂) may develop after weeks to months of undernutrition, whereas deficiencies of fat-soluble vitamins and vitamin B₁₂ may take more than a year to develop because of relatively large body stores.

In developed countries, traditional medical thinking suggests that vitamin deficiencies result mainly from poverty, food faddism, poor diets, malabsorption, drugs, alcoholism, or prolonged and inadequately supplemented parenteral feeding, with groups at particular risk including pregnant women, children, the institutionalized, and the frail elderly. However, mild functional vitamin deficiency is probably very common, since, although it would be expected that our nutritional needs would easily be met from food alone, our biology did not evolve in the context of the modern western diet, which may have a low micronutrient content. Furthermore, the relatively high activity levels of our ancestors meant that, in general, they would have consumed quite a lot of food daily. This therefore raises the question as to whether some sedentary individuals, eating relatively little, may not be meeting their full 'functional' vitamin requirements even if they are not thin and, certainly, there is good biochemical evidence that many apparently healthy, older individuals are not functionally replete in one or more of the vitamins needed for adequate hepatic transamination (i.e. vitamin B₁₂, vitamin B₆, and/or folate). In addition, the fact that folic acid supplements in early pregnancy dramatically reduce the incidence of neural-tube defects suggests that vitamin intake in this group is also suboptimal.

In developing countries, deficiencies often result from all these factors, which are often coupled with simple lack of access to adequate nutrition.

Typical symptoms of the disease, and less common symptoms

Typical problems related to vitamin deficiency are summarized in Table 333.1.

Natural history and complications of the disease

Deficiencies in water-soluble vitamins

Vitamin B₁ (thiamine) deficiency

Individuals with high alcohol intakes are at particular risk of vitamin B₁ (thiamine) deficiency. The provision of carbohydrate to malnourished individuals can precipitate thiamine deficiency, leading to the reversible Wernicke's encephalopathy (ataxia, ophthalmoplegia, and confusion), which, if not rapidly corrected, can then lead to the irreversible Korsakoff's dementia and impairment of short-term memory.

Beriberi (cardiac failure and peripheral neuropathy) can also occur, although it happens less often than the Wernicke–Korsakoff syndrome, but can go unrecognized, as poor cardiac function is often put down to other problems. Thiamine overdosage (more than 3 g/day) can lead to toxicity, with headaches, irritability, and insomnia, as well as weakness.

Vitamin B₂ (riboflavin) deficiency

Vitamin B₂ (riboflavin) deficiency is probably more common than generally appreciated, due to the non-specific nature of symptoms. Vegans are at particular risk.

Vitamin B₃ (niacin; nicotinic acid) deficiency

Vitamin B₃ (niacin; nicotinic acid) deficiency is most commonly seen in alcoholics and in patients with long-term malabsorption. Rarely, this deficiency can be seen in three specific settings: carcinoid syndrome, prolonged use of isoniazid, and Hartnup disease. High doses can be toxic to the liver and the kidneys.

Vitamin B₅ (pantothenic acid) deficiency

Deficiency of vitamin B₅ (pantothenic acid) in humans is extremely rare. No reports of toxicity with overdosage have been identified.

Vitamin B₆ (pyridoxine) deficiency

Vitamin B₆ (pyridoxine) is required for amino acid metabolism. Some genetic syndromes (e.g. homocystinuria) may mimic pyridoxine deficiency. Some drugs (e.g. isoniazid) interact with pyridoxal phosphate, producing a deficiency.

Vitamin B₇ (biotin/vitamin H) deficiency

Vitamin B₇ (biotin/vitamin H) deficiency can be seen in patients on haemodialysis, and with long-term therapy with some anticonvulsants. Toxicity has not been reported.

Vitamin B₁₂ and folate deficiency

Vitamin B₁₂ and folate deficiencies are common and can be particularly seen in patients with poor diet and alcoholism, pernicious anaemia, or terminal ileal Crohn's disease, as well as in those who are post gastrectomy. Bacterial overgrowth also utilizes vitamin B₁₂ within the small bowel. Overdosage does not seem to be a problem.

Table 333.1 Vitamin deficiency and associated syndromes

Vitamin	Symptoms of deficiency	Rare manifestations
<i>Water-soluble vitamins</i>		
Thiamine (vitamin B ₁)	Subclinical deficiency: <ul style="list-style-type: none"> • headache • tiredness • anorexia • muscle wasting Severe deficiency: <ul style="list-style-type: none"> • dry beriberi: symmetrical peripheral polyneuropathy (sensory and motor) • wet beriberi: neuropathy and congestive cardiac failure • Wernicke's encephalopathy • Korsakoff syndrome 	Leigh's syndrome: necrotizing encephalomyopathy
Riboflavin (vitamin B ₂)	Sore throat Oedema of mucous membranes Cheilosis Stomatitis Glossitis Normocytic–normochromic anaemia Seborrhoeic dermatitis	
Niacin (vitamin B ₃)	Glossitis Diarrhoea Vomiting Insomnia Fatigue Visual loss Anxiety Delusions Dementia Encephalopathy	Pellagra: photosensitive pigmented dermatitis, diarrhoea, and dementia; can be fatal.
Pantothenic acid (vitamin B ₅)	Paraesthesiae Dysesthesiae Gastrointestinal disturbances Irritability Malaise	Implicated in 'burning feet' syndrome of prisoners of war
Pyridoxine (vitamin B ₆)	Marginal deficiencies: <ul style="list-style-type: none"> • stomatitis • glossitis • cheilosis • irritability • mood disturbance Severe deficiency: <ul style="list-style-type: none"> • hypochromic anaemia • convulsions 	
Biotin (vitamin B ₇ ; vitamin H)	Myalgia Dysesthesias Nausea Glossitis Anorexia Hair loss Desquamating dermatitis	
Folic acid (folate; vitamin B ₉)	Anaemia Lemon-yellow tinge Glossitis	Megaloblastic anaemia Neural-tube defects at time of conception Hyperhomocysteinaemia
Cyanocobalamin (vitamin B ₁₂)	Anaemia Lemon-yellow discolouration Glossitis Stomatitis Progressive peripheral polyneuropathy Cognitive slowing	Subacute combined degeneration of the dorsal and lateral spinal columns Dementia Optic atrophy Megaloblastic anaemia Increased risk of osteoporosis Hyperhomocysteinaemia
Ascorbic acid (vitamin C)	Early symptoms: <ul style="list-style-type: none"> • fatigue • weakness • aching joints • muscles 	Late stages: <ul style="list-style-type: none"> • anaemia • petechial and sheet haemorrhages • delayed wound healing • bleeding gums

Vitamin	Symptoms of deficiency	Rare manifestations
<i>Fat-soluble vitamins</i>		
Vitamin A	Xerophthalmia Poor bone growth Skin problems Impairment of humoral and cell-mediated immunity Impaired hearing Taste and smell Reduced male fertility	In pregnancy, deficiency can result in malformations in offspring
Vitamin D	Subclinical deficiency may contribute to: <ul style="list-style-type: none"> • osteoporosis • bone pain • reduced immune function • hypophosphataemia • hypocalcaemia 	Persistent hypocalcaemia causes secondary hyperparathyroidism leading to osteomalacia Implicated in aetiology of several cancers
Vitamin E	Ataxia Hyporeflexia Dorsal column signs Skeletal myopathy Haemolysis	
Vitamin K	Prolongation of clotting time	Skeletal deformities or calcium deposition in the vasculature

Vitamin C deficiency

Marginal vitamin C deficiency compromises wound healing and limits antioxidant defences, while overt deficiency leads to scurvy, which in UK practice can be seen not uncommonly in alcoholics, patients with anorexia nervosa, and in those with long-term gastrointestinal disease with malabsorption. Scurvy manifests as gum hypertrophy, inflammation, loss of teeth, and skin rashes. Vitamin C toxicity does not seem to cause problems.

Deficiencies in fat-soluble vitamins

Vitamin A deficiency

Most people associate vitamin A deficiency with night blindness. This is rare in the UK, except in patients with severe fat malabsorption and, even worldwide, depletion to levels severe enough to cause retinal problems is rare. However, less severe depletion leading to increased vulnerability to gastrointestinal and respiratory infections and measles is common, with good evidence that oral vitamin A supplementation can reduce mortality by around 50%. Excess vitamin A can cause hepatotoxicity.

Vitamin D deficiency

Severe vitamin D deficiency leads to osteomalacia in adults, who may present with fractures but more commonly suffer from pelvic bone pain, muscle aches, and general weakness.

Many cells within the body exhibit vitamin D receptors and hence there must be many functions of this vitamin that are still poorly understood. At least 16 types of cancer, including breast, colon, ovary, and prostate cancer, have been linked to vitamin D deficiency due to poor sunlight exposure.

Deficiency occurs as a result of overt fat malabsorption and malnutrition, chronic kidney disease, or poor sunlight exposure. Modern life at high latitudes may not provide enough skin exposure to sunlight to permit full functional levels.

Overdosage can lead to metastatic calcification, hypercalcaemia, or pseudogout.

Vitamin E deficiency

Vitamin E has a role as an antioxidant and in immunity. Deficiency due to malabsorption can lead to neuropathy, myopathy, and compromised immunity.

Vitamin K deficiency

Deficiency in vitamin K is unusual, as this vitamin is produced by gut flora. However, long-term antibiotic use can diminish the

numbers of the colonic bacteria that synthesize absorbable vitamin K, and therefore can contribute to vitamin deficiency. Overdosage can lead to difficulty in achieving therapeutic effectiveness with warfarin.

Approach to diagnosing the disease

The most difficult step in diagnosing vitamin deficiency is frequently simply considering the diagnosis in the first place, especially since, as noted, deficiency is often subclinical without the signs and symptoms of the specific deficiency syndromes. A high index of suspicion for vitamin deficiency or risk of deficiency is therefore needed, with suspicions aroused for malnourished patients or those at risk on nutritional screening (i.e. all individuals with a body mass index of less than 20 kg/m², unintentional weight loss of over 5% in the previous 3 months, or those who have been eating or will be eating very little). Findings of brittle nails, angular stomatitis, glossitis, hair thinning, or oedema of unknown cause should prompt particular concerns and either specific investigation or pragmatic treatment.

After taking the initial step of considering vitamin deficiency, it would be good, if possible, to confirm any deficiency with simple blood tests. However, although most hospital pathology services can provide measurements of vitamin B₁₂, folic acid, and vitamin D, blood samples to confirm deficiencies of other vitamins or trace elements usually need to be sent to specialist centres; in addition, interpretation of results is problematic since:

- plasma or even red-cell vitamin levels may not reflect true functional tissue availability in vivo
- acute phase responses alter levels of binding proteins, and the degree of binding may increase or decrease levels found in plasma
- inflammation within the liver may lead to leakage of vitamins into the circulation, leading to artificially high levels (e.g. of vitamin B₁₂)

In view of these difficulties, a pragmatic approach will often need to be taken in making a diagnosis of vitamin deficiency in clinical practice.

Other diagnoses that should be considered

The differential diagnoses of the many vitamin deficiency syndromes are extremely broad and overlap with each other, as the associated symptoms and signs are generally fairly non-specific.

'Gold-standard' diagnostic tests

The gold-standard diagnostic tests for vitamin deficiency are shown in Table 333.2.

Acceptable diagnostic alternatives to the gold standard

Acceptable diagnostic alternatives to the gold-standard tests for vitamin deficiency are shown in Table 333.2.

Other relevant investigations

Other relevant investigations for vitamin deficiency are shown in Table 333.2.

Treatment and its effectiveness

Vitamin deficiencies should be treated in the wider context of dealing with malnutrition. General principles include ensuring generous micronutrient and vitamin supplementation during early feeding while avoiding excess provision of micronutrients that might encourage microbial growth or increase free radical damage. Additional specific vitamin supplements should be given to patients with overt deficiency states.

Giving single vitamin supplements to malnourished individuals can pose potential problems, both from direct toxicity of the vitamin itself (e.g. hepatotoxicity from vitamin A overdosage) but also by the possible unmasking of other deficiencies by driving certain metabolic pathways and, in the process, depleting substrates for these pathways, while possibly generating toxic excess products. A prime example of

Table 333.2 Vitamins: Deficiency and diagnosis

Vitamin	Gold standard	Acceptable diagnostic alternatives	Other relevant investigations
<i>Water-soluble vitamins</i>			
Thiamine (vitamin B ₁)	Thiamine status may be assessed by measurement of thiamine levels in blood or urine, before and after loading	Erythrocyte transketolase activity or its activation coefficient in haemolysed red blood cells is a functional measure of thiamine status	
Pyridoxine (vitamin B ₆)	High-pressure liquid chromatography	Pyridoxal phosphate has been determined enzymatically using tyrosine apodecarboxylase or by fluorimetric methods	Vitamin B ₆ status has also been assessed using erythrocyte aminotransferases and the tryptophan loading test
Folic acid (folate; vitamin B ₉)	Red-cell folate levels are more stable and reflect long-term intake	Serum folate is a short-term indicator of folate status	
Cyanocobalamin (vitamin B ₁₂)	As plasma levels may not be reliable, other markers have been identified (including methylmalonic acid, homocysteine, holotranscobalamin, anti-intrinsic factor antibodies) to establish functional activity	Measurement of vitamin B ₁₂ in plasma is routinely used to determine deficiency, but may not be a reliable indication in all cases; in pregnancy, for example, tissue levels are normal but serum levels are low Carrier levels are also influenced by the oral contraceptive pill, which may lead to apparently low blood levels when there is no real functional deficiency	Several methods have been devised (Schilling test, cobalamin absorbance test, serum gastrin deoxyuridine suppression test) to distinguish different causes of deficiency
Ascorbic acid (vitamin C)	Leucocytes contain higher concentrations of vitamin C than plasma, whole blood, or serum but measurement of leucocyte vitamin C is technically more difficult than estimation of plasma or urinary levels	Plasma and urinary vitamin C levels may be measured but reflect recent dietary intake rather than the level of vitamin C in body stores	
<i>Fat-soluble vitamins</i>			
Vitamin A	Hepatic concentration of retinyl esters is the most objective measure of vitamin A status, but cannot be readily determined in living individuals	The plasma retinol concentration is under homeostatic control by the synthesis of retinol-binding protein, and therefore is an insensitive indicator of status, except in cases of extreme depletion, when other signs of deficiency are already evident	Retinal function tests and assessment of retinol-binding proteins can also be used to assess vitamin A status
Vitamin D	The conventional marker of vitamin D status is plasma 25-hydroxyvitamin D; this marker is employed because it reflects the main storage form of precursor substrate for vitamin D, 1,25-dihydroxyvitamin D, the formation of which is under homeostatic control		DEXA
Vitamin E	Measurement of serum plasma concentration of alpha-tocopherol provides the simplest and most direct evidence of vitamin E status		
Vitamin K	A radioimmunoassay which measures the ratio of prothrombin to partially carboxylated prothrombin in plasma (the latter is formed during vitamin K deficiency) is now available	Functional tests of blood clotting can be used to assess vitamin K status	

this problem is that, due to the interaction between B₁₂ and folate, the administration of one can lead to severe depletion of the other.

We would therefore recommend that, since there are only limited means of determining which vitamin levels are compromised, a balanced preparation of all vitamins and micronutrients should be administered in suspected cases of deficiency. Care should be taken when prescribing, however, as some oral multivitamin preparations lack some vitamins and trace elements and, currently, there are no complete liquid vitamin preparations.

Some specific examples of patients for whom supplementation is essential are patients at risk of refeeding syndrome, patients suffering with alcoholic liver disease, patients who are elderly, and patients with non-healing wounds; in these cases, vitamin B₁ (thiamine) and multivitamin supplements should be provided.

If the result of a vitamin assay shows probable depletion, given the limitations in interpretation as outlined in 'Approach to diagnosing the disease', it is usually appropriate to provide additional specific

supplementation for around 2 weeks before rechecking levels. In general, total provision should be both balanced and supra normal in order to meet normal maintenance needs, possible raised demands of illness, and correction of depletion.

Successful treatment of vitamin deficiency depends on the underlying cause; simple inadequate nutritional intake due to poor diet is easy to correct, while complex malabsorptive disorders may require long-term IV nutrition.

334 Nutritional support in the critically ill

Matt Wise and Paul Frost

Rationale for nutritional support in the critically ill

Major injury evokes a constellation of reproducible hormonal, metabolic, and haemodynamic responses which are collectively termed 'the adaptive stress response', the purpose of which is to facilitate tissue repair and restore normal homeostasis.

The stress response is characterized by activation of the sympathetic nervous system, with concomitant increases in circulating catecholamines and increased secretion of pituitary hormones. Adrenocorticotropic hormone stimulates the release of cortisol, promoting protein catabolism as well as lipolysis and gluconeogenesis.

Additionally, injury and sepsis are associated with the release of cytokines such as tumour necrosis factor alpha, interleukin 1, and interleukin-6. These cytokines contribute to glucose intolerance and protein catabolism. The net effect of critical illness is an increased energy requirement coupled with a loss of total body protein.

If critical illness is prolonged, the adaptive stress response may become maladaptive, in essence exerting a parasitic effect leaching away structural proteins, (typically around 17% of muscle mass is lost after about 3 weeks) and impairing host immunity. This may be manifested by diaphragmatic weakness and prolonged ventilator weaning; impaired wound healing; and an increased propensity to infection.

Primarily, therapy should be directed towards the underlying illness, as nutritional support per se will not reverse the stress response and its sequelae. Nonetheless, adequate nutritional support in the early stages of critical illness may attenuate protein catabolism and its adverse effects.

Nutritional assessment of the critically ill

The main aims of nutritional assessment in the critically ill are to detect prior malnutrition, estimate energy and protein requirements, and monitor the effectiveness of nutritional replacement.

Detecting malnutrition in the critically ill

Malnutrition can be defined as a pathological state resulting from a relative or absolute deficiency in one or more essential nutrients. Malnutrition is associated with increased mortality and morbidity, and it is essential to screen all acutely ill patients for this condition. Although a variety of anthropometric (e.g. mid-arm circumference, triceps skinfold thickness), biochemical (e.g. levels of retinol-binding globulin, transferrin, pre-albumin); immunological (e.g. delayed hypersensitivity), and functional (e.g. skeletal muscle function) parameters have been utilized in the assessment of nutritional status, none is ideal, as they all lack sensitivity and specificity.

Nutritional assessment is best done using a combination of simple clinical parameters such as those incorporated in the Malnutrition Universal Screening Tool (MUST). MUST is a five-step screening tool which can be used to determine whether an adult is malnourished, at risk of malnutrition, or obese; it also provides guidelines for developing an appropriate management plan. Step 1 is to measure the BMI, Step 2 is to assess unintentional weight loss over the last 3–6 months, and Step 3 is to assess the acute disease and its effect on nutritional intake. At each of these steps, the result is given a score between 0 and 2. In Step 4, the scores obtained for the three steps are added together to provide a final score indicating the overall risk of malnutrition. This score then dictates the nutritional management plan, which is determined in Step 5. The majority of critically ill patients screened in this way have been shown to be at high risk of malnutrition and require nutritional support.

Energy and protein requirements in the critically ill

The energy required during critical illness depends on the type, severity, and phase of the illness, as well as the patient's activity levels. Burns, polytrauma, and septic shock are characterized by an enhanced hypermetabolic response and an increased energy expenditure, compared to other types of critical illness. As recovery occurs, the metabolic response to the illness converts from a catabolic to an anabolic phase, which is associated with an increase of fat and protein stores, and weight gain. Moreover, as activities such as spontaneous breathing and mobilization increase, energy expenditure increases further and should be accounted for when calculating nutritional requirements.

While underfeeding is obviously undesirable, gross overfeeding can cause hyperglycaemia, hepatic steatosis, and immune dysfunction, as well as increase carbon dioxide production and contribute to respiratory failure.

Indirect calorimetry devices allow non-invasive measurement of respiratory gas exchange, from which the energy expenditure can be calculated. While there are a number of formulae available for this purpose, the following equation, called the modified Weir equation, is most often utilized:

$$EE = (3.94 \times VO_2) + (1.1 \times VCO_2)$$

where EE is energy expenditure (in kilocalories per day), VO_2 is oxygen consumption (in millilitres per minute), and VCO_2 is carbon dioxide production (in millilitres per minute).

Although indirect calorimetry can reduce incidences of over- and underfeeding by providing accurate measurements of energy expenditure, there are a number of potential sources of error when using this technique. In critically ill patients, steady state conditions are easily disturbed by intercurrent illness such as seizures or sepsis; pain; anxiety; catecholamine use; altered ventilation; airway leaks; and increased inspired oxygen concentrations. Over the course of the day, measurements of energy expenditure may vary by as much as 23%.

Predictive equations can also be utilized to estimate energy expenditure in the critically ill. Examples include the Harris–Benedict equation and the Schofield equation. The Schofield equation estimates a basal metabolic rate based on age, sex, and weight, and per cent adjustments are made according to 'stress factors' for particular illnesses, the level of the patient's activity, and diet-induced thermogenesis. Such equations are frequently inaccurate in critically ill patients, often overestimating caloric requirements.

Amino acids released during protein catabolism are largely recycled, so the minimal daily protein requirement for adults is only about 20 g/day. During critical illness, this value varies, depending on the stage and severity of the illness, but is unlikely to be in excess of 80 g/day. Protein given in excess of this is used or is stored as energy.

A 24-hour urinary urea nitrogen test (UUN) can be used to calculate the nitrogen balance and hence determine the patient's protein requirements (1 g of nitrogen is equal to 6.25 g of protein). Nitrogen intake should be around 25% greater than the measured UUN to take account of other protein losses, for example from the digestive tract and skin. Nitrogen balance studies are of limited usefulness if extra-renal nitrogen losses are increased, for example from burns, wounds, drains, or stomas, or if the UUN cannot be measured because of renal failure.

An expert group from the European Society of Enteral and Parenteral Nutrition (ESPEN) have recognized the limitations of estimating energy and protein requirements in critically ill patients and

have made pragmatic recommendations. Thus, during the initial acute phase of critical illness, an exogenous energy supply in excess of 20–25 kcal per kilogram of body weight per day may be harmful but, during recovery (the anabolic flow phase), the aim should be to provide a total of 25–30 total kcal per kilogram of body weight per day. (This is inclusive of protein, which is usually administered at between 1.2 g/kg per day and 1.5 g/kg per day).

Monitoring the effectiveness of nutritional replacement in the critically ill

ICU patients receiving nutritional support need to be screened daily to ensure that nutritional goals are being met and that there are no complications associated with feeding.

Nutritional delivery in the critically ill

Nutrition can be administered directly into the gastrointestinal tract, as enteral nutrition, or given intravenously, as parenteral nutrition. In critically ill patients, there is a paucity of evidence that clearly demonstrates the superiority of enteral nutrition over parenteral nutrition. Indeed, because of gastrointestinal intolerance, it is frequently difficult to administer the prescribed amount of feed by the enteral route. Moreover, the increased rates of infection that have been historically described as being associated with parenteral nutrition may actually have been related to the under-treatment of hyperglycaemia, or excess lipid administration. Nonetheless, safety, cost, and feasibility generally favour enteral nutrition over parenteral nutrition as the preferred route of nutritional support in the ICU.

Enteral nutrition

Enteral nutrition is indicated in all critically ill patients who are not expected to be on a full oral diet within 3 days. It is usually administered via a gastrointestinal feeding tube and should be initiated within 24 hours of ICU admission, providing the patient has a functioning gastrointestinal tract and is haemodynamically stable.

Feed formulae for enteral nutrition

Polymeric feeds for enteral nutrition contain a mixture of nutrients similar to those encountered in a normal diet, and the majority of critically ill patients can be fed with such formulations. There are many commercially available polymeric feeds; typically, they are iso-osmotic (approximately 300 mOsmol/kg) and contain 1 kcal/ml as a mixed fuel system (45%–60% carbohydrates, 20%–35% lipids, and 15%–20% proteins). Micronutrients (i.e. trace elements and vitamins) are added so that full feeding matches recommended daily allowances for these micronutrients. These solutions are gluten-free, lactose-free, and sucrose-free.

Semi-elemental and elemental feeds are designed for patients with impaired digestion or absorption. These feeds contain predigested nutrients in the form of oligopeptides or amino acids, medium-chain triglycerides, and glucose. Such formulations have a high osmolality (approximately 630 mOsmol/kg) and often induce diarrhoea. These feeds should only be prescribed in the ICU for a specific indication (e.g. short bowel syndrome, pancreatitis, inflammatory bowel syndrome).

Soluble fibre, such as guar gum and pectins, is an important source of energy for the colonic enterocyte, while insoluble fibre, such as soy polysaccharides) increases stool bulk and shortens intestinal transit times. Despite these important properties, the efficacy of fibre in critically ill patients has not been proven, and not all polymeric feeds contain fibre.

Special-formulae feeds have been designed for patients with specific organ failures; for example, patients with chronic respiratory failure may benefit from feeds containing more fat than carbohydrate. The reason for this is that the respiratory quotient of fat is less than that for carbohydrate so that less carbon dioxide is produced from the oxidation of this feed. Other feeds have lower sodium and potassium contents and so may be helpful in the setting of renal or hepatic failure.

Immunonutrition

In recent years, it has been suggested that certain nutrients may have a beneficial effect on immune function in critically ill patients. These substances have been termed 'nutraceuticals'.

Glutamine

Glutamine is the most abundant non-essential amino acid in the body; it becomes conditionally dependent (i.e. requiring exogenous supplementation) during critical illness, as it is the preferred oxidative substrate for rapidly proliferating cells such as lymphocytes and enterocytes. Moreover, as a nucleotide precursor, it is intimately connected to protein synthesis. Consequently, glutamine is essential for preserving normal intestinal mucosal structure and function and may prevent translocation of harmful bacteria and bacterial products. Additionally, as an essential precursor of glutathione, glutamine has an important role as an antioxidant and as a regulator of ammonia balance and acid–base balance.

There is moderate evidence that glutamine reduces infection rates and days of mechanical ventilation in critically ill patients but it seems to have minimal or no effect on length of intensive care stay or risk of death.

Arginine, nucleotides, and omega-3 fatty acids

The amino acid arginine can modulate immune cells in several ways; for example, it can increase the number and activity of T-cells and enhance neutrophil phagocytosis. In addition, arginine metabolism is responsible for nitric oxide synthesis, which is of central importance in the inflammatory response. Although arginine levels are decreased in septic patients, supplementation does not appear to be beneficial.

Nucleotides are used in the synthesis of essential substances such as nucleic acids and adenosine triphosphate and have been shown to have immunostimulating effects on T-cells in vitro.

Omega-3 fatty acids are found in fish oil and have anti-inflammatory effects. Dietary substitution of omega-6 fatty acids, which are found in vegetable oils, by omega-3 fatty acids favours the synthesis of less active eicosanoids such as prostaglandin E3 and leukotriene B5, which may attenuate the inflammatory response.

A commercially produced feed enriched with arginine, omega-3 fatty acids, and nucleotides improved mortality in patients undergoing upper gastrointestinal surgery, as compared to a standard feed. Similarly, in patients with acute respiratory distress syndrome, a nutritional formula containing omega-3 fatty acids and antioxidants reduced the number of ventilator days, the length of the ICU stay, and the number of organ failures.

Administration of enteral nutrition

The majority of patients in the ICU are fed with a fine-bore (internal diameter 1.5 mm) nasogastric tube. These tubes are inserted with the aid of a wire stylet, and their position in the stomach is confirmed radiologically.

Post-pyloric feeding is indicated following upper gastrointestinal surgery (e.g. oesophagectomy) or if the small bowel is normal but there is refractory gastroparesis. Jejunal tubes can be placed intraoperatively (feeding jejunostomy) or endoscopically (nasojejunal tube).

The rate of accidental removal of nasoenteric tubes, either by agitated, uncooperative patients or during routine care, can be decreased by using a nasoenteric 'bridle.' This is fashioned from soft tape, which is passed through the nostrils and looped around the nasal septum and provides an anchor to which the nasoenteric tube can be secured.

Commercial feeds are usually presented in 500 ml containers, which are convenient for storage as well as being easy to handle at the bedside. Tubing is used to connect the container to the nasoenteric tube, and the feed is administered continuously using a pump. Enteral nutrition is usually managed according to locally agreed feeding protocols. The patient should be fed in a semi-recumbent position, as this is associated with a decreased incidence of ventilator-associated pneumonia. Typically, gastric residual volumes are checked every 4 hours. If the volumes are excessive (i.e. >300 ml), then consideration should be given to the causes of gastroparesis (e.g. sepsis, morphine derivatives) and to the instigation of prokinetic agents. Metoclopramide and erythromycin given intravenously improve gastrointestinal motility and tolerance to enteral nutrition. However, although gastroparesis is common in the ICU (e.g. affecting 40% of patients with head injuries), these drugs should not be used routinely; rather, they should be reserved for patients with high gastric residual volumes.

Complications of enteral feeding

Malposition of the feeding tube can have devastating consequences; for example, endobronchial placement can lead to pneumothorax or to the infusion of feed into the lungs. Tube insertion can cause significant bleeding and injury to the nasal pharynx, the oral pharynx, the oesophagus, or the stomach; in addition, it can cause sinusitis. Moreover, the aspiration of feed may lead to pneumonia. Finally, the feed may cause gastrointestinal intolerance, which can manifest as abdominal distension, nausea, vomiting, and diarrhoea.

Parenteral nutrition

Patients should receive parenteral nutrition when enteral nutrition is likely to fail or is contraindicated. Conditions where these circumstances can arise include prolonged ileus following major intra-abdominal surgery; high-output fistulae; short bowel syndrome; pancreatitis; enteritis; and thoracic duct injury with chylothorax.

Parenteral nutrition should be progressively introduced, starting at no more than 50% of estimated requirement and then increased to full feed over 3 days. Ideally, daily energy requirements should be measured but, when this is not possible, a target of 25 kcal per kilogram of body weight per day should be selected. Parenteral nutrition is given as a complete formulation in a single bag and infused continuously via a dedicated central or peripheral venous catheter.

In parenteral nutrition, carbohydrates and lipids are the principal energy sources, while amino acids are given to attenuate protein catabolism and reduce the loss of lean muscle mass.

Parenteral lipid solutions are composed of triglycerides, with phospholipids as emulsifiers. As an alternative energy substrate, lipids have a glucose-sparing effect and so help prevent hyperglycaemia. Moreover, lipid solutions provide linoleic and linolenic acid; deficiencies of these essential fatty acids can result in dermatitis, increased susceptibility to infection, and delayed wound healing. A number of lipid formulations are commercially available but, in the ICU, soybean oil-based emulsions, often referred to as long-chain triglycerides, tend to predominate.

Parenteral nutrition protein is provided as a balanced amino acid solution (i.e. one that is composed to maintain normal fasting plasma levels of essential amino acids).

According to ESPEN guidelines, parenteral nutrition for ICU patients should contain glucose, at a minimum of 2 g per kilogram of body weight per day (no more than 5–6 g per kilogram of body

weight per day), and lipids, at 0.7–1.5 g per kilogram of body weight per day. A balanced amino acid mixture should be infused at 1.3–1.5 g per kilogram of ideal body weight per day (this solution should contain glutamine at 0.2–0.4 g per kilogram of body weight per day). Finally, parenteral nutrition should contain one daily dose of multivitamins and trace elements.

Parenteral nutrition monitoring

In the ICU, parenteral nutrition monitoring includes 4-hourly vital signs (temperature, pulse, blood pressure, and respiratory rate), 1–6-hourly glucose levels, a daily full blood count, a daily INR, and daily liver function tests, as well as daily measurements of plasma electrolytes and magnesium, phosphate, and calcium levels. Baseline levels of trace elements, folate, ferritin, and vitamin B₁₂ should also be monitored.

Complications of parenteral nutrition

Complications of parenteral nutrition include catheter complications such as trauma, malposition, arrhythmias, air embolus, infection, and occlusion. In addition, solution-related complications, such as hyperglycaemia, electrolyte disturbances, metabolic acidosis, vitamin and trace element deficiencies, pulmonary oedema, and hepatic dysfunction, can occur.

Refeeding syndrome

Refeeding syndrome can occur when previously severely malnourished patients receive high carbohydrate loads. It is characterized by hypophosphataemia, hypokalaemia, hypomagnesaemia, and fluid abnormalities. These disturbances can lead to cardiorespiratory failure, cardiac arrhythmias, coma, and even death. Management includes electrolyte repletion and a reduction in feeding rate.

335 Poor diets

Rob Andrews and Clare England

Introduction

Apart from breast milk, no single food contains all the essential nutrients the body needs to be healthy and function efficiently. The nutritional value of a person's diet depends on the overall balance of foods eaten over a period of time, as well as on the needs of the individual.

Over the last 60 years, there has been increasing agreement about the balance of nutrients and foods that make up a 'good' diet. This consists primarily of wholegrains (i.e. cereal grains, or foods made from them, containing bran, germ, and endosperm, e.g. wholemeal breads, oatmeal, and dark rye); vegetables and fruit, including nuts and pulses; moderate amounts of fish and low-fat dairy foods; and limited amounts of meat. The consumption of saturated fat should be low, with saturated fat being replaced by mono- and polyunsaturated vegetable fats and fish oils. Trans-fatty acids should be minimized, and added sugar should provide no more than 10% of energy intake. However, as omnivores, humans can survive on a wide range of different foods, and many people worldwide eat diets that fall far short of this ideal.

The effect of poor diets

Poor diets are patterns of food intake that do not provide the right balance of nutrients for health. A poor diet can lead to an individual becoming deficient in or taking an excess of one or more nutrients. Excessive energy intake is associated with diabetes, cardiovascular disease, and cancer, whereas diets rich in fibre, fruit, and vegetables are associated with reduced risk. In 2001, some 33.9 million reported deaths worldwide were due to chronic diseases in which diet is known to have an impact, and about 3.9 million deaths in children under 5 each year are associated with undernutrition. Worldwide, there is a move away from 'traditional' diets rich in a variety of vegetables and wholegrains towards a pattern that has been described as a 'Western' dietary pattern: high in red and processed meats, high-fat dairy foods, refined grains, processed foods, and sugary foods and drinks, and low in fibre, fruit, and vegetables, contributing to the levels of chronic disease worldwide.

Nutrient excesses and deficiencies

Energy excess

Energy needs are affected by one's genome, activity levels, health, and environment. As a benchmark, 1900–2550 kcal/day will provide most adults with sufficient energy.

Energy intake in excess of requirements leads to obesity. The prevalence of obesity has increased worldwide and no longer occurs only in developed countries. Developing countries are experiencing a rapid shift to industrialized, more urbanized economies, alongside the globalization of mass media and increased advertising. This leads to changes to traditional dietary patterns, referred to as the 'nutrition transition'. The results of this are an increased consumption of animal fats, and foods high in fat and sugar and low in fibre. Simultaneously, there is a reduction in physical activity. These two changes result in increased obesity levels. This has produced a worldwide rise in diseases linked with obesity: diabetes, coronary heart disease, stroke, and certain cancers (e.g. oesophageal cancer, pancreatic cancer, colorectal cancer, breast cancer, endometrial cancer, and renal cancer).

To prevent obesity, the WHO recommends a shift away from diets containing a high proportion of high-fat, high-sugar, energy-dense foods and high-sugar drinks towards greater consumption of

foods that are lower energy and micronutrient (vitamins and minerals) rich—vegetables, legumes, fruit, and wholegrains—alongside an increase in physical activity.

Energy/protein deficiency

Despite the global rise in obesity, energy deficiency remains widespread. In 2007 some 923 million people worldwide had energy intakes below that required for an active, healthy life; this represents an increase of 75 million over 2 years. Most of these people live in developing countries. In the UK, energy deficiency is most commonly seen in the elderly, 70% of whom are not diagnosed.

Energy deficiency results in weight loss due to loss of body fat and muscle mass. Essential tissue is preserved for as long as possible. Involuntary energy deficiency is accompanied by deficiencies in protein and micronutrients. Protein-energy malnutrition (PEM) results in general muscle wasting which causes the muscle fibres to shrink. The spaces between the cells fill with extracellular fluid, leading to oedema and thus masking tissue loss. Protein is lost from the skin and internal organs, increasing the risk of infections, although brain tissue is preserved. In severe PEM, the gut ceases to function normally, and diarrhoea can occur in the absence of infection, causing life-threatening dehydration.

Fetal, chronic infant, and childhood undernutrition causes retarded growth and stunting and increases the risk of coronary heart disease, stroke, diabetes, and hypertension in later life. Chronically undernourished people reduce non-essential activity, are more likely to take naps, and tend to be less socially active than their better-nourished peers.

Undernutrition coexisting with overnutrition

Undernutrition remains prevalent in developing countries but there is also a rise in the number of people affected by obesity. In China, overweight has increased fastest amongst low-income and rural adults, due to a shift towards diets consisting primarily of cheap refined starches, vegetable oils, and cheap and processed meats. These energy-dense diets are low in fibre, vegetables, and fruit and can be deficient in essential micronutrients. Individuals living on these diets can simultaneously be overweight and at risk of poor health due to deficiency. The burden of ill health is further worsened if an individual experienced chronic undernutrition early in life: excessive weight gain in people affected by stunting further increases the risk of diabetes, cardiovascular disease, and certain cancers. An estimated 2 billion people suffer from 'hidden' hunger, meeting or exceeding calorie and protein needs but being deficient in one or several micronutrients.

Effective interventions include government regulation to ensure a healthier composition of staple foods, and programmes involving diet and physical activity advice in the workplace, community, schools, and primary healthcare settings. Pricing strategies to encourage healthier choices have been found to be moderately effective.

Protein excess

The reference dietary value for protein in the UK is 0.75 g of protein per kilogram of body weight. Most non-vegetarians, and many lacto-vegetarians, in the developed world eat intakes in excess of this and may easily exceed twice this if physically active.

In the UK, guidance exists to avoid daily protein intakes in excess of 1.5 g of protein per kilogram of body weight, due to concerns of the effect on renal function, bone health, blood pressure, kidney stones, and certain cancers. An FAO/WHO panel discounted these

concerns in individuals at low risk of kidney failure in 2007, concluding there is no need for protein restriction. High intakes of red and processed meats have been linked with colorectal cancer, although this does not appear to be due to high intakes of protein per se.

Athletes, keen to increase muscle mass, may consume 3 g of protein per kilogram of body weight from food and a further 1 g of protein per kilogram of body weight from supplements. These levels are not harmful in the short term, but it is unknown what impact, if any, they have on chronic diseases later in life. Protein intakes at this level result in increased oxidation of amino acids rather than increased synthesis of muscle, making them ineffective for the purpose used. An upper level of around 2.0–2.5 g of protein per kilogram of body weight is more appropriate.

Very high intakes of protein (>45% energy intake; >5 g of protein per kilogram of body weight) can cause 'rabbit starvation', symptoms of which are nausea, diarrhoea, hyperaminoacidaemia, hyperinsulinaemia, and hyperammonaemia and which can lead to death.

Vitamin and mineral deficiencies

Micronutrients (vitamins and minerals) are nutrients that are needed in small quantities throughout life. They are necessary for a wide range of processes, including immunity; brain and nervous system development; cognitive processes; skeletal and muscular growth and function; gastrointestinal function; and vision. Deficiencies lead to specific illnesses as well as an increased susceptibility to infection, delayed recovery, and reduced response to vaccination. This can contribute to further deficiency. There are various approaches to tackling micronutrient deficiency worldwide. The main approaches are food fortification of commonly eaten staples (e.g. cereal foods fortified with folic acid; salt fortified with iodine); the mass provision of supplements, such as vitamin A, via community-based volunteers or during immunization programmes; improving access to food by encouraging home gardening and local cooperatives; and providing nutritional education to change habits and promote dietary diversity. Also important is the treatment of illnesses that result in nutrient deficiencies, such as diarrhoea, malaria, and worms.

It is unclear how many people are affected by micronutrient deficiencies. However, some 500 000 children become blind annually due to xerophthalmia (vitamin A deficiency), and half of pregnant women worldwide are anaemic (half due to iron deficiency), with anaemia being associated with 20% of maternal deaths. In addition, 1.9 billion people do not get enough iodine, and iodine deficiency disorders (e.g. cretinism, deaf mutism, mental retardation, and increased risk of miscarriage) affect 13% of the world's population. Folate deficiency, which is responsible for neural tube defects, appears to be widespread, ranging from 26%–80%, and is probably the most common micronutrient deficiency in developed countries; it is caused by low intakes of green leafy vegetables and wholegrains.

Low vegetable and fruit consumption

Low fruit and vegetable consumption is estimated to contribute to 2.6 million deaths, 11% of strokes, and 31% of ischaemic heart disease. About 1.8% of the global burden of disease is attributable to low consumption of fruit and vegetables, with the greatest burden seen in middle-income European countries, and South East Asia.

The WHO recommends consuming 400 g of fruit and vegetables per day, not including starchy vegetables like potatoes, yams, taro, and cassava. This represents a minimum amount and is of particular importance for reducing the risks of developing cardiovascular disease, diabetes, and obesity, as well as avoiding micronutrient deficiencies. Attempts have been made to quantify the protective effects of increased fruit and vegetable intake on health: an increment of one serving per day is associated with a 6% reduction in ischaemic stroke and a 4% lower risk of fatal ischaemic heart disease. Small inverse associations have been found for overall cancer risk.

Fruits and vegetables are high in fibre, vitamins, phytonutrients, and potassium and low in energy. The health benefits from increased consumption of fruits and vegetables seem to be due to the foods as a whole rather than to individual nutrients.

To increase consumption, many countries run public health campaigns, such as the 'five a day' message. In the UK, consumption is, on average, 2.8 servings/day. People cite barriers such as disliking vegetables and fruit, not being confident in preparing vegetables, lack of time, and lack of availability. Worldwide, though, the greatest barrier is cost.

Poor diets, and types of fat

An unsaturated fat is a fat or fatty acid in which there are one or more double bonds in the fatty acid chain. A fat molecule is mono-unsaturated if it contains one double bond, and polyunsaturated if it contains more than one double bond. Unsaturated fatty acids show geometric isomerism: the doubly bonded carbon atoms either have their attached hydrogens on the same side (cis) or have them on opposite sides (trans). Cis fatty acids are bent and cannot stack easily, so they have a lower melting point. Where double bonds are formed, hydrogen atoms are eliminated. Thus, a saturated fat is 'saturated' with hydrogen atoms.

Diets high in saturated fats are strongly associated with coronary heart disease, perhaps because these fatty acids raise total and LDL cholesterol. The main sources are meat and dairy products; this fact perhaps explains why the traditional Northern European, American, and Australian diets are associated with a higher risk of coronary heart disease.

Trans-fatty acids, produced by the partial hydrogenation of vegetable oils, raise LDL cholesterol, lower HDL cholesterol, and raise triglycerides, making them particularly atherogenic. They may promote inflammation, having been associated with increased levels of interleukin 6 and C-reactive protein. Diets high in deep-fried fast foods, manufactured baked goods, sweets, and savoury snack foods may be high in trans fats. In northern India, the consumption of vanaspati, made from vegetable oil and containing over 40% trans fats, can be as high as 20 g per person per day; its use is widespread in food manufacturing and street foods. In recent years, legislation, voluntary changes by food manufacturers, and better food labelling has reduced the amount of trans fats used in many countries.

Ideally, saturated fats should make up less than 10% of total energy intake and should be replaced with monounsaturated fats such as rapeseed or olive oil. High-fat dairy produce should be replaced with low-fat dairy; consumption of fatty meats should be kept low; and it is recommended that people aim to eat between one and two portions of fish each week, with one of these being a portion of oily fish (e.g. mackerel, sardines, herring, salmon, or trout). Trans fats should account for less than 2% of total energy intake.

Poor diets associated with food preparation

High consumption of meats preserved by smoking, salting, or the addition of nitrates or nitrites (i.e. bacon, ham, and salami) was strongly linked to an increased risk of colorectal cancer and less strongly linked with cancers of the oesophagus, stomach, lung, and prostate by the World Cancer Research Fund. It has been proposed that this is due to the formation of mutagenic *N*-nitroso compounds during the preservation of the meat, and to haem-induced carcinogenesis. However, high consumption of preserved meat products has also been linked to a generally poorer diet containing low levels of fruit and vegetables, and high levels of refined carbohydrates and alcohol.

High consumption of red meat has been strongly associated with colorectal cancer and less strongly associated with stomach cancer. This may be due to cooking methods, as the high temperature cooking of meat, to 150°C or higher, also produces mutagenic heterocyclic amines and polycyclic aromatic hydrocarbons.

Heavy metals from cookware may contaminate food, although it is not known how this impacts upon the burden of disease worldwide. Lead can leach from glazed earthenware into *leben*, a traditional Tunisian acidified milk drink, and can contaminate food when unheated spices are ground in earthenware pots in Mexico.

'Junk food'

The term 'junk food' is a shorthand term for foods that either have little nutritional value or are high in nutrients considered undesirable. This is an inexact definition, and classification depends on what cultural role foods play in the diet: chips are considered to be 'junk food', but roast potatoes are not; takeaway fried chicken is considered to be 'junk food', but Wiener schnitzel is not. The term is also used to refer to cheap, highly processed, ready-to-eat or takeaway foods that are energy dense, high in fat and salt/sugar, and low in fibre and contain few micronutrients.

Inexact or not, the term is widely used. A dietary pattern of high levels of processed, low-nutrient, energy-dense foods is identified as a 'junk food pattern' and is associated with hyperactivity, smoking, and sedentary behaviour in children and adolescents.

336 Obesity

Mimi Chen and Rob Andrews

Introduction

Obesity has been around for more than 20 000 years, as evidenced by statuettes produced in the Stone Age. Body mass index (BMI), calculated as weight divided by the square of the height, is one of the simplest and most common ways of defining obesity. A BMI between 18.5 and 24.9 is classed as normal. BMI values of 25.0–29.9 suggest overweight, and any values over 30 are deemed obese (see Table 336.1). Across populations, BMI is closely associated with whole body adiposity, and the cut-off levels for overweight and obesity reflex the increasing risk of metabolic, cardiovascular, and other complications of obesity as BMI increases above the normal range.

Obesity is widely agreed to be caused by a prolonged period of energy imbalance. In 95% of cases, it is due to the impact of an obesogenic lifestyle (overconsumption of energy and/or insufficient energy expenditure) on a variable background of genetic susceptibility. The remaining cases are caused by certain drugs, specific endocrine diseases, and monogenic syndromes (see Box 336.1).

Epidemiology of obesity

Worldwide, obesity is common and rapidly increasing. Currently, more than 1 billion adults are overweight (BMI 25.0–29.9) and at least 300 million of them are clinically obese (BMI >30). Obesity is most prevalent in Westernized countries, with up to one-third of adults being affected, but it is rapidly increasing in the developing world. The global distribution of overweight, including obesity, is shown in Figure 336.1.

Most countries are showing a steady rise in the prevalence of overweight and obesity. In the UK and USA it is predicted that by 2020 37% of men and 40% of women will be obese.

Cost of obesity to society

The cost to society of obesity is huge, with it accounting for 6% of direct health expenditure in Europe. In the UK, the current cost to the National Health Service is estimated to be £4.2 billion and is forecasted to more than double by 2050.

Table 336.1 The WHO international classification of adult underweight, overweight, and obesity according to BMI

Classification by BMI (kg/m ²)	
Underweight <18.5	
Severe thinness	<16.0
Moderate thinness	16.0–16.9
Mild thinness	17.0–18.49
Normal weight 18.5–24.9	
Overweight ≥25.0	
Pre-obese	25.0–29.9
Obese ≥30.0	
Obese class I	30.0–34.9
Obese class II	35.0–39.9
Obese class III	≥40.0

Box 336.1 Causes of human obesity

Common or lifestyle-related obesity >95% of cases

- genetic susceptibility (polygenic)
- obesogenic lifestyle (overconsumption of energy and/or insufficient energy expenditure)

Secondary obesity (<5%)

Obesogenic drugs

- corticosteroid
- diabetes medication
- antipsychotic drugs

Endocrine disorders

- hypothyroidism
- Cushing's disease
- hypopituitarism

Inherited syndromes

- Prader–Willi syndrome
- fragile X syndrome
- Alström syndrome

Monogenic disorders

- leptin
- melanocortin-4 receptor

Cost of obesity to the individual

Obesity subjects a person to unwanted social, psychological, and physical disadvantages. The combination of these factors inevitably creates negative impacts on the individual's quality of life. Socially, obesity is still associated with undesirable stigma, and this affects all aspects of life. Over the last 50 years, many surveys and reports have found that obese children perform less well and are more likely to be placed into remedial classes at school; obese adolescents, especially young overweight women, have lower acceptance rates for universities and receive less financial support from home; and obese adults are subjected to a higher percentages of prejudice in their employment and are often perceived as lacking in self-control and drive. Obesity has also been shown to impinge on personal relationships as well as marriage prospects.

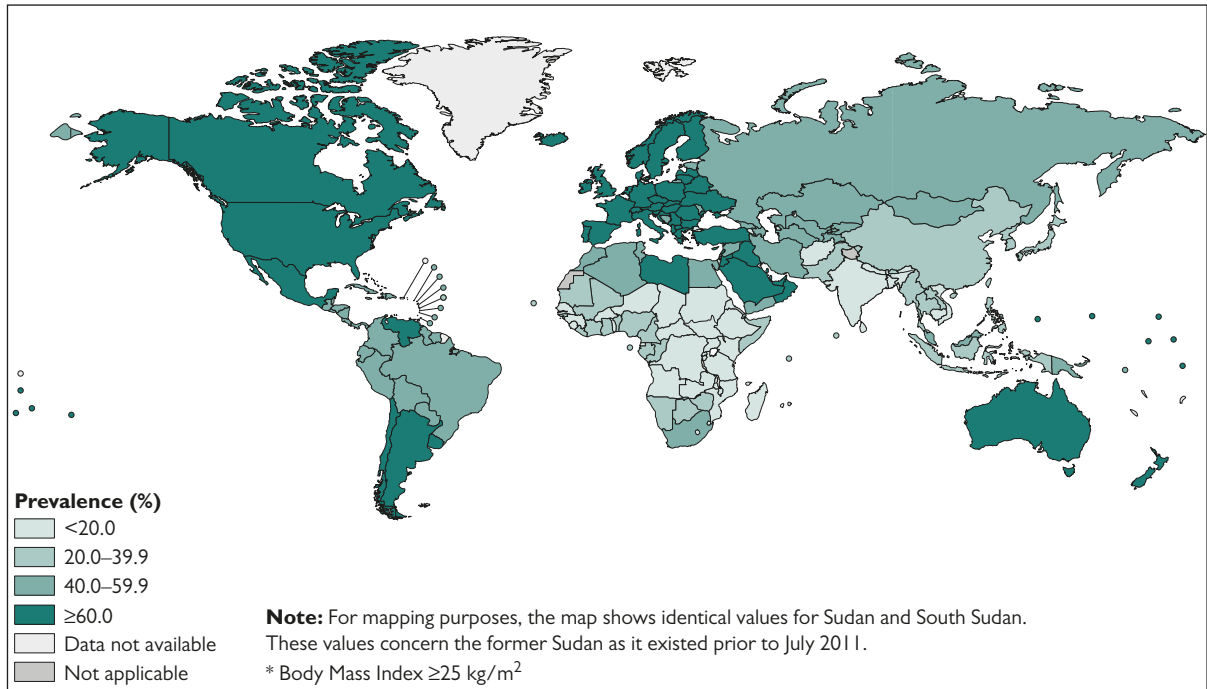

Health hazards of obesity

Obesity has been linked with various diseases. Associations are recognized with type 2 diabetes mellitus (T2DM), hypertension, dyslipidaemia, and coronary heart disease, as well as osteoarthritis, polycystic ovarian syndrome, obstructive sleep apnoea, and obesity-hypoventilation syndrome. Obesity has also been implicated in several malignancies and in chronic renal failure. Population surveys have estimated that obesity accounts for 60% of the risk of developing T2DM, 30%–40% of the risk of developing hypertension or endometrial cancer, 20%–25% of the risk for coronary heart disease and stroke, and approximately 10% of the risk of developing carcinoma of the breast or of the colon (see Figure 336.2).

Psychiatric diseases associated with obesity include anxiety, depression, bipolar disease, and two distinct eating disorders: binge eating disorder and night-eating syndrome. In women, obesity is associated with a higher risk of major depression; in contrast, the risk

Figure 336.1 Continued

Figure 336.2 Percentage of risk of disease due to obesity.

in men is decreased. As well as affecting the patients' quality of life, these disorders can reduce their adherence to obesity management and thus affect the clinical outcomes.

Obesity also significantly shortens life expectancy, especially in men. The risk from premature death increases with each increment in BMI, such that individuals with a BMI >30 are at a two- to fourfold increased risk of dying prematurely. In England, obesity has been estimated to shorten life on average by 9 years. Physical inactivity further increases this risk of dying early, with the combination of physical inactivity and obesity thought to account for 30% of all premature deaths worldwide.

Prevention of obesity

Given the long list of diseases that it causes and the poor record of treating it, obesity is a disease that needs to be prevented. Prevention should be distinguished from treatment, with it aiming to reduce or stabilize weight or, in the case of children, limiting weight gain so that overweight children grow into normal-weight adults. Prevention of obesity comprises three stages: primary (to prevent normal-weight subjects from becoming overweight), secondary (to prevent overweight patients from becoming obese), and tertiary (to prevent obese subjects from developing the comorbidities of obesity).

Primary and secondary prevention

Many primary and secondary prevention strategies have been tried. The majority of these have failed to improve obesogenic behaviours and/or reduce the prevalence of overweight or obesity. Those that have succeeded involve multidisciplinary teams, are population wide, sustainable, and address social, ethnic, and cultural diversity.

Breastfeeding reduces the risk of overweight and obesity by as much as 20% for 4 years and should be encouraged. Strategies to encourage the whole family to exercise are also helpful for limiting weight gain in preschool children. School-led programmes, with parental support, that promote healthy eating and increased exercise to replace sedentary play have been successful, although the benefits are often short-lived. A few workplace and community-based programmes that target adults have been successful but few have had lasting effects.

Tertiary prevention

In people with established obesity, it is imperative to prevent subsequent development of comorbidities. Lifestyle modifications are still the central theme in this population and have met with some success. The majority of programmes have targeted the prevention of diabetes. One such example is the Diabetes Prevention Program study, which showed that, with lifestyle modification, including a low-fat, low-calorie diet and moderate exercise of 150 minutes per week, that they could reduce the incidence of diabetes by 58% in a group of overweight participants with impaired glucose tolerance. These results indicate that changes in diet and physical activity can be introduced and sustained in a clinical trial. The challenge is to find methods for achieving similar changes in the community.

Special circumstances

Certain population are at increased risk of gaining weight and, where possible, help should be provided.

Smoking cessation

Many smokers are reluctant to stop smoking for fear of weight gain. Although most people will gain less than 4.5 kg, 13% of the people may gain as much as 11 kg. Weight gain mostly occurs within the first 2 months of smoke cessation and is due to increased energy intake, reduced metabolic rate, and reduced physical activity. Prevention strategies should be considered to lessen the possibility of weight gain after smoking cessation.

Exercise should be recommended, as it reducing craving and withdrawal symptoms and halves weight gain. Greater benefits are seen when it is used as part of a cognitive behavioural smoking cessation programme.

Bupropion, an atypical antidepressant, may be considered as a supplement to help patient minimize weight gain after smoking cessation, although the evidence of its effectiveness is not robust. Nicotine replacement therapy is commonly given as part of the cessation programme and can be very effective in limiting weight gain. However, on withdrawal of nicotine replacement, the patients can gain as much weight as those who were not on the replacement.

Pregnancy

There is substantial evidence that obesity in pregnancy contribute to increased morbidity and mortality for both mothers and babies. The CEMACH maternal death enquiry has found that 35% of women who died were obese, and 30% of mothers who had stillbirths were also obese.

Prior to pregnancy, obese women should be provided with information about the possible complications of obesity, and encouraged to lose weight before conception. Diet, exercise, and behavioural therapy again should comprise the first-line therapy. If pharmacological therapy is required, then metformin and orlistat can be safely used.

Weight loss is not advocated during pregnancy; the aim instead is to limit weight gain to 7–11 kg for overweight women, and to 7 kg for obese women. Screening for glucose intolerance should be carried out at presentation and repeated later in pregnancy if the initial screening test is negative; in addition, blood pressure should be monitored closely, as obese women are at increased risk of pre-eclampsia.

Family histories of T2DM and obesity

In those with a family history of T2DM and obesity, the risk of developing obesity and its associated comorbidities is higher than in the general population. These patients should be provided with information on the importance of weight management and possible complications related to obesity. Lifestyle modification is likely to be the most cost-effective way of obesity prevention.

Iatrogenic obesity

Weight gain can be a side effect of many treatments such as corticosteroids, anti-diabetic medications, and some antipsychotic drugs. Where possible, a non-obesogenic drug should be used (Table 336.2); if this is not possible, then the lowest dose for the least time possible should be used.

Endocrine diseases such as hypothyroidism, Cushing's disease, and hypopituitarism can cause weight gain and, where appropriate, looked for. Weight generally falls on treatment of these conditions.

Treating obesity or limiting the impact of obesity

Established obesity is very difficult to treat with the currently available medical treatment, and often the effects are not long-lasting.

Lifestyle modification

Lifestyle modification is essentially the first-line treatment in all cases of obesity. A low-fat, low-calorie diet of 1000–1500 kcal per day in combination with moderate exercise of 150 minutes a week, with additional support from health professionals often produces good

Drug class	May cause weight gain	Less weight gain, weight neutral or weight loss
Antipsychotics	Clozapine Risperidone Olanzapine	Ziprasidone Aripiprazole
Antidepressants and mood stabilizers	Citalopram Lithium MAOIs TCAs Venlafaxine Mirtazapine Paroxetine	Bupropion Sertaline Fluoxetine
Anticonvulsants	Carbamazepine Gabapentin Valproate	Lamotrigine Topiramate
Diabetes drugs	Insulin Sulfonylureas Thiazolidinediones	Metformin Acarbose Exenatide and liraglutide Sitagliptin, vildagliptin & saxagliptin
Antihypertensives	Alpha blockers Beta blockers	ACE inhibitors Calcium channel blockers
Oral contraceptives	Progesterone-only pill Combination pill with progesterone	Barrier method IUDs

Abbreviations: ACE, angiotensin-converting enzyme; IUD, intrauterine device; MAOI, monoamine oxidase inhibitor; TCA, tricyclic antidepressant.

results for people in a weight management program. However, lifestyle change can be difficult to adhere to in the long run for some, and they may require medical intervention to achieve weight loss.

Eating disorders have higher prevalence in the obese population. They can impinge on the obesity treatments and reduce their long-term effectiveness. Studies have shown that behavioural interventions, cognitive behavioural therapy, and interpersonal psychotherapy are useful treatment tools for patients with eating disorders, as these methods are effective for both treating eating disorders and achieving weight reductions, especially when used as part of a weight management program.

Complementary and alternative medicine

Complementary and alternative medicine therapies have become popular for weight reduction as they are viewed as natural and easily accessible and are perceived to be effective. The methods of choice for weight control are yoga, meditation, massage, acupuncture, and eastern martial arts such as tai chi and qi gong, as well as hypnotherapy, homeopathy, and herbal remedies.

Many reviews of non-prescription supplements have shown that the weight reduction achieved is statistically significant, but the effect is modest. With inappropriate use, some supplements can have unwanted adverse effects, such as increased risks of psychiatric symptoms, gastrointestinal symptoms, and palpitations. Hypnotherapy has shown to produce reasonable weight reduction (5–6 kg) when used as an adjunct to dietary advice or in combination with cognitive behavioural therapy as part of a weight management plan. However, the results are, again, clinically debatable and, due to the general lack of substantial randomized controlled trials or larger clinical trials, complementary and alternative medicine is not recognized as a definitive treatment for obesity. However, it may be used to supplement pharmaceutical agents and surgical interventions to obesity.

Weight loss drugs

When weight reduction is not achieved through lifestyle modification alone, anti-obesity medications (Table 336.3) are often considered. These are available for obese individuals who have been on lifestyle modification for at least 6 months duration with minimum weight reduction. The current National Institute for Health and Care

Name	Average weight loss (kg)	Patients selection	Side effect
Orlistat	2.9	In patients with or without diabetes mellitus	Gastrointestinal symptoms & Steatorrhea
Metformin	0.5–4		Gastrointestinal symptoms
Topiramate	6–9		Mood changes and cognitive dysfunction
Exenatide/ Liraglutide	2–3	In patients with diabetes mellitus only	Gastrointestinal symptoms
Pramlintide	4–6		Gastrointestinal symptoms and hypoglycaemia

Excellence (2006) guideline on obesity prevention suggests that orlistat, the only remaining simple anti-obesity agent, following the recent withdrawal of sibutramine due to increased cardiovascular risks, should be considered for both first- and second-line treatment after lifestyle modification. Orlistat should only be continued if patients have achieved the required weight loss, which is 3% weight loss at 3 months or 5% weight loss at 6 months, while on treatment. More specialized anti-obesity agents, such as metformin, selective serotonin reuptake inhibitors, and topiramate, are often tried in specialist obesity clinics if patients fail to achieve weight loss with this treatment plan. Saxenda® (liraglutide 3mg), a GLP-1 analogue, was marketed in January 2017 in the UK as a weight loss medication for obese patients with a BMI >30 or BMI greater than or equal (please us sign) 27 in the presence of at least one weight related comorbid condition. In clinical studies it produced on average a 5.7 Kg weight loss. Mysimba® (naltrexone-bupropion), recently launched in the UK can be used in a similar population and on average causes a 3.5 kg weight loss. Both of these drugs are only currently available on private prescription in the UK.

Bariatric surgery

Bariatric surgery has now, in selected groups, been shown to improve the cardiovascular risk factor profile, reduce cancer incidence, and reduce mortality. In recent years, bariatric surgery has been made available on the NHS for those who have a BMI >40 and those who have a BMI >35 and have comorbidities (e.g. T2DM, hypertension, cardiovascular disease, and obstructive sleep apnoea), or BMI > 30 with T2DM diagnosed in the last 10 years after they have received medical intervention and are deemed suitable for surgery. There are three types of bariatric surgery that are performed in the UK: gastric banding and vertical sleeve gastrectomy, both of which are restrictive procedures, and the Roux-en-Y gastric bypass, which is a malabsorptive procedure.

Surgery is currently the only treatment that has shown to produce long-lasting weight reduction and lasting improvement on comorbidities.

However, even in the hands of an experienced surgeon, bariatric surgery is still associated with a mortality rate of up to 0.3%. Post-operatively, patients require long-term follow-up and monitoring for potential surgery-related complications. Therefore, this approach should only be considered as a last resort and offered to people who are unable to maintain long-term weight loss.

337 Physical activity and its role in disease prevention

Melvyn Hillsdon and Tim Anstiss

All parts of the body which have a function if used in moderation and exercised in labours in which each is accustomed, become thereby healthy, well-developed and age more slowly, but if unused they become liable to disease, defective in growth and age quickly.

Hippocrates

Introduction

Regular physical activity is one of the most powerful protective and therapeutic factors known to medicine, and this has been recognized for millennia. It protects people from a wide range of health problems and benefits over 20 conditions and diseases, including coronary heart disease, stroke, diabetes, chronic pain, depression, frailty, and cancer. It is also associated with positive mental well-being and a healthy body weight. Among older people, physical activity is associated with better health and cognitive function and can reduce the risk of falls in those with mobility problems.

Taking insufficient physical activity has been estimated to be the fourth leading risk factor for deaths and burden of disease globally, ahead of overweight or obesity. Lack of physical activity may contribute to almost one in ten premature deaths from coronary heart disease (CHD) and one in six deaths from all causes. Population levels of physical inactivity are also hugely costly, with direct costs to the National Health Service estimated at over £900 million in 2009/10. Inactivity is detectable and reducible in individuals and groups.

Definition and measurement

Physical activity can be defined as any bodily movement produced by contraction of skeletal muscles and resulting in caloric expenditure. It includes, but is not limited to, exercise, which can be defined as a subcategory of physical activity that is planned, structured, and repetitive. Physical activity includes occupational physical activity, recreational physical activity, transport physical activity, domestic physical activity (housework, gardening, etc.), and sport. The amount of physical activity a person takes can be measured in terms of frequency, intensity, duration, and type (e.g. aerobic, strength, flexibility, and speed).

Mechanism of benefit from exercise

Recommended amounts

A distinction should be made between physical activity (which is a behaviour) and fitness (which is a measure of a person's capacity to do physical activity, e.g. the maximum amount of oxygen that their muscles can take up per kilogram of body weight per minute, or their maximum strength). Physical activities, such as walking, running, playing sport, or lifting weights, will typically result in improved fitness, but a significant percentage of the variation in fitness levels is genetically determined. Becoming more active and becoming more fit are both likely to yield health and well-being benefits, and a skilled practitioner can tailor a physical activity programme to deliver the specific health, well-being, and functional benefits desired by the patient.

Some of the benefits of a session of physical activity only last a few hours—for instance, the blood-thinning effects, the blood-pressure-lowering effect, the reduction in sugar and fats in the blood, the muscular relaxation effects, and the psychological well-being effects (e.g. the feelings of pleasant fatigue). They cannot be

stored up but, like medication, need to be taken regularly to have a health benefit. This has been called the 'last dose' effect.

UK and global physical activity guidelines recommend that all adults should aim to be physically active each day and, over the course of a week, should undertake at least 150 minutes (2.5 hours) of moderate intensity (equivalent to brisk-to-fast walking) physical activity in bouts of 10 minutes or more. Comparable benefits can be achieved through 75 minutes of vigorous intensity activity spread across the week, or combinations of moderate and vigorous intensity activity. In addition to taking moderate or vigorous aerobic activity, current UK guidelines recommend that adults aged 19 and over should also undertake muscle strengthening resistance-type activity on at least two days a week to increase bone strength and muscular fitness. Current UK guidelines also recommend that adults aged 65 and over at risk of falls should perform activities to improve balance and co-ordination at least twice each week.

Size of the risk, and strength of the evidence

There is strong evidence that physical inactivity reduces life expectancy and is a major cause of non-communicable diseases, including coronary heart disease (CHD), type 2 diabetes, breast cancer, and colon cancer. Globally, inactivity increases the risk of premature mortality by 28%, the risk of CHD by 16%, type 2 diabetes by 20%,

Table 337.1 The strength of the evidence for the health benefits of regular physical activity

Health benefit	Strength of evidence
Lower risk of:	
• premature death	Strong
• coronary heart disease	Strong
• stroke	Strong
• high blood pressure	Strong
• adverse blood lipid profile	Strong
• type 2 diabetes	Strong
• metabolic syndrome	Strong
• colon cancer	Strong
• breast cancer	Strong
• depression	Strong
Prevention of weight gain	Strong
Weight loss in conjunction with a reduced calorie intake	Strong
Prevention of falls	Strong
Better cognitive function in older adults	Strong
Better physical function for older adults	Moderate to strong
Lower risk of:	
• hip fracture	Moderate
• lung cancer	Moderate
• endometrial cancer	Moderate
Increased bone density	Moderate
Improved sleep quality	Moderate
Weight maintenance following weight loss	Moderate

breast cancer by 33%, and colon cancer by 32%. The strength of the evidence linking regular physical activity to a range of health benefits is summarized in Table 337.1.

Disease burden

It is estimated that 9% of deaths worldwide are due to physical inactivity, equivalent to 5.3 million deaths per year globally and similar to the global burden of mortality associated with smoking. It is also estimated that physical inactivity is the cause of 6%–10% of cases of CHD, type 2 diabetes, breast cancer, and colon cancer.

It is estimated that physical inactivity contributed over £1 billion to the direct health cost burden to the NHS. In England alone, over 35 000 deaths (from just five conditions: postmenopausal breast cancer, lower gastrointestinal cancer, cerebrovascular disease, cardiovascular disease, and diabetes) might be avoided if the population were physically active at recommended levels.

Prevalence of inactivity as a risk factor

Data from 20 countries report prevalence rates of inactivity range between 37% and 79%. The most recent Health Survey for England (2016) found that 66% of men and 58% of women aged 16 and over met the aerobic guidelines of at least 150 minutes of moderate activity or 75 minutes of vigorous activity per week or an equivalent combination of both, in bouts of 10 minutes or more (see Figure 337.1). The proportion of adults meeting the aerobic activity guidelines varied by quintile of the Index of Multiple Deprivation (IMD), ranging from 50% in the most deprived quintile to 68% in the least deprived quintile. Fewer adults – 31% of men and 23% of women aged 16 and over – met both the aerobic and muscle-strengthening guidelines (see Figure 337.2). As mentioned above, current UK guidelines recommend that adults aged 65 and over at risk of falls should perform activities to improve balance and co-ordination at least twice each week. Of those adults aged 65 and over taking low levels of aerobic activity, only 11% of met the balance and co-ordination guidelines, and of those adults aged 65 and over classed as inactive, only 2% met the balance and co-ordination guidelines.

Screening for inactivity

Tests are available to help clinicians determine the presence of physical inactivity as a risk factor and can be used as part of a comprehensive screening battery (e.g. for cardiovascular disease). Results of the test can be used to inform evidence-based interventions to improve patient health and well-being. A simple, pragmatic self-report measure has been developed that classifies people into four levels of physical activity and has predictive validity for all-cause mortality and incident cardiovascular disease. Individuals are classified as 'active', 'moderately active', 'moderately inactive', or 'inactive'. Compared to the inactive group, the active group had an approximately 30% lower risk of all-cause mortality and cardiovascular disease, even after adjustment for age and other risk factors.

The questionnaire has been adapted for screening patients for physical inactivity in primary care (see <http://webarchive.nationalarchives.gov.uk/20130107105354/http://www.dh.gov.uk/en/>

Publicationsandstatistics/Publications/PublicationsPolicyAndGuidance/DH_063812) and is the basis of a physical activity care pathway developed by the Department of Health in England (see http://webarchive.nationalarchives.gov.uk/+//www.dh.gov.uk/en/PublicHealth/Healthimprovement/PhysicalActivity/DH_099438).

The effectiveness of interventions to reduce inactivity

An individual's level of physical activity is determined by factors operating at individual, social, and environmental levels. Interventions to increase physical activity have primarily been at the individual level. A review of interventions found that informational interventions (e.g. prompts to encourage stair use), community-wide campaigns, and behavioural and social interventions can be effective at increasing physical activity levels. Based on available evidence, the National Institute for Health and Clinical Excellence recommends that primary care practitioners should take the opportunity, whenever possible, to identify inactive adults and advise them to aim for 30 minutes of moderate activity on 5 days of the week (or more)—taking into account an individual's needs, preferences, and circumstances, and providing patients with written information about the benefits of physical activity, and local opportunities to become and stay more active.

Behaviour-change interventions are modestly effective at increasing physical activity in the short- and long- term. Person-centred, autonomy-supporting communication styles, such as motivational interviewing, together with techniques of behavioural self-regulation such as self-monitoring and goal-setting, are more likely to bring about sustained increases in physical activity.

Summary

Physical inactivity is a prevalent and powerful risk factor for a wide range of disease. Its presence can be detected, and effective, brief interventions exist to help clinicians reduce this risk factor and improve their patients' health and well-being, while reducing disease progression and the risk of complications in some patients.

338 Smoking

Keir Lewis

Why is smoking dangerous?

The UK government, in its White Paper in 1998, declared that 'smoking is the greatest single cause of preventable illness and premature death in the UK. Cigarette smoke is inhaled because it contains nicotine, which is highly addictive. Nicotine itself has some adverse physiological effects but it is mainly the 4000+ chemicals (including acetone, arsenic, paint stripper, pesticides, and over 60 known carcinogens), added to make the cigarette such an extremely potent nicotine delivery device, that cause so much damage.

A smoker dies on average 8–10 years before a non-smoker. The commonest causes of premature death in smokers are cardiovascular disease, lung cancer, and COPD. However, smoking also leads to much morbidity, causing or worsening many illnesses in every system of the body, such as:

- in the cardiovascular system, myocardial infarctions, ischaemic heart disease, hypertension, arrhythmias, cardiomyopathies, peripheral vascular disease, aneurysms, and venous stasis/thromboses
- in the respiratory system, chest infections, rhinitis, COPD, asthma, and several interstitial lung diseases
- in the gastrointestinal system, peptic ulcer disease, reflux, pancreatitis, and Crohn's disease
- in the musculoskeletal system, osteoporosis, delayed fracture healing, and Perthe's disease
- in the neurological system, strokes, probable dementia, and multiple sclerosis
- in the reproductive system, erectile dysfunction, reduced fertility (male and female), poor pregnancy outcomes, and increased infant mortality
- in the skin and soft tissues, poor wound healing, premature ageing, psoriasis, hidradenitis suppurativa, peridontitis, and hair loss
- in the endocrine system, Graves' disease, insulin resistance, and testicular and ovarian dysfunction
- in the eyes, cataracts, optic nerve toxicity (tobacco-related amblyopia), and macular degeneration
- in the ears, otitis media

In addition, smoking is associated with a number of cancers, including lung cancer, nasopharyngeal cancer, laryngeal cancer, oesophageal cancer, stomach cancer, pancreatic cancer, colonic cancer, kidney cancer, bladder cancer, cervical cancer, and acute myeloid leukaemia.

Stopping smoking at any age has been shown to improve health and increase life expectancy. Even with advanced smoking-related diseases, observational studies show clinically meaningful benefits in stopping smoking. Some generic health benefits in stopping smoking are given in Table 338.1.

Magnitude and demographics of smoking

Taxation, advertising bans, public health messages, legislation for minimal age, and banning smoking in work and enclosed public places has helped to reduce tobacco use in many high-income countries. In Britain in 2008, just 22% of men smoked compared with 65% in 1948. Furthermore, the rates of some major tobacco-related diseases, such as lung cancer, are now falling (at least in men). Around 24% of adult women smoke.

The rate of decline in smoking has slowed; for example, in US adults, smoking declined on average by only 0.39% per year after 1990, with no significant drop in prevalence from 2004 to 2006, and the cost to the NHS per quitter in the UK has risen over the last 5 years.

Moreover, the world is still in the midst of an epidemic of tobacco-related illness. The substantial decline in smoking in the West has not

Table 338.1 Some generic health benefits in stopping smoking

Time since quitting	Beneficial health changes that take place
24 hours	Lungs start to clear out mucus and other smoking debris
48 hours	Carbon monoxide will be eliminated from the body Ability to taste and smell is greatly improved
72 hours	Breathing becomes easier Bronchial tubes begin to relax and energy levels increase
2–12 weeks	Blood circulation improves
3–9 months	Coughs, wheezing, and breathing problems improve as lung function is increased by up to 10%
1 year	Risk of heart attack falls to about half that of a smoker
10 years	Risk of lung cancer falls to half that of a smoker
15 years	Risk of heart attack falls to the same as someone who has never smoked

happened elsewhere: 1.2 billion people (about 40% of all men and 10% of women) worldwide are smoking 5 trillion cigarettes annually, particularly in low- and middle-income countries. Cigarette production and consumption in developing countries are rising by just under 1% a year. About 6 million people now die each year because of tobacco and, without a rapid change in the epidemic's course, this figure is estimated to rise to 8.3 million, and tobacco will be the biggest worldwide killer by 2030.

How do you reduce smoking uptake and help patients quit?

Helping populations reduce smoking

National and international control strategies are best summarized by the WHO Framework Convention on Tobacco Control (available at http://www.who.int/fctc/text_download/en/); 168 nations have now ratified it, committing themselves to a broad set of initiatives addressing issues such as advertising and promotion; minimum price and taxes; labelling; protection against second-hand smoke; education and cessation; gender issues; illicit trade; and sales to minors. Despite continuing opposition by the tobacco industry, the framework sets deadlines for implementing measures and, in 2008, the process was reinforced by a package of six measures known as MPOWER, drawn up by the WHO to help countries cut demand for cigarettes.

The bans on smoking in enclosed public spaces consistently show high (and progressively higher) levels of public support (even in smokers), very good compliance, improvements in the health of hospital-workers, improvements in public health (e.g. reduction in hospital admissions for myocardial infarctions in Scotland), and no clear evidence of adverse economic impact or a switch to increased smoking at home.

Efforts to reduce smoking at more local community levels using mass media campaigns, the internet, mobile texts, or telephone quit lines have a very weak but positive effect on quit rates. They are probably still cost-effective because they can reach large numbers of smokers. The best content of these packages is still not known.

Preventing uptake of smoking in children is difficult; mass media campaigns or educational programmes seem to have little effect. Some promising interventions include using a respected classroom peer to advocate non-smoking.

Helping individuals stop smoking

Around 70% of smokers say they want to stop. The least effective way for an individual smoker to try to quit is to go 'cold turkey' and try without behavioural support. However, it remains the most popular method and, because of the large numbers involved, more smokers quit by this method than any other.

Any health professional can have a positive impact on someone's chances of quitting. Meta-analyses of 20 randomized controlled trials suggests nursing-delivered interventions significantly increase the odds of quitting (odds ratio 1.47, 95% confidence interval 1.29–1.68), particularly for hospitalized patients but also in non-hospitalized patients.

Pooled data from randomized and observational trials since 1972 confirm that even brief doctor advice is better than no advice in improving validated quit rates over at least 6 months (odds ratio 1.74, 95% confidence interval 1.48–2.05). There is also a clear dose response with better quit rates following more intensive advice and when offering follow-up visits.

Community pharmacists have a role in smoking cessation and can reach large numbers of smokers but more research is needed to establish what training and type of intervention is most effective.

Pharmacotherapy to aid smoking cessation

Nicotine replacement therapy (NRT) has been licensed since 1982, with inhalators, microtabs, lozenges (short-acting), and transdermal patches (long-acting) all being used today. Repeat Cochrane reviews of well-designed randomized controlled trials suggests all types of NRT roughly double a smoker's chance of quitting over at least 1 year. Trials sponsored by manufacturers of NRT are more likely to show positive results but compulsory registration of all trials should reduce publication bias in future.

Varenicline is an oral partial agonist of the alpha-4 beta-2 subtype nicotinic acetylcholine receptor. It has both agonistic and antagonistic properties, so it can both reduce craving and withdrawal and block the rewarding effects of smoking. It appears to be at least as or probably more effective than effective NRT and probably superior to bupropion. Overall, it is well tolerated, its main side effects being nausea and sleep disturbance. Recent major studies show it causes no more increased neuro-psychiatric effects above NRT or placebo, even in those with neuro-psychiatric illness. More studies in patient subgroups, using prolonged dosing (for more than 12 weeks) and even in combination with NRT, are eagerly awaited.

The atypical antidepressant bupropion also roughly doubles the odds of quitting. Its main side effect is a seizure rate of around 1 in 1000. It is much more widely used in the US and Europe than in the UK. Nortriptyline has been recommended as a second-line treatment for smoking cessation but no other antidepressant or anxiolytic has been shown to help cessation.

Two large trials suggest that the generic plant-based alkaloid cytisine is well tolerated and can aid smoking cessation, being at least as effective as varenicline and NRT. Further work on dosing, side effects, and longer-term quit rates is ongoing.

E-cigarettes, which are much safer than cigarettes as they superheat nicotine containing liquids, have been reported by smokers to help them quit: two open-label trials suggest they may be as effective as NRT in the short to medium term. However, they are not subject to medicines manufacturing standards, their long-term safety especially the condensate, is not proven, they are increasingly owned by the tobacco industry, and their role in 'renormalizing' smoking (e.g. in public) is controversial although there is no evidence they lead to smoking uptake.

New pharmacological treatments, including novel ways to deliver nicotine, selective inhibitors of the nicotine metabolizing enzyme CYP2A6, and nicotine vaccines, are being evaluated.

The success claimed by practitioners of aversive smoking, and alternative therapies such as acupuncture and hypnotherapy, has not yet been shown to be superior to placebo or sham treatments in pooled analyses of well-designed randomized trials, and these methods are not recommended.

Who should be offered smoking cessation treatment?

In the UK, the National Institute for Health and Care Excellence (NICE) guidelines recommend that 'everyone who smokes should

Table 338.2 Typical validated sustained quit rates by level of intervention

Intervention	Quit rates at 1 year (%)
None (spontaneous quit rate)	2–3
Generic health professional: <ul style="list-style-type: none"> • minimal counselling (<3 min) • brief counselling (3–10 min) • counselling (>10 min) 	4 5 8–10
Interactive internet programmes	6
Interactive telephone programmes	10
Group classes or individual sessions with specialist without medication	15
Group classes or individual sessions with specialist combined with medication	25

be advised to quit, unless there are exceptional circumstances' and 'smoking cessation advice and support should be available in the community, primary and secondary care settings for everyone who smokes'.

Few health professionals have received specific training on smoking cessation, such as how to recognize symptoms of nicotine withdrawal, what pharmacotherapy is most appropriate (or is contraindicated), what key facts are specific to each illness, and so on. Not all hospitals have access to in-house specialists and there is evidence that those who do have them may not be using them appropriately. A healthcare provider sees 70% of all smokers at least once every year, yet only 39% of tobacco users reported being offered any advice or assistance to quit, and the majority of quit attempts and even pharmacotherapy prescriptions remain patient instigated. Within hospitals, in developed countries, another meta-analysis concluded that 'levels of smoking cessation care are less than optimal, and the levels of some important care practices are particularly low.'

Following brief advice, if the smoker expresses a desire to quit, they should ideally be referred to a specialist service that can tailor advice. Services combining intensive early support (at least weekly sessions for the first month) with pharmacotherapy and then with less intensive follow-up (e.g. at 6 months and at 1 year (to allow for annual celebrations, anniversaries)) are extremely effective (see Table 338.2), with numbers needed to treat of only around 6–7. They are also cost-effective and well below the benchmark used by NICE, for cost per quality-adjusted life-year gained, to justify treatment on the NHS.

Amelioration of the impact of smoking-reduction strategies

Traditionally, smoking cessation was deemed only effective if a patient completely stopped. Some work (e.g. on patients with COPD) has shown similar long-term validated and sustained quit rates in those smokers advised to cut down their smoking, compared to those advised to stop completely.

The relative health benefits from reducing smoking and strategies to prevent relapse are being examined. Other studies identifying those at highest risk of relapse, the neurogenetics of nicotine addiction, the interaction between certain genes and smoking in causing certain cancers, and so on, are being reported each year.

339 Alcohol

Sir Ian Gilmore and William Gilmore

Demographics of alcohol consumption in the UK and beyond

Alcohol has been used for thousands of years and, indeed, in very different ways. Two thousand years ago, the occupying Romans sipped wine regularly but reasonably moderately, and marvelled at the local English serfs who celebrated bringing in their crops with brief episodes of unrivalled drunkenness. Its use was not only tolerated but sometimes encouraged by the ruling classes as a way of subjugating the population and dulling their awareness of the conditions in which they had to live and work. The adverse impact of gin consumption was famously recorded by Hogarth's painting of 'Gin Lane' but, at the same time, beer was reckoned a safer alternative to water for fluid intake and was linked to happiness and prosperity in the sister painting of 'Beer Street'. It was against the 'pernicious use of strong liquors' and not beer that the president of the Royal College of Physicians, John Friend, petitioned Parliament in 1726. Some desultory attempts were made by Parliament in the eighteenth century to introduce legislation in order to tax and control alcohol production but they were eventually repealed. It was really the onset of the Industrial Revolution in nineteenth-century England that brought into sharp relief the wasted productivity and lost opportunity from excess consumption. England moved from a rural, relatively disorganized workforce to an urban, more closely scrutinized and supervised one—for instance, in factories, where men needed their wits about them to work heavy machinery, workers who were absent (in body or mind) were noticed. And, in Victorian Britain, there arose a greater social conscience—an awareness, for example, of the harm, through neglect, inflicted on the children of those who spent their wages and their days in an alcoholic stupor. Nonetheless, per capita consumption of alcohol in the UK at the end of the nineteenth century was greater than it is today (see Figure 339.1). It fell progressively through the first half of the twentieth century, with two marked dips. The first

coincided with the introduction of licensing hours' restrictions during the First World War, and the second with the economic depression of the 1930s.

Following the Second World War, there was a doubling of consumption between 1950 and the present day, to about 10 l of pure alcohol per capita. There has been a small fall of 9% in the last 5 years; this may be, in part, related to the changing ethnic mix and increasing number of non-drinkers. There has always been a mismatch between self-reported consumption in lifestyle questionnaires, and the data from customs and excise, with the latter being 40% greater. From the latter, it can be estimated that the average consumption of non-teetotal adults in England is 25 units (0.25 l of pure alcohol) per week, which is well above recommended limits of 14 units for women, and 21 units for men. Of course, average figures hide population differences, and it is estimated that the heaviest-consuming 10% of the population account for 40% of that drunk. While men continue to drink, on average, about twice the amount that women do, the rate of rise of consumption in women has been steeper. Average consumption is comparable across socio-economic groups but there is evidence of both more teetotallers and more drinking in a harmful way in the poorest group. In 2007, 13% of those aged 11–15 admitted to having drunk alcohol during the previous week. This figure is falling, but those who do drink are drinking more. The average weekly consumption of pupils who drink is 13 units/week.

Binge drinking estimates are unreliable, as they depend on self-reporting in questionnaires; in the UK, they are taken as drinking twice the daily recommended limits of 4 units for men, and 3 units for women, on the heaviest drinking day in the previous week. In 2010, 19% of men, and 12% of women, admitted to binge drinking, with the figures being 24% and 17%, respectively, for those aged 16–24. The preferred venue for drinking in the UK has changed markedly, mainly in response to the availability of cheap supermarket drink. Thirty years ago, the vast majority of alcohol was consumed in pubs

Figure 339.1 Annual alcohol consumption per UK resident from 1900 to 2010 (litres of pure alcohol consumed, by beverage type).

Figure 339.2 Number of alcohol-attributable deaths in England in 2005 by age group and cause. With permission from Alcohol Misuse, Department of Health

and restaurants, whereas, in 2009, the market share of off-licence outlets was 65%. However, drinkers under 24 years of age still drink predominantly away from home.

The UK per capita consumption of alcohol is close to the European average, but consumption has been falling in Mediterranean countries and rising in northern and eastern Europe. Europe has the highest consumption of all continents, but there is undoubtedly massive under-reporting in many countries, particularly because of local unregulated production and consumption. It is estimated that less than 10% of consumption is captured in statistics in parts of Africa.

The health impact of alcohol consumption

The UK's accelerating consumption in the last half century has been accompanied by an increasing toll on morbidity and mortality. The economic costs of alcohol misuse in England alone is about £3.5 billion, although this figure is dwarfed by crime costs of £11 billion, and lost productivity of £7 billion. Of course, these figures could be offset against the economic benefits of alcohol in terms of jobs and trade, but the net figure would still be grossly in the red. The annual number of alcohol-related deaths in 2010, reported by the Office for National Statistics, was 6669, although some estimate that the figure could be as high as 40 000 if the attributable fraction of all alcohol-related diseases, such as cancer and heart disease, were taken into account. In the UK, the number of deaths from liver disease, which is a surrogate marker for alcohol-related harm as it is responsible for about 80% of liver deaths, has risen fourfold in the last 40 years and has now exceeded that for European Union. Even more striking is the age distribution of alcohol-related deaths, with the majority of such deaths occurring in younger age groups (see Figure 339.2). Cigarette smoking continues to be an even bigger factor overall than alcohol in premature deaths, but alcohol is more significant in those under 60 years of age, highlighting the fact that alcohol is often responsible for morbidity and mortality when people would otherwise be at their most productive. On average, the number of years lost in England for each alcohol-attributable death is 20 in men, and 15 in women.

Hospital admissions mirror this rise in mortality in recent years, and these now are estimated by the North West Public Health Observatory to exceed one million per annum in England. These are not, as might be imagined, mainly from the acute effects of drunkenness but from chronic sequelae and dependence, as figures from Liverpool show (Figure 339.3).

These figures emphasize the burden of alcohol dependence, which is rising alongside physical diseases and for which the incidence has risen from 1.0 million to 1.6 million people in England in the last decade. The wide range of conditions linked to alcohol is shown in Box 339.1. The risks can be divided into those acute harms that accompany bingeing, such as violence, accidents, and sudden death, and the chronic ill effects, such as cirrhosis and cancer. There is increasing awareness of alcohol as a risk factor in various cancers; in a recent European study, it was estimated that 1 cancer in 10 in men, and 1 in 30 in women, are caused by alcohol. Furthermore, there can be significant risks of consumption within limits thought of as safe; for example, a women consuming a bottle of wine each week (10 units; 80 g of alcohol) increases her risk of breast cancer by about 10%.

The apparent reduction in all-risk mortality from moderate alcohol consumption before a steep rise in mortality linked to heavy drinking (the so-called J-shaped curve) remains contested by some, on the grounds that studies fail to take sufficient account of confounding factors of diet and exercise in light drinkers. However, on the basis of several meta-analyses, it is likely that moderate drinking reduces deaths from coronary heart disease and ischaemic stroke. This effect is likely to be mediated through changes in HDL cholesterol. However, this benefit is seen only in those aged 55 or more, and the benefit is likely to be derived from very low levels of consumption (less than one unit daily).

A very significant burden of harm that is difficult to quantify is the harm to others, sometimes referred to (unsatisfactorily) as passive drinking. This harm is felt across the age spectrum. The full fetal alcohol syndrome, where there is profound neurocognitive damage and a characteristic facial appearance including wide-set eyes and a flat-bridged nose and which results from heavy in utero exposure, is relatively uncommon in the UK (about 100 cases reported each year). However, it is thought likely that many more subtle alcohol-related abnormalities may be present in up to 1 in 100 births; these make up what is now called fetal alcohol spectrum disorder, where hyperactivity and inattention may be prominent features. The impact of alcohol dependence on other family members, including children, is thought to be underestimated, and alcohol is a significant factor in at least half of cases of domestic violence. These and other alcohol-related causes of damage to others are listed in Box 339.2.

Alcohol Related Admissions for Liverpool PCT (residents) 2002/03 to 2008/09 by Condition Group.

- family problems
- road traffic accidents
- work problems

Evidence-based public health policy for prevention of harm from alcohol

Public health policies to reduce the harm from alcohol must draw on best evidence and, in principle, use the minimum amount of intervention needed to produce the desired result. This has been adopted in the Nuffield Council on Bioethics Intervention Ladder (Box 339.3) and in 'nudge theory'. However, when dealing with a substance so pervasive in our culture as alcohol, which is so cheap, so readily available, and of such addictive potential, it is unlikely that lower rungs of the ladder will be effective.

There is overwhelming evidence that price is a key driver of both consumption and harm and, in the face of market competition, this requires regulation. The commonest way to regulate price in most countries has been through general taxation or a specific alcohol duty. This approach is effective but adds to the cost of all beverages, whether cheap or expensive, and whether consumed in pubs or at home. This has led to interest in setting a minimum floor below which a set amount of alcohol in a beverage cannot be sold: a minimum unit price (MUP). This has been used to regulate beer prices in some provinces in Canada, and, at the University of Sheffield, the results of modelling the impact of an MUP in the UK

suggest that the health gain could be large if a unit of alcohol (8 g) could not be sold for less than, say, £0.50 (€0.60, \$0.80). The heaviest drinkers and those who are underage favour the cheapest alcohol, so an MUP effectively targets those most vulnerable to harm. There are plans to instigate this in the four nations within the UK and in the Republic of Ireland, but it is likely to face challenge in the European Court because it runs counter to the principle of free competition in markets.

The next area where evidence is strong for the effectiveness of public health intervention is on physical availability. This can be targeted through regulation of hours of opening, location, and density of retail outlets, and also by strengthening existing measures to prevent sales to underage drinkers and those already drunk. There is also an opportunity for change further down the ladder of intervention, such as putting alcoholic products in shops within a defined area with separate checkout facilities.

Drink-driving countermeasures are known to be effective. The introduction of random breath tests of drivers has been shown to reduce alcohol-related road traffic accidents. This can be complemented with the reduction of blood alcohol concentration limits, and requiring drivers under the legal age of purchase to have a blood alcohol concentration limit of zero.

The promotion of alcoholic beverages is a multimillion-pound business, and one where there is evidence, particularly in children, that harm ensues. The evidence suggests that children are likely to drink younger, and to drink more when they start, if exposed to alcohol marketing. In many countries, advertising standards are monitored by forms of industry self-regulation, but these clearly fail. Regulation is getting progressively more difficult as the methods of marketing

Box 339.3 Nuffield Council on Bioethics Intervention Ladder: A range of intervention options available to policymakers

Eliminate choice. Regulate in such a way as to entirely eliminate choice, for example through compulsory isolation of patients with infectious diseases.

Restrict choice. Regulate in such a way as to restrict the options available to people with the aim of protecting them, for example removing unhealthy ingredients from foods, or unhealthy foods from shops or restaurants.

Guide choice through disincentives. Fiscal and other disincentives can be put in place to influence people not to pursue certain activities, for example through taxes on cigarettes, or by discouraging the use of cars in inner cities through charging schemes or limitations of parking spaces.

Guide choices through incentives. Regulations can be offered that guide choices by fiscal and other incentives, for example offering tax-breaks for the purchase of bicycles that are used as a means of travelling to work.

Guide choices through changing the default policy. For example, in a restaurant, instead of providing chips as a standard side dish (with healthier options available), menus could be changed to provide a more healthy option as standard (with chips as an option available).

Enable choice. Enable individuals to change their behaviours, for example by offering participation in an NHS 'stop smoking' programme, building cycle lanes, or providing free fruit in schools.

Provide information. Inform and educate the public, for example as part of campaigns to encourage people to walk more or eat five portions of fruit and vegetables per day.

Do nothing or simply monitor the current situation.

The Nuffield Council on Bioethics report on Public health: ethical issues, Box 3.2

become more varied and pervasive, particularly through the internet. However, there are simple steps that could be taken, for example banning the drinks industry from engaging in sports sponsorship, as in France, or restricting cinema alcohol advertisements to films suitable only for those over 18 years of age.

There continues to be little evidence that public education and information are useful tools for reducing alcohol-related harm. This may be because they are given in the wrong format or in insufficient quantity. There is evidence that knowledge may be improved but, when used alone, information does not seem to bring about sustained behaviour change. It may be, however, that it has a role in informing the public of the scale of the problem so that firmer measures, such as regulation, are more acceptable when implemented.

Box 339.4 Identification and brief advice in a hospital setting

The Alcohol Health Work project at St Mary's Hospital, London, has been running since 1988. They have developed an evolving, brief, and effective screening tool for use in accident and emergency (A & E)—the Paddington Alcohol Test (PAT). On presentation to A & E, medical and nursing staff use the PAT to screen the alcohol consumption of patients attending for reasons commonly associated with alcohol misuse and offer brief advice. Those that screen positive are referred (with patient's agreement) to an alcohol nurse specialist (ANS). Referrals to the ANS may also be made from other wards in the hospital. The ANS provides a patient-centred assessment offering either advice and information or, in some cases, referral to community alcohol services. In 2007–8, 848 patients accepted referral to the ANS, with 63% attending. Public Health England, Alcohol Learning Resources.

Diagnosis and treatment of alcohol misuse

The scale of the problem from alcohol misuse is so great in some developed countries, such as the UK and Ireland, that we cannot afford to wait to see if public health measures are effective in reducing misuse and harm—there is an urgent need for the early detection and treatment of drinkers who are already at risk of or suffering physical, mental, or social damage. Interventions are effective and good value for money, but the problem lies in getting access to these treatments. There is, overall, a lack of treatment services; in addition, healthcare workers are often slow to refer patients to such treatment services, in the mistaken belief that nothing can be done.

When patients are detected before the signs of severe alcohol dependence appear, real and lasting benefits can accrue from administering structured brief advice. This can be given by a trained health worker in about 15 minutes and may be repeated. It has been shown to be effective even 12 months after it was given, and only eight patients need to be treated for there to be benefit in one. This is more effective, for example, than smoking cessation programmes and is highly cost-effective. This programme of identification and brief advice (IBA) has been shown to work in different settings, including primary care, A & E departments, and criminal justice settings (an example of good practice is included in Box 339.4). The key is to increase the frequency with which the initial identification of alcohol misuse takes place, and this will not happen until opportunistic screening for hazardous or harmful drinking begins to be carried out on a routine basis when individuals come into contact with health services for apparently unrelated reasons.

As approximately 80% of the UK population visits their GP at least once a year, the GP's office is an opportune setting for IBAs. However, at present, there are no financial incentives for GPs in primary care to undertake this, on top of time constraints and a lack of training in this area. At a local level, some primary care trusts have introduced locally enhanced services that cover alcohol screening and brief intervention but there is a possibility of this being lost in the changing landscape of primary care funding.

It is less certain whether IBAs are effective in cases of more severe dependence, as detected by tools such as the Alcohol Use Disorder Identification Tool; however, specialist alcohol treatment services have been shown to be of proven benefit in these patients and should be available to take referrals. It is only by matching problem drinkers with the correct avenue of treatment that it will prove possible to break the 'revolving door' cycle of recurrent admissions into acute hospitals, a cycle that so many of these patients currently experience.

Conclusions

Alcohol use poses a really important public health challenge to many developing and developed countries, and this is particularly true in the UK at present. Any potential cardiovascular benefit of light consumption is swamped by the consequences of heavy drinking, and there is little sign that attempts at public health messages or setting recommended limits is having an impact. The consequences of societal harm to health, crime, and productivity are so great as to justify legislative measures around price, marketing, and availability, even though such measures are at odds with politicians' natural instincts to respect free will and personal choice. This move to increase regulation is being seen first in Scotland, where the amount of alcohol-related harm is currently greatest, but other parts of the UK are following. There is also a need to improve services to detect those with early signs of physical or mental harm, as early intervention can be both effective for the individual and economically sound for the country.

340 Environmental radiation

Mark P. Little

Introduction

Risks associated with ionizing radiation have been known for almost as long as ionizing radiation itself. Within a year of the discovery of X-rays by Röntgen in 1895, skin burns had been reported and, within 7 years, a case of skin cancer was observed, all associated with high-dose X-ray exposure. In general, the risks associated with ionizing radiation can be divided into what have been termed (by the International Commission on Radiological Protection) stochastic effects (e.g. genetic risks in offspring, and somatic effects (cancer) in the directly exposed population), and deterministic, or tissue-reaction, effects. Deterministic effects are typically associated with high-dose exposures, and will not be considered further here.

Types of ionizing radiation, sources of exposure, and units

Ionizing radiation is any electromagnetic wave or particle that can remove an electron from an atom or molecule. The process of ionization in living material necessarily changes atoms and molecules, at least transiently, and may thus damage cells. If cellular damage occurs and is not adequately repaired, the cell may die or senesce, or the damage may result in a viable but modified cell which can go on to become cancerous, if it is a somatic cell, or lead to inherited disease, if it is a germ cell.

The basic quantity used to measure absorbed dose from radiation is the gray (Gy), defined as one joule (J) of initial energy (of charged particles released by the ionization events) per kilogram of tissue. The biological effects per unit of absorbed dose differ with the type of radiation, so that a weighted quantity called the equivalent dose is used, which is measured in sieverts (Sv). Low-level linear-energy transfer (LET) radiation (e.g. photons, electrons, muons) is assigned a radiation weighting factor of 1, whereas high-LET radiation (e.g. neutrons, protons, alpha particles) is assigned radiation weighting factors of between 5 and 20, depending on the energy of the particles.

All living organisms are continually exposed to ionizing radiation, for example from cosmic and terrestrial gamma rays, ingestion of potassium-40, and radon exposure. Worldwide, the average human exposure to radiation from natural sources is 2.4 mSv per year, about half of which is due to the effects of radon daughters (Table 340.1).

Major studies examining environmental exposure in relation to cancer

Natural radiation exposure

Indoor radon exposure

Although it has long been recognized that radon causes lung cancer in underground miners, the possible hazard of exposure to radon at the generally low levels found in homes was not appreciated until more recently. There have been a number of studies of lung cancer in relation to indoor radon exposure, culminating in two sets of independent pooled analyses, one in North America and the other European, both of which clearly demonstrate a significant association between radon daughter exposure and lung cancer. There have also been studies of radon daughter exposure in relation to other malignancies, in particular leukaemia, but these have, for the most part, been inconclusive.

Gamma radiation exposure: High-background studies

Natural background radiation varies tremendously between and within countries. An area with high natural background radiation is

defined as an area or a complex of dwellings where the sum of cosmic radiation and natural radioactivity in the soil, air, water, food, and so on, leads to chronic exposures that result in an annual effective dose that is above a defined level. Studies of the health effects of high-background radiation exposure have thus far been inconclusive.

Man-made radiation exposure

Studies of populations exposed to fallout from nuclear weapons testing have suggested that such populations have an increased risk of thyroid and other cancers. A substantial increase in the incidence of thyroid cancer has also been observed amongst those exposed to radioactive iodines in childhood and adolescence in the most highly contaminated territories of Ukraine, Belarus, and Russia following the Chernobyl accident. Iodine deficiency may have increased the risk of developing thyroid cancer following exposure to radioactive iodines, while prolonged stable iodine supplementation in the years after exposure may reduce this risk. There is evidence of risk associated with obstetric *in utero* exposure to diagnostic X-rays, and with paediatric exposure to computerized tomography, although this is still controversial.

Prevention of disease

Heritable genetic and cancer-related effects are the main late health consequences of environmental exposure to ionizing radiation; somatic risks dominate the overall estimate of health detriment. For both somatic and genetic effects, the probability of their occurrence, but not their severity, is taken to depend on the radiation dose. The dose response may be non-linear (e.g. for leukaemia). For most

Table 340.1 Current sources of exposure, annual effective doses (in millisieverts per year), and typical ranges

Source	Source sub-type	Worldwide average (mSv/year)	Typical range (mSv/year), other notes
Natural	External exposure

Heritable genetic risk[‡]		
Autosomal dominant, X linked	Risk to first generation	0.075–0.15
	Risk to second generation	0.05–0.10
Autosomal recessive	Risk to first generation	~0
	Risk to second generation	~0
Chronic multifactorial disease	Risk to first generation	0.025–0.12
	Risk to second generation	0.025–0.12
Developmental abnormalities	Risk to first generation	0.20
	Risk to second generation	0.04–0.10
Total	Risk to first generation	0.30–0.47
	Risk to second generation	0.12–0.32

*Risk calculated for a UK population, assuming a test dose of 0.1 Gy administered, and using a generalized excess absolute or relative risk model which is linear–quadratic in dose.

[†]Ninety per cent Bayesian credibility interval.

[‡]Risk calculated for radiation exposure only in one generation, with a dose and dose-rate effectiveness factor of 3 applied.

Data from

United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) (2001). Hereditary effects of radiation. UNSCEAR 2001 report to the General Assembly, with scientific annex. Volume E.01.IX.2. pp. 1–160.

United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR) (2008). UNSCEAR 2006 Report. Annex A. Epidemiological Studies of Radiation and Cancer. pp. 13–322. ISBN 978-92-1-142263-4.

stochastic effects, it is generally accepted that, at sufficiently low doses, there is a non-zero linear component to the dose response (i.e. there is no threshold), but contrary opinions have also been expressed.

Heritable genetic effects

The heritable genetic risks associated with radiation exposure are estimated directly from animal studies in combination with data on baseline incidence of disease in human populations. There is little or no evidence of human radiation-induced genetic disease, and the results of the most comprehensive of human epidemiological studies, namely that carried out on the children of the Japanese atomic bomb survivors, are negative. Table 340.2 summarizes estimates of risk, based on a mutational doubling dose of 1 Gy. This is derived from human data on spontaneous mutation rates, and mouse data on induced mutation rates.

Somatic effects (cancer)

Most of the information on radiation-induced cancer risk comes from (a) the Japanese atomic bomb survivors, (b) medically exposed

populations, and (c) occupationally exposed groups. The Life Span Study cohort of Japanese atomic bomb survivors is unusual amongst exposed populations in that both genders and a wide range of ages were exposed, comparable with those of a general population. Most medically treated groups are more restricted in the age and gender mix. Table 340.2 summarizes estimates of cancer mortality risk for a UK population.

Non-cancer late health effects

For some time, there has been evidence of excess cardiovascular morbidity associated with high-dose radiotherapeutic procedures. The mechanisms for such effects at high radiation doses are reasonably well understood, being probably inflammatory in nature, resulting from inactivation of large numbers of cells and associated functional impairment of the affected tissue. There is emerging evidence of excess risks of non-cancer late health effects, specifically circulatory disease and cataract, in the Japanese atomic bomb survivors and in some of those who are occupationally exposed. The most current biological data imply that the mechanisms for circulatory disease are unlikely to involve somatic cell mutation, but this mechanism cannot be excluded for cataract.

Screening for disease

As described in 'Prevention of disease' and shown in Table 340.2, the main diseases that should be screened for are cancers in the directly exposed population. Genetic effects will occur at relatively low prevalence and may not be easily detectable, especially given the multifactorial nature of many diseases. The cancers to be screened for will be determined by the organ-specific doses. When the exposure is uniform whole body, as is often the case following environmental radiation exposure, the main radiogenic cancer sites should be examined (e.g. breast, thyroid, bone marrow, lung, and skin). However, the use of X-rays or mammograms for screening purposes should only be conducted after careful analysis of the risks and benefits—for example, the use of annual mammographic screens of the general female population for breast cancer is justified above the age of 40 (the breast cancer deaths averted by screening exceed the breast cancers induced by the mammographic X-rays), but not below that age. Cataract should also be assessed.

341 Air pollution

Anthony Frew

Why is air pollution dangerous?

Any public debate about air pollution starts with the premise that air pollution cannot be good for you, so we should have less of it. However, it is much more difficult to determine how much is dangerous, and even more difficult to decide how much we are willing to pay for improvements in measured air pollution. Recent UK estimates suggest that fine particulate pollution causes about 6500 deaths per year, although it is not clear how many years of life are lost as a result. Some deaths may just be brought forward by a few days or weeks, while others may be truly premature. Globally, household pollution from cooking fuels may cause up to two million premature deaths per year in the developing world.

The hazards of black smoke air pollution have been known since antiquity. The first descriptions of deaths caused by air pollution are those recorded after the eruption of Vesuvius in AD 79. In modern times, the infamous smogs of the early twentieth century in Belgium and London were clearly shown to trigger deaths in people with chronic bronchitis and heart disease. In mechanistic terms, black smoke and sulphur dioxide generated from industrial processes and domestic coal burning cause airway inflammation, exacerbation of chronic bronchitis, and consequent heart failure. Epidemiological analysis has confirmed that the deaths included both those who were likely to have died soon anyway and those who might well have survived for months or years if the pollution event had not occurred.

Clean air legislation has dramatically reduced the levels of these traditional pollutants in the West, although these pollutants are still important in China, and smoke from solid cooking fuel continues to take a heavy toll amongst women in less developed parts of the world.

New forms of air pollution have emerged, principally due to the increase in motor vehicle traffic since the 1950s. The combination of fine particulates and ground-level ozone causes 'summer smogs' which intensify over cities during summer periods of high barometric pressure. In Los Angeles and Mexico City, ozone concentrations commonly reach levels which are associated with adverse respiratory effects in normal and asthmatic subjects.

Ozone directly affects the airways, causing reduced inspiratory capacity. This effect is more marked in patients with asthma and is clinically important, since epidemiological studies have found linear associations between ozone concentrations and admission rates for asthma and related respiratory diseases. Ozone induces an acute neutrophilic inflammatory response in human and animal airways together with release of chemokines (e.g. interleukin 8 and growth-related oncogene- α). Nitrogen oxides have less direct effect on human airways, but they increase the response to allergen challenge in patients with atopic asthma. Nitrogen oxide exposure also increases the risk of becoming ill after exposure to influenza. Alveolar macrophages are less able to inactivate influenza viruses, and this leads to an increased probability of infection after experimental exposure to influenza.

In the last two decades, major concerns have been raised about the effects of fine particulates. An association between fine particulate levels and cardiovascular and respiratory mortality and morbidity was first reported in 1993 and has since been confirmed in several other countries. Globally, about 90% of airborne particles are formed naturally, from sea spray, dust storms, volcanoes, and burning grass and forests. Human activity accounts for about 10% of aerosols (in terms of mass). This comes from transport, power stations, and various industrial processes. Diesel exhaust is the principal source of fine particulate pollution in Europe, while sea spray is the principal source

in California, and agricultural activity is a major contributor in inland areas of the US. Dust storms are important sources in the Sahara, the Middle East, and parts of China. The mechanism of adverse health effects remains unclear but, unlike the case for ozone and nitrogen oxides, there is no safe threshold for the health effects of particulates. Since the 1990s, tax measures aimed at reducing greenhouse gas emissions have led to a rapid rise in the proportion of new cars with diesel engines. In the UK, this rose from 4% in 1990 to one-third of new cars in 2004 while, in France, over half of new vehicles have diesel engines. Diesel exhaust particles may increase the risk of sensitization to airborne allergens and cause airways inflammation both *in vitro* and *in vivo*.

Extensive epidemiological work has confirmed that there is an association between increased exposure to environmental fine particulates and death from cardiovascular causes. Various mechanisms have been proposed: cardiac rhythm disturbance seems the most likely at present. It has also been proposed that high numbers of ultrafine particles may cause alveolar inflammation which then exacerbates preexisting cardiac and pulmonary disease. In support of this hypothesis, the metal content of ultrafine particles induces oxidative stress when alveolar macrophages are exposed to particles *in vitro*. While this is a plausible mechanism, in epidemiological studies, it is difficult to separate the effects of ultrafine particles from those of other traffic-related pollutants.

Air pollution: The magnitude of the problem

There are several different components of air pollution, with distinct exposure profiles. Black smoke and sulphur dioxide are principally generated by the burning of coal for industrial and domestic purposes. In the developing world, many women and children are exposed to fumes from solid cooking fuels, with those of biological origin being particularly toxic. Poor ventilation of huts and other enclosed cooking spaces is an additional factor in increasing exposure.

Nitrogen oxides are primary pollutants generated by the burning of fossil fuels. Maximum levels are found in cities and along major roads, with lower levels in the countryside. Indoor exposure levels reflect external levels but can vary considerably if there are local internal sources (e.g. gas cookers, unflued heaters, motor vehicles in garages).

Ozone is a secondary pollutant which is generated from atmospheric oxygen exposed to nitrogen oxides in the presence of sunlight. Consequently, levels are highest on sunny days, and there is considerable variation at different times of day, with peaks in the afternoon and troughs at night. Ozone is more widely distributed than nitrogen oxides, and levels tend to be higher in the countryside than in towns, because ozone is absorbed by other pollutants generated in cities. In the UK, levels associated with adverse health effects are only rarely encountered. This contrasts with the case in cities like Los Angeles and Mexico City, where ozone levels commonly reach the point where even normal healthy individuals may be affected.

Fine and ultrafine particulates are mostly generated by incomplete combustion of fossil fuels, resulting in carbon particles which vary in size and shape. Diesel engines produce much more particulate than gasoline engines do; due to the high temperatures in the engine, small amounts of transitional metals and volatile organic compounds adhere to the surface of the carbon particles. This makes characterization of particulates very difficult. For most practical and regulatory purposes, exposure is measured by mass per unit volume of air, while biological activity depends primarily on the exposed surface area, which depends on the square of the particle radius (weight being a function of the cube of the radius).

Radon is a naturally occurring radioactive gas which forms during the decay of uranium and thorium. It is the second most important cause of lung cancer (after cigarette smoking), causing about 21 000 deaths per year in the US. Radon exposure is highest in uranium miners, and in locations where granite is at the surface or used in buildings. It also accumulates in domestic houses, especially in areas with restricted ventilation (e.g. basements and attics).

Controlling pollution exposure

The principal means of controlling pollution exposure is through understanding and regulating the sources of pollution. In doing so, it is vital to recognize that pollution does not respect national boundaries. Indeed, much of the pollution that affects the UK is generated in the Ruhr and other industrial areas of Northern Europe, while the prevailing weather systems export much of the UK's pollution towards Scandinavia. Sources such as coal-fired power stations can be replaced by 'cleaner' power stations burning gas; this will reduce the particulate levels but still contribute to levels of nitrogen oxides and ozone. Nuclear power has its own issues, but does not contribute to air pollution, while wind and tidal power is essentially pollution-free, except for any products released during manufacture of the turbines.

Diesel engines contribute a substantial proportion of fine particulate matter (PM₁₀: respirable particles with a diameter of <10 µm) in urban settings. Particle traps will dramatically reduce the amount of PM₁₀ released. Engineering solutions, such as increasing the engine compression ratio, will alter the type of particle generated (i.e. they produce more small particles <2.5 µm in diameter (ultrafine particles)), although the health impact of such changes has not been fully worked out.

Where source control is not practical (e.g. for ozone), understanding the diurnal cycle and time trends may allow those affected to adjust their activities to the most appropriate times. For example, there are higher ozone levels in the afternoon, so less exposure will occur if exercise is taken in the morning or late evening.

A number of steps have been taken to reduce release of volatile organic compounds (VOCs) and products of incomplete combustion which, together with sunlight, trigger the generation of ground-level ozone. Engineering solutions to reduce VOC emissions, such as improving fuel efficiency and using catalytic converters, seem to be the best way forward at present. In the long term, there needs to be a consensus about how the seemingly inexorable increase in the use of personal motorized transport can be mitigated or reduced. This is clearly part of a much wider debate about the way future generations wish to live, work, and play.

Amelioration of the impact of air pollution

Given that the impact of the various pollutants is different, a number of separate strategies have been considered to alleviate their potential impact.

In sub-Saharan Africa, steps are being taken to encourage switching away from traditional solid fuels that are associated with respiratory morbidity. While ozone and nitrogen oxides induce oxidant stress, and deplete antioxidants in bronchoalveolar lavage fluid, clinical trials of increased dietary intake of antioxidant vitamins have not shown any evidence that this will protect against ozone-induced inflammation. As regards the ability of pollution to trigger asthma, management consists of reducing exposure and using standard antiasthma medication to prevent and control exacerbations. The principal risk with fine particulates is cardiac mortality and morbidity. However, there is no obvious way to mitigate this cardiac risk apart from limiting exertion (and hence exposure) during pollution episodes. The main problem is that we do not understand the mechanism involved, mainly because the individual events seem to be rare (albeit catastrophic for those affected).

342 Non-prescription drugs

Bryan Timmins

Why are non-prescription drugs dangerous?

The use of non-prescription drugs is widespread and has a major impact on the health of the individual user and society. In 2006, the British Crime Survey reported that 10% of adults had used one or more illicit drugs in the preceding year, with 3% reporting using a Class A drug. Over 11 million people in the UK are estimated to have used an illicit drug at least once in their lifetime (35%). Drugs abused vary in their intrinsic potential to cause addiction and, with it, more regular and harmful use. Drug users are influenced by trends and fashions, adopting new compounds such as crack cocaine and experimenting with routes of ingestion. Some drugs may become less popular over time, such as LSD, and others, such as cannabis, experience a revival as more potent strains (e.g. Skunk) are developed. A problem drug user is best defined as a person whose drug taking is no longer controlled or undertaken for recreational purposes and where drugs have become a more essential element of the individual's life.

The true economic and social cost of drug use is likely to be substantially greater than the published figures, which are derived from a variety of health and crime surveys which may overlook vulnerable groups such as the homeless. The majority of non-prescription drugs used in the UK are illegal and covered by the Misuse of Drugs Act 1971. The drugs most commonly abused gave rise in 2003–4 to an estimated financial cost in England and Wales of 15.4 billion pounds to the economy, with Class A drugs such as heroin and cocaine accounting for the majority of this. Some 90% of the cost is due to drug-related crime, with only 3% (£488 million) due to health service expenditure, which is mainly on inpatient care episodes. This still represents a major health pressure, which in 2006–7 amounted to 38 000 admissions, in England, for primary and secondary drug-related mental or behavioural problems, and over 10 000 admissions recorded for drug poisoning.

Clinicians in all specialities can expect to encounter harmful drug use, especially those working in primary care, A & E, and psychiatric services. Presenting problems are protean, ranging from mood disorders, delirium, and psychosis to sepsis, malnutrition, and hepatitis. Blood-borne infections such as hepatitis C and HIV are widespread, as contaminated needles and syringes are shared by up to a quarter of problem drug users. Even smoking drugs such as crack cocaine can lead to increased transmission of hepatitis C through oral ulceration and contact with hot contaminated smoking pipes. Amongst the UK population, over half of IV drug users have hepatitis C, a quarter have antibodies to hepatitis B, and, by 2006, 4662 had been diagnosed with HIV.

Non-prescription drug abuse is a leading cause of death and morbidity amongst the young adult population (those aged 16–35). In 2006 there were 1573 deaths where the underlying cause was poisoning, drug abuse, or dependence on substances controlled under the Misuse of Drugs Act. The vast majority (79%) were male. Young men, in particular, are at greater risk of violent death through associated criminal activity such as drug supplying and from deliberate and accidental overdose. The male-to-female ratio for deaths associated with mental and behavioural disorder is 6:1.

Magnitude/demographics of non-prescription drug use

In order to understand the risks of non-prescription drug taking, it is necessary to have knowledge of the legal classification system used to correlate data on health and social harm. The law defines three major

classes of illicit drugs (A, B, and C), according to their perceived dangerousness. Some drugs can appear in both higher and lower classes, depending on how the drug is prepared for use. Drugs are reviewed by the home secretary, and their classification may change when evidence suggests the risk warrants it. The most harmful drugs are Class A drugs and include the opiates heroin and methadone, stimulants such as cocaine, crack cocaine, and ecstasy (MDMA), the hallucinogens, LSD, and, recently added, all forms (fresh and prepared) of magic mushrooms. Amphetamines prepared for injection are also considered to be Class A drugs.

Although, broadly, all Class A drugs are harmful, the impact and scale of opiate and cocaine use are vastly greater than those caused by magic mushrooms. There were an estimated 327 000 problem users of Class A substances in England in 2003–4, with the majority (60%) using heroin and/or cocaine. Equally, the lower classification of cannabis as a Class B drug conceals a growing problem of chronic, drug-induced psychosis. The newer forms of potent cannabis plants now commonly contain five times the amount of active substance, THC, than was found in strains in the 1970s. Current users will invariably be smoking the more potent form 'Skunk', and many have little knowledge of the increased risk, especially the risk in children of developing schizophrenia-like disorders. Ten per cent of children asked thought it was ok to try cannabis, and 75 % of those in formal treatment under the age of 18 are receiving therapy for cannabis abuse.

Some drugs, such as anabolic steroids (designated as Class C drugs) are hardly thought of as harmful by users, despite evidence of serious health risks, and remain, in their various forms, a common problem in the world of performance sports. Solvents and glues are highly toxic yet remain unclassified, although it is an offence to supply them if it is likely that they will be abused.

Criminal prosecution is possible for any class of drug possession but the tariffs are greatest for Class A drugs, and imprisonment for supplying or allowing drug use on your premises is to be expected. Possession with intent to supply carries a term of 2.5 years at present in UK.

The demographics available support the clinical impression that problem drug use is positively correlated with socially vulnerable groups. Contributing factors include financial deprivation, male gender, alcohol abuse, unemployment, school exclusion, and criminality. Those at greater risk of Class A drug use also include young adults and children who have ever been homeless, truanted, looked after in care homes, or fostered. Parental attitudes also condition children to accept drug use. Families with substance-abusing parents show higher rates of drug use amongst children. Overall, vulnerable groups represent only 28% of those surveyed but account for 61% of users of Class A drugs.

Prevention of drug abuse

Prevention of drug abuse by means of health promotion initiatives and education in schools, as with smoking and alcohol education, has certainly increased awareness amongst children and young adults of the risks associated with drug misuse. Surveys show that very few (2%) children aged 11 are uninformed about drug abuse. Despite this, large numbers of 14-year-olds admit to having taken illicit substances. The drug that those aged 14–15 most commonly report to have taken is cannabis (22%), although younger children are more likely to abuse solvents. Children surveyed give a variety of reasons for using drugs. Many admit experimenting with friends. Boys are more likely to try harder drugs and report doing so to get high or feel good.

Health education programmes have been successful in many areas of public health. Providing information does change attitudes. Clinicians play an important role in promoting healthy lifestyles and motivating patients to change habits and make use of available treatment services. NHS initiatives have, for example, reduced the prevalence of cigarette smoking from 28% to 21%; most smokers who wish to give up support initiatives that help them quit. A similar attitude is found amongst problem drug users, with up to three-quarters saying they want to stop.

The UK government has made the identification of and accessing treatment by drug abusers a major target, and doing so is now one of the eight key performance indicators for the NHS. The investment of resources into this was enhanced by the establishment of a special health authority for England: the National Treatment Authority (NTA). Funding from the Department of Health and the Home Office has been pooled into a treatment budget which was allocated annually to 150 local drug action teams (DATs). These are partnerships of social services, housing, education, health, and prison and probation services, as well as private and voluntary sector providers. The DATs determined how resources were spent locally and, as well as commissioning treatment services, were responsible for monitoring and reporting on performance. The result of this major investment in what had, for decades, been a poorly resourced area of healthcare is published in the NTA annual reports. The NTA and its functions were absorbed into the Department of Public Health in 2012.

The treatment system appears from recent data to be very effective in identifying young problem drug users (using heroin and crack cocaine). The time taken from first use of drugs and receiving treatment has fallen by a year to 2.9 years for those aged 18–24. GP and criminal justice referrals appear to be effective in targeting treatment-naive problem drug users. This is reflected in the reduced number of young adults in services being treated for problem drug use between 2006 and 2008 (from 68% to 53%).

There has been a significant reduction in some forms of drug misuse reported by children aged 11–15 between 2001 and 2007. The percentage reporting being offered drugs has fallen from 42% to 36%, and the percentage of those admitting to any form of drug misuse within the previous month has decreased from 12% to 10%. The sharpest fall has been in the percentage of those using cannabis (from 13% to 9%), although the use of Class A drugs remains static at 4%. It seems likely that the reduction is as a result of targeted health education within schools, with parents and teachers showing a greater awareness of the risk of problem drug use amongst children, as well as the increased availability of treatment.

While the overall impact of new treatment services is presently being assessed, the initial results appear impressive. Over half of the estimated 330 000 heroin and crack addicts in England are now receiving effective treatment. The population of problem drug users is getting older, as fewer younger people progress into or remain involved with heroin and crack cocaine. Twenty per cent of those entering treatment in 2008 are now over 40 years old.

The majority of treatments are carried out by community teams. Only 3% of drug users receive inpatient care or rehabilitation. Individuals are assessed and offered a variety of therapeutic interventions, according to their needs. In 2008, some 43% were prescribed medication, with the commonest medication being methadone, which reflects the large number (49%) presenting to services with recent or current IV drug abuse.

The majority of those entering services will also be offered a range of psychosocial interventions based on motivational techniques which are based on increasing the user's sense of discomfort with their habit (dissonance) and guiding them through selective feedback to a point where they can commit to stopping. These cognitive

therapy methods are well established for the treatment of other disorders such as alcohol abuse and depressive disorders.

Amelioration of the impact of drug abuse

Not all those entering treatment can be expected to achieve recovery; on average, 12% will successfully complete treatment and be free from dependency, a figure which has doubled since 2005. A troubling 10% will prematurely leave treatment, although some may return later. A major goal of all clinicians is to use the opportunities presented by any contact with a health service to promote safer drug use. There is a range of harm reduction initiatives on offer, including the website <http://www.harmreduction-works.org.uk>.

Dispelling myths and encouraging patients to believe that simple changes in their habits, such as washing out syringes with thin bleach or getting vaccinated against hepatitis B, are tasks every clinician should embrace. A drug user may have no idea about the risk of sharing syringes or have received poor advice from other users about how to clean equipment. Many wrongly believe that boiling water will kill HIV when, in fact, it tends to preserve the virus under a protective film of denatured blood proteins. Drug users need to know how long the viruses survive inside dirty syringes. Viable HIV can be recovered for up to 6 weeks from the void spaces in most syringes. Although hepatitis C virus (HCV) is much less resilient, it is far more likely to transmit, as the typical viral load is vastly greater. Most crack cocaine addicts are surprised to find they are at risk of HCV transmission by sharing smoking pipes or that injecting crack causes much more damage to veins due to higher acidity and local anaesthetic effects.

Harm reduction strategies have been offered to IV drug users for many years. The best known are the needle exchange schemes. Uptake by addicts varies across the UK but rarely exceeds 25%. There remain a large number (48%) who report dangerous habits such as sharing injecting equipment (works).

Heroin users can reduce their risk of accidental overdose by being made aware of signs that they or other users may be becoming more vulnerable. Typical warning signs are longer history of use, not being in treatment, simultaneous use of benzodiazepines or alcohol, recent release from prison or a completed detoxification, and near miss events where consciousness was impaired, as revealed by pressure injuries and lost days.

The reluctant user needs to survive until they can be encouraged into treatment.

PART 18

Prevention of disease

343 Prevention of cardiovascular disease

Amitava Banerjee and Kaleab Asress

Introduction

The global scale of the cardiovascular disease epidemic is unquestionable, causing a greater burden of mortality and morbidity than any other disease, regardless of country or population. With demographic change and ageing populations, the prevalence of cardiovascular disease and its risk factors is set to increase. The commonest cardiovascular diseases are atherosclerotic, affecting all arterial territories. Figure 343.1 illustrates the major contributors to cardiovascular disease, showing the predominance of coronary artery disease and cerebrovascular disease (stroke and transient ischaemic attack (TIA)).

The 'burden of disease' approach has highlighted the fact that cardiovascular disease and non-communicable diseases are not simply diseases of affluence but affect people of all countries, with enormous costs in terms of public health, healthcare, and overall economies. Coronary artery disease is the leading cause of mortality in all regions of the world apart from sub-Saharan Africa, followed by cerebrovascular disease. It should be noted, however, that there has been a major decline in age-standardised cardiovascular disease mortality in Western Europe, the US, and Japan over the past 40 years. There are multiple factors underlying these favourable trends but understanding the epidemiology and characterizing individual risk factors for cardiovascular disease has been central in formulating preventive and treatment strategies. The INTERHEART study showed that 90% of cardiovascular risk can be explained by nine easily identifiable risk factors; an awareness of these, and the discovery of novel factors, will continue to serve in the fight to reduce the burden of cardiovascular disease. These risk factors for cardiovascular disease, traditional and novel, are discussed in Chapter 86. Geoffrey Rose first championed population-wide approaches versus strategies which target only high-risk individuals. Prevention aims to 'catch the disease' upstream, therefore delaying, reducing, or eliminating the risk of coronary artery disease. Surrogate markers for coronary artery disease have emerged in efforts to detect disease at earlier

stages, and in order to better understand the pathophysiology. For example, coronary artery calcium scoring is emerging as a marker of future risk of coronary artery disease. Risk stratification scores are increasingly used as tools to individualize a person's future risk of coronary artery disease in order to better target treatment and prevention strategies.

Causes of coronary artery disease

Large-scale epidemiologic studies over the last 50 years have firmly established the commonest risk factors for coronary artery disease, notably cigarette smoking, hypertension, diabetes mellitus, hypercholesterolaemia, and a family history of coronary artery disease. The 'risk factors approach' to coronary artery disease has looked at these factors, individually and in combination, in the causation of disease (Figure 343.2). The complex causation pathways involve interplay of individual factors, whether genetic or environmental. More recently, there has been increasing interest in 'epigenetics' or the way in which the environment interacts with genes in the process underlying coronary artery disease and other cardiovascular diseases.

Prevention of coronary artery disease

There is increasing recognition that the processes underlying coronary artery disease begin early in life, and possibly in utero.

Primary prevention of coronary artery disease

Primary prevention involves the prevention of disease before its biological onset. Primary prevention strategies include reducing environmental exposures, improving human resistance to disease, and providing education and tend to act at a broader, population-wide level. In the case of coronary artery disease, examples of primary prevention are the use of the aspirin and statins in individuals with no coronary artery disease but early stage risk factors. The polypill is a 'combination approach' to primary prevention, originally suggested by Wald and Law in 2002, which treats multiple risk factors with one pill that has a larger, cumulative effect on prevention than its individual components do. Several different formulations are in development, and clinical trials are underway to test the utility and safety of the polypill approach.

However, there is controversy regarding the evidence base for primary prevention in coronary artery disease. For example, although earlier meta-analyses of the use of statins in primary prevention of coronary artery disease have shown a beneficial effect, several of the statin trials recruited individuals with pre-existing disease (and are therefore not true primary prevention trials). Current guidance only advocates the use of statins for primary prevention in adults with a 20% or greater 10-year risk of developing cardiovascular disease. The most effective and cost-effective intervention for primary prevention in lower-risk adults is currently unclear. However, many of these calculations are based on the cost of interventions, and as potent drugs such as statins come off patent, many primary prevention strategies previously felt not to be cost effective become viable.

Secondary prevention of coronary artery disease

Secondary prevention aims to identify and treat existing disease in order to reduce morbidity and mortality. The reason for highlighting the secondary prevention group is that these patients have very high rates of further events, much higher than those who have not

Global deaths from CVD (millions)

had symptoms from cardiovascular disease. Secondary prevention may involve the treatment of individuals with single potent or multiple risk factors (together creating such a risk that the individual falls into the same risk category as those with established cardiovascular disease) and/or disease. The treatment of hypertension and hypercholesterolaemia in asymptomatic individuals with multiple risk factors (especially if they include diabetes) risk factors, or in individuals with symptoms such as angina or intermittent claudication, is classified as secondary prevention. The evidence base for secondary prevention strategies, such as the use of aspirin, statins, and/or antihypertensive therapy, is stronger than for primary prevention.

Tertiary prevention of coronary artery disease

Tertiary prevention aims to soften the impact of an ongoing illness or injury that has lasting effects. Tertiary prevention targets individuals with established, symptomatic coronary artery disease, to prevent further disease progression, morbidity, and mortality. After a myocardial infarction, interventions that improve prognosis include smoking cessation, increased physical exercise, and participation in a comprehensive cardiovascular rehabilitation programme.

Primordial prevention of coronary artery disease

Primordial prevention lies upstream in the continuum and can be defined as 'prevention of risk factors themselves'. This process may begin with change in social and environmental conditions in which these factors are observed to develop, and continues for high-risk children, adolescents, and young adults. Primordial prevention aims to change the socio-economic status of society. Improved socio-economic status has an inverse correlation with lifestyle risk factors such as smoking, poor nutritional status, and lack of exercise.

The Barker hypothesis, also known as the 'developmental origins of adult disease' hypothesis, was first described in detail in the early 1990s to explain how the intrauterine environment may have far-reaching effects on later adult life. The risk of coronary artery disease is higher in people who have low birthweight, and this risk decreases progressively across the range of birthweights; these findings have been replicated in several populations throughout the world. Placental growth, maternal nutrition, and early postnatal growth have all been associated with increased risk of coronary artery disease, and there is also evidence of association for stroke, hypertension, and insulin resistance. A pragmatic recommendation for primordial coronary artery disease prevention on the basis of the Barker hypothesis is

the need for to educate women of childbearing age about the importance of health and nutrition during and after pregnancy.

High-risk versus population approaches to the prevention of coronary artery disease

The level of patient care changes with the level of prevention. Primordial and primary prevention are activities at the population level, whereas secondary and tertiary prevention involves the treatment of individual patients. The latter two activities tend to occur in the inpatient setting, whereas the former two occur at the societal level.

Geoffrey Rose championed the concept that small changes in risk factor levels in low-risk individuals (the 'population approach') across a population may have a greater impact on disease prevention than large changes in the same risk factors in high-risk individuals (the 'high-risk approach'). The reality is that both approaches are required for the adequate treatment and prevention of cardiovascular disease. For example, education about lifestyle, smoking cessation, and exercise are necessary alongside improved access to secondary and tertiary prevention strategies such as drugs, primary angioplasty, and coronary artery bypass graft surgery.

A unified approach to the prevention of coronary artery disease

There are shared risk factors across several cardiovascular diseases. For example, atherosclerotic diseases (namely coronary disease, cerebrovascular disease, peripheral artery disease, and aortic disease) all share the same traditional risk factors of hypertension, history of smoking, diabetes mellitus, hypercholesterolaemia, and a family history of cardiovascular disease. Therefore, health professionals and the health systems they work in must recognize the synergism which can result from prevention in 'vascular medicine'. Adequate secondary prevention with aspirin, angiotensin-converting-enzyme inhibitors, and statins after a stroke will not only reduce the risk of future stroke and TIA but also reduce the risk of coronary and peripheral vascular disease in such patients.

However, different approaches are required for individual risk factors, depending on the type of vascular disease. Hypertension is relatively more important in the development of cerebrovascular disease, so strict blood pressure monitoring and control may be more important after stroke than for acute coronary syndrome. Nonetheless, at the level of primary prevention, greater benefit can be achieved by using the same approach for all risk factors across all types of vascular disease.

Risk prediction in the prevention of cardiovascular disease

The decision to initiate preventive therapy (whether life-long statin treatment or coronary stent insertion) is based on the assessment of the risks and benefits of the particular treatment, alongside the patient's personal preferences. An assessment of a patient's baseline risk of disease without therapy can help when the risk associated with a treatment is above a certain threshold. Research and clinical practice in vascular disease has been at the forefront of development of risk prediction tools to quantify and personalize an individual's future risk of cardiovascular events.

The Framingham Heart Study led to the first 'risk calculator' for quantifying an individual's future risk of coronary artery disease on the basis of their risk factor profile. There has been increasing recognition that overall risks and the contributions of individual risk factors vary between populations and over time, leading to prospective studies in different populations with the development of population-specific risk prediction tools. In the UK, the Q-RISK and ASSIGN risk calculators are recent examples of cardiovascular calculators developed for the UK populations, with the novel addition of risk factors such as social deprivation, ethnicity, and family history. Tools have also been derived and validated for use in lower-income settings without laboratory testing facilities for cardiovascular risk factors.

Disease- and situation-specific risk prediction tools have also emerged for the range of cardiovascular diseases. The potentially

Table 343.3 Approach to thromboprophylaxis in patients with atrial fibrillation

Risk category	CHA ₂ DS ₂ -VASc score	Recommended
One 'major' or ≥2 'clinically relevant non-major' risk factors	≥2	OAC, given as well-controlled VKA (INR 2.0–3.0) or direct-acting oral anticoagulant (DOAC)*
One 'clinically relevant non-major' risk factor	1	OAC or aspirin 75–325 mg daily. Preferred: OAC
No risk factors	0	Either aspirin 75–325 mg daily or no antithrombotic therapy. Preferred: no antithrombotic therapy

Note: CHA₂DS₂-VASc = cardiac failure, hypertension, age ≥75 (doubled), diabetes, stroke (doubled)-vascular disease, age 65–74, and sex category (female); INR = international normalized ratio; OAC = oral anticoagulation, such as a vitamin K antagonist (VKA) adjusted to an intensity range of INR 2.0–3.0 (target 2.5).

*OAC, such as a VKA, adjusted to an intensity range of INR 2.0–3.0 (target 2.5), or a direct-acting oral anticoagulant.

Reproduced with permission from A. John Camm et al., 2012 focused update of the ESC Guidelines for the management of atrial fibrillation, *European Heart Journal*, Volume 33, Issue 21, pp. 2719–2747, Copyright © 2012 Oxford University Press.

ABCD2 algorithm, 2-day risks for a subsequent stroke are 1% for a score of 0–3, 4% for a score of 4–5, and 8% for a score of 6–7 (Table 343.1).

The CHADS₂ and CHADS₂-Vasc tools are used to predict risk of stroke and thromboembolism in patients with atrial fibrillation (AF) and influence the decision to start oral anticoagulation (OAC) with warfarin or novel anticoagulants such as dabigatran. Table 343.2 summarizes these two risk stratification scores as well as the novel HAS-BLED score, which can be used to assess bleeding risk in patients with AF prior to initiation of OAC. Table 343.3 shows how the CHADS₂ and CHADS₂-Vasc tools are used in clinical practice. The risk of the outcome without therapy and the risk of an adverse outcome with the therapy (measured using the HAS-BLED score) are balanced to make the treatment decision regarding OAC.

Risk scores should only be used in patients who have characteristics similar to those of the patient cohort in which the risk score was originally validated. For example, risk scores for predicting coronary artery disease should not be used to predict stroke, as they have not been validated for that purpose.

In patients with one 'clinically relevant non-major' stroke risk factor (i.e. CHA₂DS₂-VASc score = 1), dabigatran 110 mg twice daily may be considered, as its efficacy is similar to that of vitamin K antagonists with respect to the prevention of stroke and systemic embolism but it has lower rates of intracranial haemorrhage and major bleeding when compared with vitamin K antagonists and (probably) aspirin.

344 Prevention of respiratory disease

Mona Bafadhel

Introduction

The prevention of disease at a population health level rather than an individual health level is aimed at reducing causes of 'preventable' death and, under the auspices of public health and epidemiology, is an integral part of primary, secondary, and tertiary care.

Classification of death is usually according to the type of primary disease or injury. However, there are a number of recognized risk factors for death, and modifications in behaviour or risk factors can substantially reduce preventable causes of death and the associated healthcare and economic burden of chronic disease management.

According to the WHO, hundreds of millions of people from infancy to old age suffer from preventable chronic respiratory diseases. There are over four million deaths annually from preventable respiratory diseases, and common respiratory disorders (e.g. lower respiratory tract infections, chronic obstructive pulmonary disease, lung cancer, and tuberculosis) account for approximately 20% of all deaths worldwide.

In this chapter, we discuss the prevention of respiratory disease, covering diseases associated with smoking (one of the biggest risk factors associated with preventable deaths), air pollution, and other lifestyle factors associated with respiratory disease; changes in legislation concerning smoking and work-related respiratory disease; and, finally, the prevention of respiratory diseases through the use of immunization and screening tools.

The history and burden of smoking

History of smoking

The spread of tobacco agriculture within Europe, Africa, and South East Asia occurred after the return of Christopher Columbus, following his journey to the Americas. However, the widespread introduction of tobacco and the act of smoking was not met without

opposition; smoking was banned by the Pope in 1590 and the cultivation of tobacco was suppressed by King James I in 1604. However, with its increasing popularity, economic revenue, and mass production, the era of the modern-day cigarette was firmly in place in the early twentieth century.

Smoking habits

Men are more likely to smoke than women, although in the UK the gender gap has narrowed over time. There is currently a downward trend in the number of people starting to smoke and, more recently, an increase in the number of people giving up smoking (Figure 344.1).

Smoking cessation

Smoking cessation is imperative in the practice of healthcare and disease prevention. Interventions to aid smoking cessation include unassisted methods such as healthcare provider advice, group cessation clinics, and one-to-one smoking cessation counselling. Nicotine replacement therapy (NRT), nicotinic receptor partial agonists (e.g. varenicline), and antidepressant medication (e.g. bupropion) are approved as smoking cessation aids. Success rates for each of these methods is varied and ranges from 10% with healthcare provider advice alone to 33% in persons who use NRT medication (the success rate being defined as the percentage of persons who remained 'quitters' after a 6-month period). Support and advice, including discussions of the short- and long-term effects of smoking cessation, need to be provided in order to maintain smoking cessation.

Legislation

Smoking legislation exists to protect individuals from the effect of second-hand smoke; the WHO Framework Convention Tobacco Control Treaty was developed in response to the tobacco epidemic, and serves to affirm the highest standard of health to all individuals, providing both measures to reduce tobacco demand (cost and taxes) and protection

Figure 344.1 The decline in smoking in recent years.

Data from an Office of National Statistics survey (http://www.ons.gov.uk/ons/dcp171776_302558.pdf).

from the effects of tobacco exposure. In the UK, the ban on smoking in public places was first introduced in Scotland (March 2006), then Wales and Northern Ireland (April 2007), and, finally, in England (July 2007). This ban involves the prohibition of smoking in all enclosed public spaces (e.g. workplaces, restaurants, bars, and pubs). Since its introduction, there has been a decline in cigarette sales, and reduced trends of all-cause smoking-related hospitalization.

The evidence for the role of smoking in respiratory disease

Lung cancer

In the UK, lung cancer is the most common cause of death from cancer and is responsible for over one-fifth of all cancer deaths. Variations in lung cancer mortality rates within the UK reflect the variations in smoking trends within geographical areas, with smoking and lung cancer rates higher in Scotland than in England and Wales. In 1956, Doll and Hill published their epidemiological findings which linked lung cancer with smoking. Heavy smokers (defined as those smoking more than 25 grams of tobacco or 25 cigarettes per day) were approximately 20 times more likely to die from lung cancer than never smokers in a 5-year follow-up period. Worldwide, almost 90% of lung cancer is attributed to smoking; after a lag time of 20 years, there is now a steady increase in the number of women being diagnosed with lung cancer. Prevention of lung cancer is the most cost-effective way of combating this disease; primary prevention with smoking cessation is unequivocally an important tool in this process, as general population screening methods have not demonstrated clear benefits.

Chronic obstructive pulmonary disease

Chronic obstructive pulmonary disease (COPD) is currently the fifth leading cause of death worldwide, and is predicted to be the third leading cause of death worldwide by 2020. It is the only common disease worldwide that continues to increase in incidence and prevalence, and rates in women are increasing three times faster than men. In the UK, approximately 1 million people are diagnosed with COPD, but there are believed to be a further 2 million persons that have not been formally diagnosed. This leads to an estimate that, in the UK alone, 1 in 10 people over the age of 40 are likely to have COPD, making it one of the most prevalent respiratory diseases. COPD is diagnosed by clinical history and spirometry and largely encompasses the terms emphysema, chronic bronchitis, and chronic asthma. The severity of COPD can also be diagnosed by spirometry, symptoms and history of exacerbations. It is an irreversible airways disease associated with a progressive decline in lung function and is accelerated in people who continue to smoke. Smoking is the main cause of COPD, although there is increasing recognition of biomass fuels and air/dust pollution as causal agents. In 1977, Fletcher and Peto published a landmark study evaluating the effects of smoking on the development of COPD; in it, they showed that regular smokers exhibited an accelerated decline in forced expiratory volume in 1 second but that this slowed to the rate of natural decline after smoking cessation.

Preventing common respiratory infections

Vaccinations

Acute respiratory infections are estimated to be responsible for 4 million deaths worldwide and are the leading causes of death in children under the age of 5. Vaccines are currently available for the prevention of disease from the following pathogens, with which there are associated respiratory disease burdens:

- *Haemophilus influenzae* B
- *Streptococcus pneumoniae*
- influenza virus

Haemophilus influenzae B

The *Haemophilus influenzae* type b bacterium is commonly present in the nose and throat, and is transmitted through droplet spread. Infection with *Haemophilus influenzae* type b may be mild and

asymptomatic; in the developed world, it can cause fatal pneumonia, while, in developing countries, it can be responsible for non-epidemic meningitis. *Haemophilus influenzae* type b infection can be prevented by vaccination.

Streptococcus pneumoniae

Streptococcus pneumoniae is a leading cause of morbidity and mortality worldwide, with pneumococcal bacteraemia episodes being common at the extremes of age. So far, there are 40 serogroups and 90 serotypes, with differences worldwide with respect to which serotypes cause disease and thus which vaccine programmes are likely to be effective. *Streptococcus pneumoniae* is carried in the human nasopharynx and spreads via droplets. Within the first year of life, almost everyone is colonized with at least one strain. In adulthood, at least 30% of cases of community-acquired pneumonia are related to *Streptococcus pneumoniae*. Vaccination is 60% effective in immunocompetent individuals, with an efficacy in the region of 20% in immunocompromised individuals.

Influenza

Influenza is highly contagious and readily transmitted via droplets. There are up to 600 million cases of influenza each year, with approximately 0.5 million deaths per year. Seasonal influenza epidemics reflect that there is continuous antigenic virus change, with the emergence of strains that cause epidemics and pandemics. Circulating influenza A human strains can acquire new genes from avian or other animal reservoirs, such as pigs, and these can cause worldwide pandemics, as was the case in 1918, 1957, 1968, and 2009. Facing this requires continually updated strain changes of influenza vaccines or the production of a universal vaccine, with vigilance and hygiene practices as routine practices. Mortality from influenza can be unpredictable, but vaccination programmes for the population at risk, including the elderly and the immunocompromised, allow for success in mortality rate reduction.

Respiratory syncytial virus

Respiratory syncytial virus (RSV) is the most important cause of viral lower respiratory tract infection in infants and children, commonly causing hospitalizations due to bronchiolitis and childhood pneumonia. Humans are the only reservoir for RSV, but the virus can persist for several hours on inanimate objects. It is common for children to have more than one RSV infection, which increases the risk of childhood wheezing episodes and the development of asthma.

TB

One-third of the world's population (2 billion people) is infected by *Mycobacterium tuberculosis* and thus exposed to the risk of developing TB. It is estimated that there are 9 million new cases of TB each year, and almost 2 million deaths from TB annually worldwide. BCG, a vaccine using *Bacillus Calmette–Guérin*, a derivative of *Mycobacterium bovis*, protects children from severe pulmonary forms of TB but has no lasting effects of protection into adulthood. The emergence of multidrug-resistant TB, extremely resistant TB, and coexistent infection with HIV underscores the importance of developing better and improved TB vaccines. TB is highly contagious; each infectious carrier of pulmonary TB will infect 15 people on average each year, as the infection spreads via droplets and the number of bacilli required to initiate an infection is low. To prevent this common and treatable yet potentially fatal infection, an effective vaccine, together with surveillance and screening programmes, is required in both the developing and the developed world.

Lifestyle factors involved in preventable respiratory disease

Obesity

Obesity is the most common risk factor for obstructive sleep apnoea (OSA), the commonest cause for sleep-related respiratory disorders. It is caused by obstruction of the upper airway, where obstruction is caused by an increased muscle relaxation that occurs during sleep.

It is characterized by repeated pauses in breathing; such pauses are termed 'apnoeas'. OSA is associated with an increased risk of systemic and pulmonary hypertension, cardiovascular disease, and metabolic syndrome. Risk factors for OSA include reduced muscular tone and increased soft tissue mass surrounding the upper airway. With the worldwide increase in obesity, OSA is becoming more prevalent. Weight reduction can reverse OSA, and at-risk individuals should be recognized early to prevent associated cardiovascular and metabolic risks.

Air pollution

Air pollution (outdoor or indoor) is defined as the introduction of chemicals, particulate matter, and/or biological materials that can cause harm or discomfort to humans and other living organisms. For outdoor air, pollution air quality standards govern atmospheric concentrations for specific known pollutants; various thresholds can also be set, to communicate to the public the relative risks of outdoor activity. Indoor air pollution, with exposure to biomass smoke, is considered a risk factor for the development of COPD, lung cancer, and acute lower respiratory infections. The levels of small soot or dust particles generated by burning solid fuels can exceed acceptable levels for outdoor pollution by 100 times. The reliance on burning wood, dung, crop waste, and coal to meet energy needs, in environments that have poor ventilation, continues to rise in developing countries. Indoor air pollution doubles the risk of pneumonia, triples the risk of COPD, and almost doubles the risk of lung cancer in non-smoking women. Provisions of measures that reduce indoor air pollution include using improved stoves and hoods that vent to the outdoors, and switching to more sustainable and cleaner alternatives.

Occupational exposure

Through regulation, it is possible to reduce occupational exposure to known carcinogens and the associated risk of respiratory disease. The most widely known occupational respiratory disease, with clear legislative recommendations for prevention, management, and counselling for compensation, is that related to asbestos. Exposure to asbestos fibres causes asbestosis (a progressive pulmonary fibrosis) and mesothelioma (pleural cancer) and increases the risk of both lung cancer and benign disease such as pleural plaques. Occupational exposure to dusts, fumes, natural, and non-natural elements also increases the risk of diseases such as asthma; hence, legal requirements for providing education and respiratory protection to at-risk individuals within the workplace can prevent respiratory illness.

Conclusion

Respiratory illness is common, and is a great burden on healthcare worldwide. Population-based methods to reduce this burden must begin with prevention, as simple measures such as education, vaccinations, screening, and hygiene can reduce the prevalence and incidence of many preventable respiratory diseases in a cost-effective manner.

345 Prevention of kidney disease

Aron Chakera, William G. Herrington, and Christopher A. O'Callaghan

Introduction

A number of factors are known to predispose to renal disease, such as diabetes mellitus, hypertension, and exposure to certain drugs (see Box 345.1) or substances (e.g. mercury and other heavy metals). In people who are at risk for these reasons, renal function should be regularly monitored as part of routine care.

Prevention of kidney disease

Kidney diseases are identified by elevations in the serum creatinine; the presence in the urine of blood, protein, or elevated levels of certain electrolytes; or evidence of anatomical abnormalities. Due to the large functional reserve of the kidneys, symptoms of impaired renal function usually occur late in the course of disease, highlighting the importance of early detection and, where available, the use of ameliorating therapies. Therapies exist for some forms of acute and chronic kidney diseases and range from inexpensive (e.g. normal saline to ensure adequate hydration prior to IV contrast administration) to very expensive (e.g. enzyme replacement in Fabry's disease). Once chronic damage is established, it may be possible to slow the rate of progression to end-stage renal disease or prevent its occurrence

Box 345.1 Risk factors for kidney disease

Vascular

- hypertension
- heart failure/coronary artery disease
- cerebrovascular disease
- peripheral vascular disease

Multisystem diseases

- diabetes mellitus
- SLE
- vasculitis
- myeloma
- rheumatoid arthritis
- scleroderma

Infectious agents

- HIV
- hepatitis B
- hepatitis C

Urological conditions

- bladder outflow obstruction
- neurogenic bladder
- urinary diversion surgery
- urinary anatomical abnormalities
- recurrent urinary tract stone formation

Drugs

- angiotensin-converting enzyme inhibitors and angiotensin receptor blockers
- NSAIDs
- lithium
- mesalazine
- calcineurin inhibitors (ciclosporin, tacrolimus)
- antibiotics (e.g. gentamicin and amphotericin)
- chemotherapy agents (e.g. cisplatin)
- radio-opaque contrast

entirely. Even when end-stage renal disease has developed, it may be possible to prevent the development of the metabolic consequences of deranged kidney function, such as acidosis, anaemia, and defective bone mineralization, all of which increase morbidity and mortality (these are discussed in Chapter 163).

Prevention of acute kidney injury

The majority of cases of acute kidney injury are predictable and are caused by impaired renal perfusion leading to tubular damage, or by the effects of substances that are toxic to the tubules. The important reabsorptive and secretory functions of tubular cells may also expose them to high concentrations of toxins, including various medications that can lead to direct damage.

Acute kidney injury is commonly seen in hospitalized patients, and particular groups of patients are at risk, as discussed in 'Introduction' (also see Box 345.2). In many cases, the kidney injury is secondary to the underlying disease process or processes responsible for the admission, but careful attention to optimizing renal perfusion and the avoidance of further insults can reduce renal damage and decrease the likelihood of needing renal replacement therapy.

In clinical practice, a combination of these risk factors often coexist, and some common scenarios include renal impairment arising as a result of hypotension, sepsis, or the use of IV contrast or nephrotoxic drugs.

In many situations, acute kidney injury may be prevented if the risk of the injury is appreciated, patients are identified early, and measures are taken to ensure adequate renal perfusion and to avoid further renal insults. Approaches include:

- prompt fluid resuscitation in volume-depleted patients; postural hypotension is a good marker for ongoing intravascular depletion,

Box 345.2 Risk factors for acute kidney injury

Reduced nephron mass

- preexisting chronic kidney disease
- elderly patients

Systemic diseases

- diabetes mellitus
- myeloma

Impaired renal perfusion

- volume depletion
 - vomiting or diarrhoea
 - burns
 - haemorrhage
- volume redistribution
 - sepsis
 - cardiac failure
- renal artery stenosis
- hypotension

Nephrotoxic medications

- antibiotics
- chemotherapy agents
- antihypertensives
- NSAIDs

Impaired drainage

- prostatic obstruction
- spinal cord injury

and repeated clinical assessment is essential in order to deliver appropriate fluid replacement

- careful prescription of maintenance IV fluid in patients with inadequate oral intake
- daily weighing, where possible; this is very helpful for monitoring fluid balance, and can be used in addition to taking input and output measures
- maintenance of an adequate mean arterial blood pressure, using invasive monitoring and inotropes if needed
- stopping angiotensin-converting-enzyme inhibitors (ACE-Is) and angiotensin receptor blockers (ARBs) in acutely unwell or dehydrated patients
- avoiding NSAIDs for post-operative analgesia in at-risk patients
- performing regular checks of renal function
- monitoring levels of nephrotoxic agents (e.g. gentamicin, ciclosporin, tacrolimus) if clinical need necessitates their use
- excluding bladder outflow obstruction

Patients with a reduced glomerular filtration rate (GFR) are at greater risk of contrast-induced nephropathy, particularly if there is concomitant dehydration or diabetes mellitus. Alternative imaging modalities should be used where possible; if contrast is necessary, the minimum possible volume should be used. Hyperosmolar and ionic contrast media should be avoided. Adequate pre-hydration is essential and should be continued for at least 24 hours after the procedure.

Prevention of chronic kidney diseases

Genetic kidney diseases

A large number of genetic diseases involve the kidneys; some are specific to the kidneys, whereas in others, renal damage occurs in the context of more generalized disease. With improvements in DNA sequencing technologies, it is becoming easier to screen for mutations prenatally and to provide counselling. For some diseases, evidence is accumulating that early interventions may slow the rate of decline in renal function associated with the disease. As a result, these patients may never reach end-stage kidney disease or even develop significant renal dysfunction during their lifespan. An example may be polycystic kidney disease (see Chapter 169), where renal impairment develops over time due to progressive cyst expansion, which compresses and compromises normal renal tissue. Early inhibition of cyst growth with vaptans, ACE-I, somatostatin analogues, or other therapies currently under investigation may prevent disease. Table 345.1 lists some genetic diseases and currently available or experimental therapies.

Acquired kidney diseases

In the developed world, diabetes and lifestyle diseases are responsible for the majority of patients who reach end-stage kidney disease. Most of these conditions are associated with either elevations of the serum creatinine (a reduction in GFR) or the presence of albuminuria or proteinuria. Several large studies demonstrate that population-based screening strategies can identify asymptomatic people with albuminuria or reduced estimated GFR and it may be that early

Table 345.1 Genetic disease causing renal impairment

Disease	Mutation	Potential therapies
Adult polycystic kidney disease	Polycystin	Angiotensin-converting enzyme inhibitors Vaptans Triptolide
Cystinosis	Cystinosisin	Cysteamine
Fabry's disease	Alpha-galactosidase	Alpha-galactosidase
Familial juvenile hyperuricaemic nephropathy	Uromodulin	Allopurinol

treatment will prevent progression to significant chronic renal impairment in these patients.

For patients with diabetes, there is good evidence that optimizing glycaemic control and the early use of ACE-Is or ARBs can reduce the rate of renal progression. Good blood pressure control can slow the rate of renal deterioration in patients with renal impairment, and current evidence would suggest using ACE-Is or ARBs if there is evidence of proteinuria.

Screening for kidney disease

In the UK, there has been widespread adoption of routine estimated GFR reporting to assist in the identification of chronic kidney disease; however, the current classification scheme is contentious, as many patients, particularly those with chronic kidney disease, may have renal function in the normal range for their age and sex, as determined by population-based studies. These people do not have any significant chronic kidney disease and there is no evidence that they will progress to end-stage disease.

In addition to questions regarding the validity of the current classification system, in many cases there is little or no evidence that any treatments will alter the progression of disease. Key exceptions where treatments can prevent progression of renal disease are diabetic nephropathy, hypertensive nephropathy, and some of the proteinuric glomerulonephritides. It is also worth mentioning that treatment of these conditions generally reduces the risk of a cardiovascular event to a greater degree than the risk of progression to end-stage renal disease.

346 Prevention of gastrointestinal disease

Satish Keshav and Alexandra Kent

Introduction

Disease prevention is usually directed where there is considerable morbidity or mortality, and etiological factors that can be controlled, treated, or reduced. The greatest morbidity and mortality from gastrointestinal disease is related to infectious diarrhoea and gastrointestinal cancer, both of which can be prevented. In addition, alcohol consumption and viral hepatitis are preventable causes of liver disease, liver failure, and hepatic cancer.

Alcohol

It is well recognized that excess alcohol consumption is associated with a wide range of different disease processes. In addition to liver disease, alcohol consumption is also an etiological factor in many cancers, and is estimated to be the cause of 6% of cancer deaths. Excess alcohol consumption probably doubles the risk of oesophageal cancer, although some studies estimate the risk to be 5–10 times that of an abstinent person. It also increases the risk of bowel and liver cancer. The concept that red wine can reduce cancer risk has been disputed by large studies, and should not be supported in clinical practice. Gastrointestinal physicians will see many patients with deranged liver function related to alcohol consumption, and it is important that the patient is educated appropriately: reducing alcohol consumption not only reduces the risk of liver disease and cirrhosis, but also reduces the risk of cancer. Prevention is difficult and dependent on patient commitment, so support services should be made available. Alcohol is discussed in more detail in Chapters 211 and 339.

Smoking

Smoking is an etiological factor in many diseases: 50% of smokers die from cancer or smoking-related diseases, and 25% of these deaths will be in patients under the age of 70 years. Smoking has been closely associated with oesophageal, gastric, and liver cancer and, consequently, smoking prevention should reduce the incidence of these and other smoking-related conditions. Smoking also has a significant effect in inflammatory bowel disease. Epidemiological studies have shown smoking to be associated with a worse outlook in Crohn's disease, with disease flares and an increased risk of surgery. Conversely, ulcerative colitis is more frequent with non-smokers, and often presents for the first time when former smokers stop. An interesting corollary of this is that life-expectancy in ulcerative colitis is equal to or greater than in the general population.

Peptic ulcer disease

The two main treatment options for patients with peptic ulcer disease are proton-pump inhibitors and eradication of *Helicobacter pylori*, as both treatments improve ulcer healing. However, there is no evidence that either treatment can be used a primary preventive measure. A recent Cochrane review established that, in the setting of NSAID-induced ulceration, proton-pump inhibitors, misoprostol, and double-dose H₂ antagonists can reduce the incidence of gastric and duodenal ulceration. The cost-effectiveness of such preventive measures is unknown. Usually, prophylactic treatment is reserved for patients who would have a poor prognosis should they develop peptic ulcers, for example, elderly patients receiving anticoagulation medication. Selective COX-2 inhibitors were initially thought to be anti-inflammatory drugs that would not cause the gastrointestinal ulceration associated with NSAIDs. Unfortunately, they are still associated with gastrointestinal ulceration and perforation, although

the risk is lower than with NSAIDs. There is a well-established association between *Helicobacter pylori* and gastric cancer, and several observational studies from Japan and China have shown that eradication of *Helicobacter pylori* reduces the incidence of stomach cancer. However, this result cannot be transferred to general medical practice without larger studies, as these findings may relate to the higher incidence of stomach cancer in these countries.

Colorectal cancer

The most effective preventive measure for colorectal cancer is the establishment of screening programmes. Currently, in the UK, those aged 60–69 are offered faecal occult blood tests, with a colonoscopy offered to people with positive results, as part of the National Bowel Cancer Screening Programme. The aim is to identify people with early and therefore treatable cancers, and also people with colorectal adenomatous polyps. Adenomatous polyps are then monitored through adenoma screening programmes. Other conditions requiring colorectal cancer surveillance include inflammatory bowel disease, acromegaly, familial adenomatous polyposis, hereditary non-polyposis colorectal cancer, juvenile polyposis, Peutz–Jeghers syndrome, a strong family history of colorectal cancer, and ureterosigmoidostomy (for further details regarding screening in gastrointestinal disease, see Chapter 354). Other etiological factors known to increase the risk of bowel cancer include diets high in fat and cholesterol, and red meat, especially processed meat. Smoking, obesity, and alcohol increase the risk of colorectal cancer. Many patients who attend hospital harbour concerns of developing cancer, and all of these factors can be discussed with them as potential preventive measures. Diabetes mellitus has also been shown to increase the risk of adenomatous polyps. Conversely, studies have shown that regular aspirin ingestion can reduce the incidence of colorectal adenomatous polyps and colon cancer.

Oesophageal adenocarcinoma

There is clear evidence that recurrent acid reflux can lead to inflammation in the oesophagus, which can lead to the development of Barrett's oesophagus. Approximately 10% of patients undergoing endoscopy for reflux symptoms have Barrett's oesophagus, and approximately of these 5% have associated dysplasia. Adenocarcinoma arises from Barrett's dysplasia; therefore, patients with Barrett's oesophagus may enter a screening programme (see Chapter 354 for further details). There is no definitive evidence that this will reduce the incidence of oesophageal adenocarcinoma as yet, but the combination of earlier diagnosis and treatment of high-grade dysplasia is expected to have this effect. Patients with Barrett's oesophagus are maintained on long-term proton-pump inhibitors, to reduce acid exposure, with the aim of reducing progression or the development of dysplasia.

Hepatitis B

There is a growing incidence of hepatitis B infection in the UK, due to immigration. The major routes of transmission are vertical, from mother to child, mainly in the Far East, and horizontal, from shared needles, unprotected sexual intercourse, and non-sterile shared equipment, for instance in tattooing. The development of a vaccine for hepatitis B offers the chance to eliminate the risk of transmission. Currently, it is offered to at-risk populations. These include medical workers, IV drug users, family members or partners of hepatitis patients, and immunosuppressed patients.

Hepatitis C

Hepatitis C is a growing concern, with patients presenting with liver complications many years after contracting the virus. Research hopes to develop a vaccine but, even if such research is successful, reaching patients at risk of contracting the virus will be difficult. Prevention includes promoting sterile-needle programmes amongst users of IV drugs. There is limited evidence of sexual transmission, and blood products are now routinely screened.

Non-alcoholic fatty liver disease

There is a growing incidence of non-alcoholic fatty liver disease (NAFLD) worldwide, with estimates of 20% of the population being affected in the UK. Risk factors for the development of NAFLD include obesity, diabetes, impaired glucose tolerance, hyperlipidaemia, and hypertension. These are obviously also etiological factors for ischaemic heart disease; thus, patients receive additional benefit from controlling each factor. Weight loss, together with control of blood pressure, cholesterol levels, and diabetes, is expected to slow the progression of liver disease, preventing the development of steatohepatitis and subsequent cirrhosis.

Gastrointestinal infection

The most important preventive measure to reduce the incidence of gastrointestinal infections is to maintain good sanitation, with hand-washing and hygienic food preparation. The main barrier to this worldwide is the lack of safe, uncontaminated drinking water, poor sanitary facilities, and poverty.

347 Prevention of neurological disease

Karen Morrison

Introduction

Neurological disease is very common. It is estimated that one-third of consultations with general practitioners involve neurological complaints, and neurological disorders are present in one-third of patients admitted to hospital. Table 347.1 shows the prevalence of some of the most common neurological diseases.

In considering how to reduce the incidence of neurological disease, one must take into account the feasibility of prevention, and the overall morbidity caused by the disease. In stroke, which is very common, interventions which reduce incidence by a small percentage have the potential to have a large impact on a population basis. A disorder such as migraine, while not life-limiting, accounts for significant morbidity and time off work (one study suggests that there are the equivalent of 112 million bedridden days per year due to migraine alone), so, again, interventions that reduce the frequency of episodes even by a small percentage can have great overall impact. In this chapter, we consider the major categories of neurological disease based on pathogenesis, and current and future approaches to prevention.

Prevention in vascular neurological disease

Prevention of stroke

Stroke is the main cause of neurological morbidity in adults and the third most common cause of death worldwide after ischaemic heart disease and cancer (all forms combined). Preventive strategies for stroke, due to either ischaemia or haemorrhage, are discussed in Chapter 348.

Prevention of epileptic seizures

Epilepsy is another of the common, serious brain disorders, with a prevalence of just under 1% of the population. Most cases of epilepsy are termed 'cryptogenic' or 'idiopathic', with no underlying structural brain abnormality identified. While surgically resected specimens from some patients with seizures can show anatomical changes such as mesial temporal sclerosis, with neuronal dropout and reactive gliosis, these morphological changes don't explain how seizures develop and propagate. There has been extensive debate over the years as to whether 'seizures beget seizures', that is, does having one epileptic seizure in some way prime or 'kindle' the brain so that further seizures are more likely to occur? If such priming does occur, it is even

more important to try to prevent seizures in those who have already suffered an event.

Overall, around 60% of people with epilepsy are well controlled (rendered seizure-free) by using a single drug at appropriate therapeutic dose; 70% are well controlled on two drugs; and around 75% on three drugs. The various classes of antiepileptic drugs have been detailed in Chapter 226. Other measures that can be effective at reducing seizure frequency include ensuring sufficient sleep, maintaining a regular routine with regular meals, and avoiding triggers as appropriate, such as flickering lights where photosensitivity has been demonstrated. Some seizures are the result of underlying structural or metabolic disease (see Table 347.2); in such instances, prevention of further attacks relies on treatment of the underlying cause, in addition to providing anticonvulsant therapy. Neurosurgery to remove an identified epileptogenic focus (such as may occur with congenital brain malformations) can be extremely effective at reducing the frequency, or even eliminating, seizures in appropriately selected patients.

One of the causes of refractory epilepsy is non-compliance with medication. Current first-line anticonvulsant drugs have many fewer long-term side effects than previously used drugs such as phenytoin and phenobarbital, although side effects such as somnolence and mental dulling or weight gain are still reported and undoubtedly influence compliance. An important specific area is that of epilepsy and pregnancy. Overall, there is no increased risk of seizures in pregnancy, but some women, concerned about the possible teratogenic effects of anticonvulsants, will reduce or stop their medications in pregnancy and thus be at increased risk of seizures. Women need clear advice on the safest and most appropriate anticonvulsants to take during pregnancy and breastfeeding, and should be referred for appropriate specialist advice, ideally prior to conceiving.

Another area of epilepsy prevention to consider is that of prophylactic use of anticonvulsants following head trauma or in relation to brain surgery. Factors that increase the risk of a seizure following head injury include the severity of the injury, whether there is depression of a skull fracture, the presence of focal neurological signs and/or intracranial haematoma, and the duration

Table 347.1 Prevalence of some common neurological disorders

Disorder	Prevalence per 100 000 population
Migraine	2000
Other severe headache	1500
Epilepsy	650
Acute cerebrovascular disease	600
Lumbosacral pain	500
Dementia	250
Parkinson's disease	200
Single seizure	60
Multiple sclerosis	60

Table 347.2 Some causes of epilepsy

Causes	Notes
Idiopathic	No underlying metabolic or structural brain disease
Structural brain disease	e.g. congenital neuronal migration disorder
Epilepsy post head trauma	
Intracranial space-occupying lesion	e.g. brain tumour, brain abscess
Epilepsy due to monogenic gene mutations	e.g. mutations in GABA _A receptor, K ⁺ channel mutations
Metabolic causes:	
• hyperglycaemia	
• hypoxia	
• uraemia	
• hypernatraemia	
• hypokalaemia	
• hypocalcaemia	
• liver disease	
Drugs	e.g. phenothiazines, tricyclic antidepressants
Drug withdrawal	e.g. benzodiazepines, alcohol withdrawal

of post-traumatic amnesia. Age is a further important factor, with young children having the highest risk of seizures post head trauma, and the risk progressively decreasing throughout life. There is reasonable evidence to support the use of prophylactic anticonvulsant medications for 6 months following severe head injury or brain surgery, but the evidence for prophylaxis decreasing the risk of later post-traumatic seizures is less secure.

Prevention of degenerative brain disease

Degenerative brain disease is an increasing burden to individuals and society in our ageing population. The most common diseases in this category are dementia and Parkinson's disease. Other degenerative disorders include motor neuron disease (also known as amyotrophic lateral sclerosis), inherited disorders such as Huntington's disease, and the Parkinson's related disorders of multiple system atrophy and progressive supranuclear palsy. While these latter diseases are, fortunately, quite rare, they cause huge suffering to individuals, carers, and families; thus, any interventions that might reduce their incidence would be highly valuable. Some of the theories proposed to account for the increasing incidence of these disorders with age include decreased mitochondrial efficiency and function, increased cellular oxidative stress with decreased repair mechanisms, and the impairment of pathways of autophagy and protein turnover.

Prevention of Alzheimer's disease

Alzheimer's disease, named after Alois Alzheimer, the German psychiatrist who first published on the disease in 1907, is the commonest form of dementia. The prevalence increases exponentially with age from 65 onwards, such that between 5% and 10% of people aged between 65 and 74 years are affected, rising to between 30% and 40% of the population aged over 85 years. The key features of memory loss, personality decline, and cognitive decline progress over years such that, by the advanced stages of the disease, individuals can no longer recognize close family and friends, are mute, incontinent, and cachectic, and may suffer seizures. Neuropathologically, Alzheimer's disease is characterized by intra-neuronal protein aggregates of hyperphosphorylated tau protein (neurofibrillary tangles), aggregation of plaques of amyloid beta protein in the brain parenchyma and in blood vessel walls, and neuronal degeneration and loss.

There has been, and continues to be, extensive research aimed at identifying risk factors for Alzheimer's disease so that preventive strategies can be undertaken. Some of these factors, confirmed in large, prospective studies, are listed in Box 347.1.

Some of the possible preventive interventions are listed in Box 347.2. While there is good evidence that treating or preventing vascular disease will reduce the subsequent risk of developing Alzheimer's disease, the evidence is less clear for strategies such as use of NSAIDs, statin therapy, or hormone replacement therapy, with most of the evidence coming from retrospective population or clinic studies rather than prospective studies.

Box 347.1 Risk factors for Alzheimer's disease

- age: the most consistent risk factor
- poor educational attainment
- vascular disease: hypertension, hypercholesterolaemia, diabetes mellitus
- family history of Alzheimer's disease
- genetic factors: polymorphisms of apolipoprotein E (the risk of developing Alzheimer's disease is 2–3× greater for APOE4 heterozygotes and 6–8× greater for APOE4 homozygotes, compared to that for those not carrying this allele)
- menopause in women
- rare genetic mutations (for familial forms of Alzheimer's disease): mutations in amyloid precursor protein, presenilin 1, or presenilin 2
- previous significant head trauma

Box 347.2 Suggested strategies to prevent Alzheimer's disease

- vascular disease: treat hypertension, avoid smoking
- retain intellectual abilities: crosswords, Sudoku, 'if you don't use it you lose it'
- maintain social interactions
- maintain an active lifestyle
- hormone replacement therapy in postmenopausal women
- statin therapy
- anti-inflammatory drug use

Prevention of Parkinson's disease

Parkinson's disease, another common neurodegenerative disorder, is characterized clinically by tremor, rigidity, and bradykinesia, with the underlying pathological feature of degeneration of dopaminergic cells and accumulation of intra-neuronal inclusions in the neurons of the substantia nigra of the midbrain. Parkinson's disease mostly occurs in people over 60 years of age, but early onset disease (onset less than the age of 40 years) is well recognized, particularly in some rare inherited forms of the disease, for example disease due to mutations in PARK2. Epidemiological studies have identified environmental risk factors for the disease (see Box 347.3), while, in the last decade, an increasing number of genetic variants have been identified (e.g. variants in SCNA, LRRK2, and GBA) that also increase susceptibility to sporadic Parkinson's disease.

The observation of decreased incidence of Parkinson's disease in cigarette smokers has been noted for at least 20 years. At one time, this was thought due to the fact that cigarette smokers die prematurely from vascular disease and cancer, such that they do not reach an age at which they are likely to develop Parkinson's disease. It is now clear that this is not the explanation and that cigarette smoking does indeed protect against developing Parkinson's disease, with greater protection accruing to those who have smoked for the longest time. The mechanism for the protective effect is not known. One theory relates to the fact that nicotine can stimulate postsynaptic dopamine receptors and so protect against their downregulation. Caffeine also protects against developing Parkinson's disease; as its chemical structure is similar to that of nicotine, it may act via a similar mechanism. The discovery that MPTP can cause a severe form of parkinsonism came in the 1980s, when a group of IV drug addicts developed the disease on injecting a contaminated synthetic heroin preparation. Although MPTP has been very useful in developing animal models to investigate underlying pathways and mechanisms in the disease, its identification as a selective toxin for dopaminergic neurons has not as yet led to any specific preventive strategies.

Prevention of multiple sclerosis

Multiple sclerosis (MS) is being included here, as it is the most common disorder which results in severe physical disability in young adults in the UK (see Chapter 231). The underlying pathology in the

Box 347.3 Environmental causes of Parkinson's disease

Increased risk

- pesticide use, particularly rotenone
- rural residence, farming
- drinking well water
- MPTP (a mitochondrial protoxin)
- heavy metal exposure (e.g. manganese, lead)
- repeated head injury (e.g. boxing)
- encephalitis lethargica

Decreased risk

- cigarette smoking
- coffee drinking

most common form of the disease is the formation of inflammatory plaques resulting in demyelination of axons within the CNS. In time (usually between 4 and 6 weeks) these inflammatory plaques resolve, the myelin sheath is repaired, and normal neuronal function returns. However, with repeated 'attacks' of demyelination, remyelination is incomplete, and axonal loss occurs, resulting in the patient accumulating long-term disability.

The cause of MS is still uncertain, although there is evidence that immune mediated mechanisms are involved, with both B-cells and T-cells implicated. There are both genetic and environmental risk factors for the disease. The disease is more common in identical twins than in non-identical twins, and the risk of developing MS if a sibling has the disease is between 3% and 5%, which is about 30–50 times higher than the background risk in the population. Considering environmental factors, the disease has a higher incidence in regions with a temperate climate. One explanation for this is that certain viruses found in these regions may trigger the disease. However, studies of EBV, measles, and various herpes viruses have yielded varying results, and there is still no firm evidence to implicate any specific infectious agent. Another explanation for the geographical distribution of the disease is that a lack of vitamin D is implicated in its pathogenesis. There is some recent evidence that adequate vitamin D levels can be protective against developing MS, but the mechanism for this effect is not clear, and it remains uncertain as to whether vitamin D supplementation can influence MS progression.

While there are no clearly identified interventions that can prevent a first episode of demyelination, there is now huge research effort directed towards immunomodulatory therapies that can reduce the chances of subsequent attacks. Currently, there are several immunosuppressive treatments, both IV and oral, that reduce the risk of relapses in the disease, and many studies in progress of immune modulators that show great promise in reducing the axonal loss and thus slow or prevent the axonal damage in the secondary progressive phase of the disease.

Prevention of infectious diseases of the brain

Prevention of bacterial meningitis

Other important causes globally of serious neurological disease are meningitis and encephalitis. Bacterial meningitis is, thankfully, not common in the developed world (i.e. its incidence is 3 per 100 000) but, worldwide, it is, particularly in sub-Saharan Africa, in the so-called 'meningitis belt', where epidemics affecting up to 800 per 100 000 have been reported. The main causes of bacterial meningitis in the UK are listed in Table 347.3. Untreated, bacterial meningitis is fatal. Overall, mortality from the disease in the UK is still about 10%.

The key to successful treatment in bacterial meningitis is to recognize the symptoms (i.e. rapid onset of generalized headache, fever, photophobia, and neck stiffness, with possibly a purpuric skin rash in meningococcal disease) and to treat promptly with high-dose, appropriate IV antibiotics. Often, the antibiotics used to treat are chosen empirically to cover a broad spectrum of organisms, and are

then later refined once the causative organism is identified from CSF analysis. The role of corticosteroid therapy in the treatment of meningitis has been the subject of intense debate. The consensus now is that adjuvant treatment with dexamethasone should be given just before the first dose of antibiotics and continued for 4 days. The benefit of such additional steroid therapy is probably greatest in those with pneumococcal disease. Some forms of bacterial meningitis, such as that due to the pneumococcus, are notifiable diseases, requiring reporting of the case to the relevant public health body. Close contacts of identified or suspected cases should be treated with prophylactic antibiotics, for example 2 days of oral rifampicin for close contacts of people with meningococcal meningitis, or 4 days of rifampicin and trimethoprim for contacts of haemophilus meningitis cases. However, although such prophylaxis reduces the risks of immediate infection with the disease, clearly this does not protect these individuals from future infections.

Key advances have been, and continue to be, made in vaccine development to prevent cases of bacterial meningitis. The Haemophilus influenzae type b (or Hib) vaccine is now used as part of routine childhood vaccination programmes in developed countries, as is the pneumococcal conjugate vaccine, which is active against seven of the common serotypes of the pathogen. Pneumococcal vaccination is often now also offered to those adults who have not had the vaccine in childhood but are living in close proximity to others (e.g. military recruits, students). There is also now a polyvalent vaccine, which is active against 23 serotypes of pneumococci, but its use tends to be reserved for specific high-risk groups, for example patients post splenectomy. Of great global importance has been the recent successful development of the MenAfriVac vaccine, a vaccine that is active against Group A meningococcus, a key organism responsible for bacterial meningitis in the 'meningitis belt'. This vaccine, which does not have to be refrigerated and thus can be efficiently delivered to those most at need, allows large numbers of people at risk to have effective vaccination for a year, at a cost of less than \$1 a dose.

Prevention of cerebral malaria

Malaria is the world's most important parasitic disease, with 40% of the world's population living in endemic areas. Cerebral malaria, caused by the plasmodium falciparum parasite, is one of the most serious forms of malaria, with about a fifth of cases being fatal, and young children being particularly susceptible to severe infection. Of those who survive the acute illness, around 10% will have severe sequelae, such as hemiplegia, ataxia, seizures, or cognitive impairment. Preventive strategies against infection include the use of insecticide-treated mosquito nets, and indoor spraying of insecticide in endemic areas. Some drugs used to treat malaria can prevent contraction of the disease, and tend to be taken by visitors to endemic areas. These drugs, such as chloroquine, mefloquine, doxycycline, or a combination of atovaquone and proguanil, are not often taken by long-term residents in endemic areas. The drugs are expensive, they have side effects, particularly with long-term use, and there is also the issue that they may increase the scourge of drug resistance in the parasite.

Efforts have been underway for years to develop an effective and cheap malaria vaccine but, as yet, this remains elusive. Many commercial, charitable, and government-backed organizations are working towards this goal. The Malaria Vaccine Advisory Committee of the WHO has a landmark objective to 'develop and licence a first generation malaria vaccine that has protective efficacy against severe disease and death' by 2015.

Prevention and genetic neurological disease

In this chapter, we will also briefly mention genetic neurological disease, as the contribution of genetically mediated disease to overall neurological disease burden is high. There are a great many inherited single-gene disorders which have prominent neurological symptoms, while many other 'sporadic' neurological disorders have significant genetic susceptibility factors acting along with environmental influences.

With the possibility of a molecular diagnosis of a genetic neurological disorder such as Huntington's disease comes the opportunity for testing of relatives to determine carrier status. Huntington's disease,

Table 347.3 Causes of bacterial meningitis in the UK

Age of patient	Organism
Newborn	Group B streptococcus <i>Escherichia coli</i> Listeria <i>Proteus mirabilis</i>
3 months old to 17 years old	<i>Neisseria meningitidis</i> Pneumococcus <i>Haemophilus influenzae</i>
17–50 years old	Pneumococcus <i>Neisseria meningitidis</i>
Over 50 years old	Pneumococcus Listeria Gram-negative bacilli

an autosomal dominant disorder, usually presents in adult life with progressive cognitive changes and choreiform movements and there is currently no curative therapy. The age at onset is dependent on the specific number of expanded (CAG) trinucleotide repeats encoding glutamine residues within the huntingtin protein, which is encoded by HTT (chromosomal location 4p16.3). In considering prevention in Huntington's disease, it is possible to perform genetic testing of those at risk of this autosomal dominant disease. This is usually performed after extensive counselling through clinical genetics services and according to nationally agreed standardized protocols. If such carrier testing is performed before those carriers themselves have had children, they can then be offered options for prenatal diagnosis for subsequent pregnancies, with fetal tissue obtained through chorionic villous sampling. Previously, such prenatal diagnosis was performed based on analysis of linked genetic markers, with those genetic markers being typed in DNA samples from both parents and from the chorionic villous or amniotic fluid samples. Now, with direct mutation analysis possible, the fetal tissue can be directly screened for the expanded trinucleotide repeat, and families given direct information on the carrier status of the fetus.

A recent new development is that of pre-implantation genetic diagnosis, in which eggs and sperm are harvested from the parents, in vitro fertilization takes place, embryos are grown to the 8- or 16-cell stage, and then genetic analysis performed on 1 or 2 cells taken from these embryos. Subsequently, only those embryos that are free from the mutation are transplanted back into the mother's uterus, allowing the birth of a child free of the disease. Protocols have also been developed to allow individuals to have such pre-implantation genetic diagnosis without the parental genotypes being revealed to the parents. This 'non-disclosure' or 'exclusion testing' means that a couple can be guaranteed to have a child free from Huntington's but not have to learn if one of them is indeed a carrier themselves.

It should be emphasized that procedures for prenatal diagnosis are carefully regulated by law, and that couples who are proceeding with these procedures require extensive and appropriate counselling via clinical genetic services. The example of Huntington's disease has been used in this section as it was one of the first Mendelian neurological disorders for which carrier screening and prenatal diagnosis was widely adopted. The reader is referred to the website <http://www.hfea.gov.uk/preimplantation-genetic-diagnosis.html> for information on the very many other genetic diseases, many of them neurological, for which such pre-implantation genetic diagnosis has been given regulatory approval in the UK.

Lifestyle modifications for the prevention of neurological disease: alcohol and other substances of abuse

No chapter on the prevention of neurological disease would be complete without a consideration of some of the neurological effects of excessive alcohol and of other drugs of abuse. Current recommended levels of alcohol consumption in the UK are, for men, no more than 21 units per week, with no more than 4 units per day, and, for women, no more than 14 units per week, with no more than 3 units per day. Clearly, if excess alcohol consumption leads

Table 347.4 Some neurological manifestations of chronic excessive alcohol intake

Manifestation	Notes
Cognitive decline	May lead to frank dementia
Cerebellar dysfunction	
Peripheral neuropathy	Often painful
Wernicke's encephalopathy	Confusional state
Korsakoff's psychosis	Amnesia, executive dysfunction
Depression	
Seizures	
Alcoholic myopathy	Painful

to intoxication, there can be neurological sequelae consequent on trauma. Several studies have shown that head injuries in those who are intoxicated are more serious, with more damage evident on CT brain scanning, and greater memory and other neuropsychological impairments in the long term than in sober patients.

Table 347.4 lists some of the neurological disorders consequent on prolonged excessive alcohol consumption. While some of these disorders are partially reversible if an individual stops drinking alcohol, others are not, and treatments are only partially effective. The best approach in this case is, undoubtedly, prevention. While various government initiatives have been tried to encourage more responsible alcohol consumption, these have tended to focus on the acute consequences of intoxication (e.g. drink-driving campaigns) or the long-term consequences of liver disease. As listed in Table 347.4, alcohol excess can have many, varied consequences on the brain and peripheral nerves. One strategy that has clearly been shown to reduce excessive, prolonged drinking is for governments to tax alcohol heavily, but this is not a universally popular solution to the problem and so is often not implemented in democratic societies.

Other illegal substances of abuse can also have devastating long-term consequences on brain function. Cocaine and amphetamine use has been linked to increasing the risk of stroke. Much recent attention has focused on the possible link between marijuana use and subsequent cognitive decline. Particularly concerning is data that shows that those who were heavy users of marijuana before the age of 18 show mental decline even after stopping the drug, suggesting that use of the drug during adolescence can have long-term consequences on subsequent brain development.

348 Prevention of cerebrovascular disease

Karen Morrison

Prevention of thromboembolic stroke

Stroke is the main cause of neurological morbidity in adults and the third most common cause of death worldwide after ischaemic heart disease and cancer (all forms combined). It is more common in older people, with three-quarters of strokes occurring in people over 65 years of age, and estimates are that overall stroke morbidity will double by the early 2020s. The worldwide figure of increasing incidence of stroke detection masks the fact that mortality from stroke has actually been falling in developed countries since the latter half of the twentieth century while the mortality has continued to rise in China, Asia, and eastern Europe. Although the incidence of stroke is greater in men than women in each decade, the absolute number of fatal strokes is greater in elderly women than men, reflecting the larger number of women in this population group.

As discussed in Chapter 227, the term 'stroke' denotes a neurological disease disorder, usually of abrupt onset, which lasts more than 24 hours, as a result of perturbation of the brain's blood supply. This disruption of blood supply is due to cerebral infarction in most (80%–85%) cases, with underlying causes that include atheroma, diabetes, smoking, obesity, and cardiac embolism, and due to cerebral haemorrhage (often as a result of underlying hypertension) in the remaining 15%–20% of cases. Other rare causes of stroke include specific types of stroke that occur during pregnancy, such as amniotic fluid embolism, stroke due to venous sinus thrombosis (the risk factors for which also include pregnancy and the puerperium, corticosteroid use, and various hypercoagulable states, including those associated with inflammatory bowel disease) and strokes due to substance misuse (particularly recognized with cocaine and amphetamine abuse). Box 348.1 lists some of the ischaemic stroke risk factors for which there is good or reasonably good evidence. For other factors, such as diet (high salt, or diets low in nutrients such as potassium, calcium, fresh fruit, or antioxidants such as vitamin C or E), type A behaviour, snoring, sleep apnoea, or dental disease, the evidence is less certain.

Despite the many risk factors for which there is reasonable evidence for a causative role in stroke, there is considerably less evidence for modification of these factors having a significant effect on incidence. The key preventive strategies, for which there is good data for reducing stroke risk, are listed in Box 348.2.

Clearly, the higher an individual's risk of having a stroke, the more they have to gain from prevention, so one strategy would be to concentrate efforts on reducing stroke risk in those at very high risk, as this could be perceived as being most 'cost-effective'. However, most strokes arise in people at moderate risk of stroke; so, at a population level, preventive measures should be introduced to all those at moderate risk too, as this will have a much greater effect on overall incidence. Specifically for hypertension, it has been estimated that treatment reduces an individual's risk of having a stroke by about 40% within 1 or 2 years of starting treatment. Individuals who have had a recent stroke or transient ischaemic attack (TIA) are at much higher absolute risk of stroke than the general population, so it is even more important that hypertension in these individuals is appropriately treated. Also, as the absolute risk of stroke increases with age, elderly patients with hypertension ought to be treated, as they stand to gain even more benefit, although they are also at higher risk of drug side effects. There is no good evidence to inform the decision as to when to start antihypertensive treatment following an acute stroke. Most physicians tend to wait for 1 or 2 weeks post stroke to start treatment, as there is some evidence that blood pressure can be elevated acutely secondary to stroke. Recent data suggests that variability in blood pressure is a key risk factor for stroke; thus, antihypertensive therapies that reduce this variability, such as angiotensin-converting-enzyme

Box 348.1 Risk factors for ischaemic strokes

Potentially modifiable or treatable

- hypertension: stroke risk is increased with both raised diastolic and systolic blood pressure, with isolated systolic hypertension, and with visit-to-visit variability in systolic blood pressure
- The WHO estimates that 62% of all strokes are attributable to hypertension
- diabetes: in addition to increasing the risk of stroke, people with diabetes are more likely to die if they suffer a stroke, compared to non-diabetics
- previous stroke or transient ischaemic attack
- smoking
- excess alcohol consumption
- obesity
- oral contraceptive use (particularly if the patient also suffers migraine with aura)
- blood lipoprotein disorders, although the relationship of stroke with raised plasma total cholesterol, increased LDL cholesterol, and decreased HDL cholesterol is less clear than with coronary artery disease
- cardiac disease (e.g. atrial fibrillation)
- lack of physical exercise
- plasma fibrinogen levels: strongly associated with stroke incidence but may be due to confounding with several of the factors listed in this section

Non-modifiable

- age: increased incidence with age
- gender: increased incidence in males, although much less excess compared with coronary events and peripheral vascular disease; equal sex incidence in the very young and the very old
- family history of vascular disease
- race: higher incidence in black populations than in white populations, and greater incidence in people of Pacific origin than in those of European origin (certainly, in people **living** in Western countries; there is a dearth of incidence data from South Asia, South East Asia, Africa, and South America)

inhibitors, may have a greater effect in preventing stroke than the traditional therapies of diuretics and beta blockers. All ischaemic stroke and TIA patients should be advised to reduce their dietary intake of saturated fat and, on the basis of recent evidence from large trials, to take statin therapy. In addition to lowering blood lipids, statins also reduce variability in blood pressure, and this may account for some of their benefit in stroke prevention.

Several large trials have clearly shown the benefit of antiplatelet therapy in secondary prevention of stroke following a stroke or TIA. Aspirin, 75 mg daily for life, is the antiplatelet therapy of first choice,

Box 348.2 Key preventive strategies in ischaemic stroke

- treat hypertension
- maintain good diabetic control
- treat atrial fibrillation with warfarin or novel anticoagulants
- give aspirin following acute stroke
- stop smoking
- lower plasma cholesterol

as it is effective, safe, and inexpensive. In one large study, immediate antiplatelet therapy following acute ischaemic stroke reduced the chances of a vascular event (myocardial infarction, angina, stroke, TIA) by 11%, corresponding to the avoidance of 12 events for every 1000 patients treated for 1 month. In those with a past history of stroke or TIA, antiplatelet drugs reduced the risk of subsequent vascular events from 22% to 18%, equivalent to avoiding 37 serious vascular events per 1000 patients treated over 3 years. Clopidogrel is equally effective for secondary stroke prevention, and is recommended for patients intolerant of aspirin. The combination of aspirin and dipyridamole is slightly more effective than aspirin alone, but there is little data to support its cost-effectiveness; thus, aspirin alone is the antiplatelet therapy of choice. Anticoagulation with warfarin is indicated for most patients with TIA or ischaemic stroke who are in atrial fibrillation, provided that there are no contraindications, such as recent gastrointestinal bleeding, a history of uncontrolled hypertension, or alcoholic liver disease, or where there is difficulty with access to a reliable anticoagulation clinic.

Considering primary stroke prevention, recent meta-analyses show no evidence for a reduction in total stroke in people who are at low risk (asymptomatic, no vascular risk factors, no history of previous symptomatic vascular disease) with aspirin therapy, so this is not recommended.

Prevention of cerebral haemorrhage

Cerebral haemorrhage accounts for about one-fifth of all strokes, and over 90% of cases of cerebral haemorrhage are due to rupture of intracranial aneurysms. Aneurysmal subarachnoid haemorrhage has a poor prognosis. Over 40% of people die within a month of admission to hospital and, of those who survive, half are left severely disabled. Risk factors for the presence of aneurysms include smoking, alcohol consumption, hypertension, and a family history of the disorder. Preventive strategies to reduce the incidence

include tackling risk factors if possible, and screening to identify and treat aneurysms prior to rupture. Estimates for the annual risk of bleeding from unruptured aneurysms vary greatly, depending on assumptions and biases in different studies, and range from 1 in 20 to 1 in 200. The risk is greater for aneurysms greater than 10 mm in diameter, for symptomatic aneurysms, and for those detected in the posterior circulation, so these are probably the aneurysms to target for intervention, either by intra-arterial coiling of the aneurysm (the preferred procedure) or by neurosurgical clipping of the aneurysmal neck.

Specific issues arise in advice regarding screening relatives of those with a family history of ruptured intracranial aneurysms. The general view is to offer screening, either by MRI or CT scanning, to detect unruptured intracranial aneurysms in families with two or more first-degree relatives affected by subarachnoid haemorrhage. There is no clear data to inform the answer to the question of how frequently scanning should be repeated in those at risk.

349 Prevention of infection

Tony Bentley

Introduction

Medicine is the science of diagnosing, treating, and preventing disease; its focus is the needs of an individual patient. Public health is the science and practice of protecting and improving the health of a community—medicine on a larger scale. The aim of government should be to create the health and happiness of its people. Politics is, therefore, public health medicine on a grand scale. Likewise, prevention of infection can be seen as an individual issue, a population issue, or a global issue. The principles of prevention of infection, whether at the level of the individual patient or at the level of a population, are the avoidance of infectious agents, the maintenance of innate immunity, and the stimulation of acquired immunity.

Cholera: Prevention of infection by the application of engineering in support of public health

The cholera bacterium is a member of the genus *Vibrio*. Vibrios are Gram-negative bacteria that live in surface water and occur in both marine and freshwater habitats. The two most important pathogens in this genus are *Vibrio cholerae* and *Vibrio parahaemolyticus*.

Asiatic cholera, or epidemic cholera, occurs when *Vibrio cholerae* is transmitted to humans from contaminated water or food. Currently, the most widely distributed strain is *Vibrio cholerae* O139 'Bengal'. The toxin produced by *Vibrio cholerae* binds to the epithelial cells of the mucosal lining of the small intestine. Part of the toxin then becomes detached and is taken into the cell by endocytosis; there, it acts by switching on production of cyclic AMP. The massive secretion of water and electrolytes that then occurs can result in severe and rapid dehydration.

The prevention of cholera and many other waterborne infections is by proper sanitation. Sanitation can be considered to be a way of promoting the health of a population through hygiene, thereby preventing contact with the hazards associated with waste. Human health can be affected by waste arising from human and animal faeces, domestic wastewater, and industrial and agricultural waste. In addition to bacteria and viruses, there are other hazards in waste, including other biological or chemical causes of disease. The hygienic measures used to prevent infection include engineering solutions such as latrines and septic tanks, closed drainage systems, and sewerage and wastewater treatment.

In the management of a cholera outbreak, hygiene begins with the proper management of affected patients, as large numbers of *Vibrio cholerae* bacilli are excreted in their faeces. Proper disposal of faecal material and contaminated clothing and bedclothes is essential. Environmental cleaning and handwashing with soap and water must accompany this.

Polio: Prevention of infection by science and political will

Polioviruses are members of the enterovirus group, infecting, and being shed from, the gastrointestinal tract of humans. Paralytic poliomyelitis occurs in approximately 1% of individuals infected by the poliovirus, as a consequence of chance viral spread to the CNS, and consequent neuronal damage. Major epidemics of polio began in Europe and the US in the last decades of the nineteenth century. As polio became one of the most feared diseases of childhood during the twentieth century, a race to develop an effective vaccine began.

For a vaccine to be successful, sufficient immunity needs to be produced to efficiently prevent disease and to block person-to-person spread. Two vaccines are now being used throughout the world in a concerted attempt to eradicate polio under the WHO Global Polio Eradication Initiative launched in 1988. The inactivated virus vaccine (the Salk vaccine) produces protective levels of antibody to all three serotypes of poliovirus after two injections, in more than 90% of individuals. The attenuated oral vaccine (the Sabin vaccine) multiplies in the gut lymphoid tissue and produces immunity to all three virus serotypes in approximately 95% of individuals after three doses. Oral polio vaccine is inexpensive and easy to administer but may, in 1 in 750 000 recipients, revert to a neurovirulent form.

By the end of 2006, only four countries remained (Nigeria, India, Pakistan, and Afghanistan) which had never interrupted endemic transmission of wild poliovirus. In February 2006, epidemics occurred in Yemen and Indonesia, which were successfully stopped. Globally in 2006, fewer than 2000 cases were reported.

Blood-borne viruses: Lifestyle, and the development of modern pandemics

Hepatitis B virus (HBV), hepatitis C virus (HCV), and HIV have much in common in the way they are transmitted from person to person (i.e. via sexual transmission, vertical transmission (from mother to baby), transmission by injecting drug use, and transmission by certain healthcare practices). The contribution of each of these modes of spread varies between the three.

HBV is thought to have infected 2 billion people worldwide, causing up to 1 million deaths each year by cirrhosis and hepatocellular carcinoma. In developing countries, particularly in Asia and Africa, HBV infection is usually acquired perinatally or in childhood. When acquired at a young age, HBV infection is more likely to become chronic, thus putting further generations at risk from mother-to-infant transmission. In the West, HBV infection is more commonly caught in adulthood as a consequence of sexual transmission or injecting drug use. These modes of transmission, of course, also exist in developing countries, as do those within healthcare settings, such as contaminated surgical instruments, unscreened blood transfusions, and, in particular, unsafe injection practice using contaminated needles.

Hepatitis B vaccination has been available for over 25 years. It was the first vaccine introduced with the specific aim of preventing a cancer and has been highly successful in reducing mother-to-infant transmission (e.g. in Taiwan, where the first national vaccination programme was initiated in 1984). In Italy, HBV vaccine was first recommended and then made compulsory for both infants and adolescents, resulting in a significant decline in the incidence of acute HBV infection in young adults.

HCV was discovered in 1989. It is a cause of both acute and chronic hepatitis and is now recognized as the leading cause of liver transplantation in the developed world. HCV has a worldwide distribution but, like HBV, has higher seroprevalence rates in Asia and Africa. Seroprevalence rates vary from country to country (e.g. 0.9% in India, 3.2% in China, and 22% in Egypt). Seroprevalence surveys in the US have revealed how the incidence has increased in recent decades to an overall rate of approximately 0.2%. In Western countries, the majority of infections occur as a result of injecting drug use, particularly in those sharing preparation equipment. HCV infection usually occurs rapidly after the start of injecting use behaviour. Thus, in long-term injecting drug users, rates can be as high as 60%–90%. A combination of donor selection, avoidance of

non-voluntary (i.e. paid) donors, and the screening of blood donations for HCV ensure the safety of blood supplies in those countries that can afford these measures.

HIV arose, probably early in the twentieth century, as a consequence of genetic reassortment in wild chimps in Africa co-infected with two distinct simian immunodeficiency viruses. The new virus had the capacity to infect humans and probably did so as a consequence of the killing and consumption of chimps as bushmeat. Human-to-human transmission of HIV is predominantly by sexual transmission. In Africa, the virus was spread along main truck routes by the interactions of drivers and prostitutes. Transfer around the world most likely occurred by workers and other travellers returning from Central Africa to places such as Haiti and the US. Once introduced into relatively closed but promiscuous communities, such as the gay community in San Francisco in the early 1980s, significant spread occurred. As a consequence, the associated illnesses caused by the immunodeficiency induced by HIV were recognized, the acquired immunodeficiency syndrome (AIDS) defined, and the virus isolated and identified. Other means of transmission of HIV that contributed to its global spread include the manufacture of factor VIII, which is used for the treatment of haemophiliacs, from pooled donor blood and, as for HBV and HCV, injecting drug abuse, and the use of contaminated needles in healthcare settings.

Healthcare-associated infection: The failure of modern medicine to prevent infection

Over the past 5 years, healthcare-associated infection has come to the top of the agendas of both politicians and those responsible for hospital accreditation in the UK and many other countries. The term 'healthcare-associated infection' now refers to infections associated with healthcare wherever it is delivered, and the term 'hospital-acquired infection' is no longer considered appropriate. Most of the focus of recent political initiatives, however, remains on *Clostridium difficile*-associated diarrhoea and bloodstream infections due to MRSA.

Significant success has been achieved in reducing the incidence of both *Clostridium difficile*-associated diarrhoea and MRSA bacteraemias as a consequence of this political pressure. Two questions need to be asked. Why was it that, almost 150 years after the era of Ignaz Semmelweis, Joseph Lister, and Florence Nightingale, did it require political interference in healthcare to deliver these improvements, and have those efforts been too narrowly focused and allowed other healthcare-associated infections to remain unchecked?

MRSA

MRSA was first reported in 1961 very soon after the introduction of methicillin into clinical practice. It was not until the early 1980s that outbreaks of MRSA with epidemic potential were first recognized. These were subject, in the early days, to attempted containment based on an aggressive search-and-destroy strategy. Control of the spread of generally virulent, potentially epidemic, MRSA is important, as these isolates are not susceptible to the cheap and effective antibiotics that are commonly used for both prophylaxis and treatment of a wide range of common infections.

In attempting to control MRSA, it should be remembered that, first and foremost, MRSA is a strain of *Staphylococcus aureus*. As a bacterium, *Staphylococcus aureus* is well adapted to the human body, colonizing the anterior nares, the groin, and the perineum in up to 30% of the population. It has the capacity to spread from person to person. The possession of virulence factors means that it remains potentially pathogenic, capable of causing a range of infections, from superficial cutaneous infection to septicaemia. Many strains of MRSA have characteristics (e.g. adhesion, dispersal, and survival within the environment) that make for potential epidemic spread. This has led to rapid local, regional, and global spread of certain clones. Sixteen such clones have been characterized in the UK, including EMRSA-3, EMRSA-15, and EMRSA-16.

The first stage of controlling an MRSA outbreak is to ensure it is known which patients are colonized or infected with MRSA. This is achieved by opportunistically screening appropriate patients (e.g. on admission to hospital). Any screening programme needs to be

supported by the maintenance of a database linked to the hospital's patient administration system, for future episodes of care. Patients who are at high-risk of MRSA colonization and could be cost-effectively screened include those with a prior history of MRSA carriage; the elderly; those with multiple previous hospital admissions; those with skin damage (ulceration or surgical wounds); those being admitted from nursing or residential homes; and those being admitted to high-risk clinical environments, such as elective orthopaedics, vascular surgery, and augmented care. The carriage rate of MRSA within these groups in the UK is approximately 7%. The cost-effectiveness of a wider screening programme which was recently adopted in England and includes all admissions to hospital, including those attending for day case surgery, is less likely to be cost-effective. The carriage rate in this wider population is approximately 0.7%–1.0%.

Once the patients have been identified, the risk of spread needs to be reduced by prompt patient isolation, application of a decolonization protocol (e.g. nasal mupirocin and anti-staphylococcal body wash), reduction of patient movement, and effective hand hygiene. Other patients within a clinical environment should have their risk of acquiring MRSA reduced by reducing the incidence of unnecessary IV devices, urinary catheters, and wound manipulation, as well as unnecessary antibiotic exposure. MRSA bacteraemias that do occur should be subject to a root cause analysis to understand why the event happened and to ensure lessons can be learnt.

It is often quoted that about 40% of *Staphylococcus aureus* bacteraemias (SABs) in the UK are caused by MRSA. This figure was based on data, reported voluntarily to the UK's Health Protection Agency, for 1999–2003. The data also shows that the number of methicillin-sensitive SABs continued to increase between 2003 and 2007, while the absolute number and overall percentage of MRSA bacteraemias has fallen as a consequence of the MRSA-focused efforts. It is important to note both that the majority of SABs are acquired in the community and that the majority of SABs are healthcare associated. The most common healthcare-associated sources of SAB are vascular catheters and wounds, skin and soft tissue infections, and catheter-related urosepsis.

SAB is associated with a significant mortality, which is higher in both community-acquired bacteraemia and MRSA bacteraemia. In order to effectively reduce healthcare-associated SABs, a joint acute/community strategy focusing on all strains of *Staphylococcus aureus*, rather than MRSA in isolation, will be required.

Clostridium difficile-associated diarrhoea

Diphtheritic colitis, or pseudomembranous colitis, has been recognized for over 100 years. However, in the first half of the twentieth century, cases were uncommon, and the cause was not understood. Following the introduction of broad-spectrum antibiotics (particularly tetracyclines and chloramphenicol) into medical practice in the early 1950s, the number of case reports increased. A further increase in incidence was seen in the late 1960s but was attributed to the use of lincomycin and clindamycin. In the 1970s, the causal link with toxins produced by *Clostridium difficile* was made. Despite an understanding of the pathogenesis of *Clostridium difficile*-associated diarrhoea, there was a continued rise in cases in the years between 1990 and 2004, punctuated by several very significant local and regional epidemics.

Although colonization of the gastrointestinal tract by *Clostridium difficile* is via an environmental source, *Clostridium difficile*-associated diarrhoea occurs when the normal bacterial flora is disturbed by antibiotics, and overgrowth of *Clostridium difficile* occurs. The release of *Clostridium difficile* toxin A (an enterotoxin) and *Clostridium difficile* toxin B (a cytotoxin) causes disease of varying severity, ranging from mild diarrhoea to fulminant pseudomembranous colitis and perforation. Currently implicated antibiotics include third-generation cephalosporins (e.g. cefuroxime) and quinolones (e.g. ciprofloxacin).

To ensure patient safety, the control of *Clostridium difficile* requires the implementation of a range of actions. The complete care bundle includes:

- active case surveillance by nursing and medical staff
- the provision of a rapid diagnostic testing service
- prompt isolation of patients, in single rooms, cohort bays, or isolation wards, as justified by the number of cases
- enhanced environmental cleaning using a combination of a detergent and chlorine-based disinfectant

- appropriate use of personal protective equipment, and increased hand hygiene using soap and water
- active case management to reduce duration of symptoms and excretion of spores, by using appropriate therapeutic antibiotics (e.g. oral metronidazole or vancomycin) and nutritional support
- aggressive antibiotic stewardship:
 - right drug–right indication
 - avoidance of broad-spectrum agents
 - minimum duration
 - single-dose prophylaxis
 - monitoring overall consumption
- adequate discharge information to future carers, to reduce the risk of recurrence, which can occur in up to 20% of cases

350 Prevention of cancer

Warren Grant and Martin Scott-Brown

Introduction

In the UK, the four commonest cancers—lung cancer, breast cancer, colon cancer, and prostate cancer—result in around 62 000 deaths every year. Although deaths from cancer have fallen in the UK over the last 20 years, the UK still suffers from higher cancer death rates than many other countries in Western Europe. In 1999, the UK government produced a White Paper called *Saving Lives: Our Healthier Nation* that outlined a national target to reduce the death rate from cancer by at least 20% in people under 75 by 2010. The subsequent NHS Cancer Plan of 2000 designed a framework by which to achieve this target through effective prevention, screening, and treatment programmes as well as restructuring and developing new diagnostic and treatment facilities. But do we know enough about the biology of the development of cancer for government health policies alone to force dramatic changes in survival? The science behind the causes of cancer tells us that its origin lies in acquired or inherited genetic abnormalities. Inherited gene mutation syndromes and exposure to environmental mutagens cause cancer, largely through abnormalities in DNA repair mechanisms, leading to uncontrolled cell proliferation. Although screening those thought to be at highest risk, and regulating exposure to environmental carcinogens such as tobacco or ionizing radiation have, and will continue to reduce cancer deaths, there are many other environmental factors that have been shown to increase the population risk of cancer. These will be outlined in this chapter. However, the available evidence is largely from retrospective and cross-sectional population-based studies and therefore limits our ability to apply this knowledge to the risk of the individual patient we may see in clinic. Although we may be able to put him or her into a high-, intermediate-, or low-risk category, the question ‘will I get cancer, doc?’ is one that we cannot answer with certainty.

The NHS Cancer Plan of 2000, designed to reduce cancer deaths in this country and to bring UK treatment results in line with those of other countries in Europe, focuses on preventing malignancy as part of its comprehensive cancer management strategy. It highlights that the rich are less likely to develop cancer, and will survive longer if they are diagnosed than those who live in poverty. This may reflect available treatment options, but is more likely to be related to the lifestyle of those with regular work, as these may be more health aware. The Cancer Plan, however, suggests that relieving poverty may be more labour intensive and less rewarding than encouraging positive risk-reducing behaviour in all members of the population.

Eating well can reduce the risk of developing many cancers, particularly of the stomach and bowel. The Cancer Plan outlines the ‘Five-a-Day’ programme which was rolled out in 2002, and encouraged people to eat at least five portions of fruit and vegetables per day. Obese people are also at higher risk of cancers, in particular endometrial cancer. A good diet and regular exercise not only reduce obesity but are also independent risk-reducing factors. Alcohol misuse is thought to be a major risk factor in around 3% of all cancers, with the highest risk for cancers of the mouth and throat. As part of the Cancer Plan, the Department of Health promotes physical activity and general health programmes, as well as alcohol and smoking programmes particularly in deprived areas.

Focusing on these healthy lifestyle points highlighted can potentially reduce an individual lifetime risk of all cancers. However, our knowledge of the biology of four cancers in particular has led to the development of specific life-saving interventions. Outlined in this chapter are details regarding ongoing prevention strategies for carcinomas of the lung, the breast, the bowel, and the cervix.

Lung cancer

Cancer of the bronchus is the leading cause of cancer death in both men and women in the UK. Its incidence currently stands at 82 per 100 000 males, and 50 per 100 000 females. Several etiological factors have been identified, including ionizing radiation, asbestos, and other industrial pollutants but, by far, the leading causative factor is tobacco smoking. Tobacco products gained favour in the returning soldiers of the First World War. Since then, a significant age-related trend in deaths from lung cancer in men has developed. In the last 50 years, more women have taken up the habit, and thus their death rates have increased over time. Despite other cancers, such as breast cancer, being more commonly diagnosed in women, lung cancer remains the commonest cause of cancer death in women in the UK. In 2000 there were 38 400 new cases of lung cancer in men and women in the UK, and 33 600 deaths from the disease.

How can we prevent lung cancer?

In 1954, Doll and Hill established that, in British doctors, the fall in death rates from lung cancer was linked to smoking cessation: after 12 years of non-smoking, the risk of lung cancer was almost as low as that for those who had never smoked, except for those who had smoked >20 cigarettes a day, as the risk never fell to this low level in that group. Doll and Hill’s work has led to several government initiatives to reduce population exposure to tobacco smoke. The carcinogens in tobacco smoke cause mutations in many genes, but current research suggests a significant effect on TP53, a key tumour suppressor gene that recognizes DNA damage and initiates apoptosis.

In the UK, it is currently illegal to smoke in public places. There is also a ban on tobacco advertising and a tight control on taxation and sale of tobacco products. In local communities, smoking cessation clinics have been developed in general practice, and workplace cessation programmes have also been rolled out.

Fifty years after his first publication, and as the knowledge of the link between tobacco and carcinogenesis had grown, Doll wrote a seminal paper showing that younger populations, who had lower numbers of heavy smokers, had significantly reduced their risk of developing lung cancer. With tobacco smoking now much less of a social activity, and much more expensive than it ever was, it is hoped that this effect will spread to the entire population and that the incidence of lung cancer will continue to fall in the years to come.

Breast cancer

In the UK, breast cancer affects approximately 11% of women. It is the commonest cancer in women, accounting for 30% of all cancer diagnoses. Up to 10% of patients may inherit breast cancer because of dominant genetic mutations. Two of the commonest genetic errors, which account for 80% of the inherited cases, are those that affect the BRCA1 and BRCA2 genes. There are likely to be other risky genetic abnormalities, and tests for some of them have been combined into disease screening programmes in the US. However, 90% of breast cancer cases appear sporadically, with no detectable inherited cause. These sporadic cases are more common in women of older age. Risk factors include early onset of menstruation, late menopause, and later first pregnancy. Chronic systemic exposure to exogenous oestrogens (e.g. oral contraceptives or hormone replacement therapy) does increase the risk of breast cancer but only by adding a further 6 cases per 1000 women. Those who stop taking the oral contraceptives or hormone replacement therapy return to the baseline risk after a period of 10 years.

How can we prevent breast cancer?

Women thought to be at high risk of developing breast cancer, most commonly due to known genetic mutations, should be counselled for bilateral mastectomy. This would aim to reduce their risk of breast cancer by around 90%. Modern surgical techniques can yield tissue reconstructions of identical size and shape. The use of chemoprevention in these high-risk cases is less clear. Trials using tamoxifen have not produced consistent results. A recent placebo-controlled trial in the UK that recruited around 2 500 women with a family history of breast cancer showed no difference in the incidence of breast cancer between the tamoxifen and placebo arms at 6 years from randomization. Although a much larger American trial of 13 000 women was stopped early because of a significant benefit in the tamoxifen arm, there was also a significant increase in the incidence of thromboembolic side effects. The use of raloxifene has also been investigated in postmenopausal women, with a suggestion of some protective effect. Again, an increased risk in thromboembolic events was seen.

Despite our knowledge of genetic and environmental causes of breast cancer, the single most powerful tool in preventing breast cancer deaths is its early detection and treatment, rather than its prevention. The UK breast cancer screening programme, first set up in 1988, will save 1250 lives per year by 2010, and involves an invitation to undergo bilateral two-view mammography for all women between the ages of 50–70. The programme will soon be extended to those aged 47–73. Since screening was introduced, the incidence of breast cancer has risen from around 80 in 100 000 per year to nearly 100 in 100 000 per year but the death rate from it has fallen from 40 in 100 000 per year to around 30 in 100 000 per year.

Colorectal cancer

Colorectal cancer is the second most common cancer (after lung) in terms of incidence and mortality in England and Wales and is commoner in men than in women. Each year, around 30 000 people in England will be diagnosed with cancers of the colon or rectum, and 13 000 will die of these diseases. Those with a family history have a significantly increased risk of developing colorectal cancer themselves, and around 5% of cases have identifiable genetic abnormalities conferring a very high risk of contracting the disease. Patients with familial adenomatous polyposis have hundreds of colonic polyps and will inevitably develop cancer before the age of 40 unless the colon is removed. Those with hereditary non-polyposis colorectal cancer are likely to develop cancer at a young age, presenting with abdominal pain or rectal bleeding, but are less likely to develop polyps.

Other risk factors for colorectal carcinoma are likely to relate to chronic inflammation and the disordered structure of the mucosal crypts on the surface of the bowel. Patients with inflammatory bowel disease have an increased risk of developing colorectal cancer, and this risk is proportional in magnitude to the duration of the diagnosis. Lifestyle and diet are environmental factors that are thought to explain some of the geographic differences in the incidence of bowel cancer. Fewer than 2 cases per 100 000 people are seen in India, rising to 55 per 100 000 men in New Zealand. Higher socio-economic class, smoking, and diets rich in processed meats and low in fibre are thought to be key risk factors.

How can we prevent colorectal cancer?

Modifying environmental factors may prevent cancer diagnoses in some patients. Non-smoking, healthy-eating, active-living individuals are less likely to die from colon cancer by a factor of between 2 and 8. There is also some limited evidence to suggest that those who add folic acid or selenium to their diets may have lower rates of colon cancer. Recent evidence has also suggested that regular aspirin may act as a chemoprotective agent, by inhibiting the COX-1 and COX-2 enzymes and suppressing polyp formation. The targeted COX-2 inhibitors such as celecoxib may also have a role in chemoprevention but worries about cardiac toxicity have slowed research in this area.

Colon cancer is curable in over 80% of patients if caught early, compared with less than 40% if lymph nodes contain metastatic deposits at the time of diagnosis. With this in mind, the National Bowel Cancer Programme was set up as a government initiative to reduce deaths from colon cancer in 2003. Its three constituent

parts were the development of a national screening programme, the streamlining of care for symptomatic patients, and the improvement of access to treatment. After many years of evaluating the appropriate screening test to use and which people are most likely to benefit, the UK's bowel screening programme currently asks all men and women between ages 60 and 69 to provide a stool sample for occult blood testing every 2 years. Those with a positive test result will go on to have further examination by colonoscopy. It is hoped that this scheme alone will reduce cancer deaths by 16%.

Cervical cancer

Squamous carcinoma of the cervix is a relatively rare cancer in the UK. Its incidence is around 12 per 100 000 women, with 4 per 100 000 dying of the disease each year. However, it is probably one of the most preventable of all the carcinomas. In 2008 Dr Harald zur Hausen of the German Cancer Research Centre in Heidelberg received the Nobel Prize in Medicine for discovering the link between HPV, a double-stranded DNA virus, and cervical cancer. HPV positivity is seen in virtually all of the 500 000 worldwide cases reported annually, particularly serotypes 16, 18, 31, and 45. Once a cell is infected, if the viral DNA is not cleared by a functioning DNA repair mechanism, sections of it are incorporated into human DNA and interfere with the function of the tumour suppressor genes TP53 and RB.

How can we prevent cervical cancer?

HPV is a sexually transmitted infection. Sexual abstinence offers almost 100% protection against developing cervical carcinoma. Cervical screening has been offered on the NHS in the form of smear test to all women between the ages of 25 and 64 since 1988. This facilitated diagnosis and treatment of early precancerous lesions: cervical intra-epithelial neoplasia I–III. It is estimated that the screening programme alone saves 5000 lives a year. In 2008 the UK introduced a national HPV vaccine campaign aiming to prevent infection in young girls before they become sexually active. The vaccine, Cervarix®, is a bivalent agent targeted against HPV-16 and HPV-18 virus-like particles and is routinely offered to girls in Year 8 (aged 12–13). Together with a one-off 'catch-up' vaccination campaign that will target 17- and 18-year-old girls from autumn 2009, and continuation of the cervical screening programme, cervical carcinoma may be eliminated from the UK over the course of the next 50 years. Cervical adenocarcinoma currently accounts for 10%–15% of cervical cancer cases. It does not have the same link to HPV and is likely to persist. In sub-Saharan Africa, where cervical cancer is common and there is largely no framework for national screening programmes, the role of HPV vaccination or one-off HPV testing is currently being investigated as a preventive strategy.

PART 19

Screening for disease

351 Screening for cardiovascular disease

Amitava Banerjee and Kaleab Asress

Introduction

Screening involves testing asymptomatic individuals who have risk factors, or individuals who are in the early stages of a disease, in order to decide whether further investigation, clinical intervention, or treatment is warranted. Therefore, screening is classically a primary prevention strategy which aims to capture disease early in its course, but it can also involve secondary prevention in individuals with established disease. In the words of Geoffrey Rose, screening is a 'population' strategy. Examples of screening programmes are blood pressure monitoring in primary care to screen for hypertension, and ultrasound examination to screen for abdominal aortic aneurysm.

The effectiveness and feasibility of screening are influenced by several factors. First, the diagnostic accuracy of the screening test in question is crucial. For example, exercise ECG testing, although widely used, is not recommended in the current National Institute for Health and Care Excellence (NICE) guidelines for the investigation of chest pain, due to having low sensitivity and specificity in the detection of coronary heart disease (National Institute for Health and Care Excellence, 2010). Moreover, exercise ECG testing has even lower diagnostic accuracy in asymptomatic patients with coronary heart disease. Figure 351.1 shows an analysis from a recent systematic review of prospective diagnostic accuracy studies of exercise stress testing for coronary artery disease. A positive likelihood ratio quantifies the likelihood of presence of disease if a test is positive; by convention, a positive likelihood ratio ≥ 5 constitutes a clinically useful diagnostic test. Conversely, a negative likelihood ratio quantifies the likelihood of absence of disease if a test is negative; a negative likelihood ratio ≤ 0.2 is acceptable.

Second, physical and financial resources influence the decision to screen. For example, the cost and the effectiveness of CT coronary angiography and other new imaging modalities to assess coronary vasculature must be weighed against the cost of existing investigations (e.g. coronary angiography) and the need for new equipment and staff training and recruitment. Finally, the safety of the investigation is an important factor, and patient preferences and physician preferences should be taken into consideration. However, while non-invasive screening examinations are preferable from the point of view of patients and clinicians, sometimes invasive screening tests

may be required at a later stage in order to give a definitive diagnosis (e.g. pressure wire studies to measure fractional flow reserve in a coronary artery).

The WHO's principles of screening, first formulated in 1968, are still very relevant today (Box 351.1). Decision analysis has led to 'pathways' which guide investigation and treatment within screening programmes. There is increasing recognition that there are shared risk factors and shared preventive and treatment strategies for vascular disease, regardless of arterial territory. The concept of 'vascular medicine' has gained credence, leading to opportunistic screening in other vascular territories if an individual presents with disease in one territory. For example, post-myocardial infarction patients have higher incidence of cerebrovascular and peripheral arterial disease, so carotid duplex scanning and measurement of the ankle-brachial pressure index may be valid screening approaches for arterial disease in other territories.

Screening for risk factors for cardiovascular disease

Risk factors for cardiovascular disease have been discussed in Chapter 86, and are summarized in Box 351.2. In Table 351.1, the effects and costs of various interventions for primary prevention interventions in cardiovascular disease are outlined. For example, aspirin therapy, lipid-lowering therapy, and blood-pressure-lowering therapy reduce the 1-year risk of coronary heart disease by 18%, 30%, and 15%, respectively, at costs of £26, £437, and £109, respectively. Primary prevention involves (i) population approaches to address behavioural risk factors (e.g. smoking, diet), emphasizing surveillance, education, and health policy interventions, and (ii) the individualized treatment of risk factors (e.g. hypertension). Opportunistic screening for risk factors can form part of both approaches to primary prevention.

Different guidelines use different risk stratification tools to predict future cardiovascular risk upon which further management will be based. Guidelines for primary prevention and screening have tended to be pragmatic and based on the availability of infrastructure and resources rather than being evidence based. For example, in the NHS setting, cardiovascular disease prevention and risk factor assessment are generally part of existing 'NHS Health Checks', where, every

Box 351.1 Principles of screening

1. The condition should be an important health problem.
2. There should be a treatment for the condition.
3. Facilities for diagnosis and treatment should be available.
4. There should be a latent stage of the disease.
5. There should be a test or examination for the condition.
6. The test should be acceptable to the population.
7. The natural history of the disease should be adequately understood.
8. There should be an agreed policy on whom to treat.
9. The total cost of finding a case should be economically balanced in relation to medical expenditure as a whole.
10. Case-finding should be a continuous process, not just a 'once and for all' project.

5 years, everyone between the ages of 40 and 74 is eligible for an NHS Health Check, which includes a number of simple tests to check for risk factors for heart and kidney disease, stroke, and diabetes.

Cardiovascular risk scores such as the Framingham risk score can be used to predict the future risk of cardiovascular events; in line with consensus guidelines, if a person's risk is above the recommended risk threshold, treatment and/or further investigation should be initiated. The 2014 NICE guidelines for cardiovascular disease state that 'people should be prioritized for a full formal risk assessment if their estimated 10-year risk of [cardiovascular disease] is 20% or more' and do not recommend opportunistic screening in unselected populations as the main strategy (National Institute for Health and Care Excellence, 2014). Ideally, risk scores should be locally or nationally validated. For example, Q-RISK and ASSIGN scores are now widely used in the UK, rather than the Framingham scores, since they were developed and validated in UK populations and therefore have greater predictive accuracy there.

Cardiovascular diseases share risk factors across arterial territories and disease processes, and, occasionally, appropriate and timely recognition and treatment of cardiovascular risk factors can have positive effects on health beyond the cardiovascular system. For example, hypertension is a risk factor for coronary heart disease and stroke as well as atrial fibrillation. Similarly, treatment with aspirin on the basis of increased risk of coronary heart disease may yield benefits in terms of cancer prevention. Therefore, opportunistic risk screening can have synergistic benefits.

Screening for risk factors does have costs in terms of human and physical resources, as well as psychological and lifestyle effects on individuals, and is only worthwhile if interventions are possible on the basis of the results of screening tests. In the words of epidemiologist and public health pioneer Geoffrey Rose, prevention occurs at the level of 'populations' as well as at the level of 'high-risk individuals', and it has been suggested by some that interventions could be made in large parts of the population in order to alter risk factors without screening for those factors. For example, government-mandated reductions in salt and saturated fats are examples of national health policies which have been successfully implemented without

associated screening of individuals. As risk factor levels for cardiovascular disease have increased globally in recent years, such considerations will grow in importance. The Global Burden of Disease Study showed that in 2010, the three leading risk factors for global disease burden of mortality and morbidity were high blood pressure (7.0%), tobacco smoking (including second-hand smoke; 6.3%), and alcohol use (5.5%), whereas, in 1990, the same study showed that the leading risk factors were childhood underweight (7.9%), household air pollution from solid fuels (7.0%), and tobacco smoking (including second-hand smoke; 6.1%).

The polypill in primary and secondary prevention of cardiovascular disease

The 'polypill' has been suggested to cumulatively reduce cardiovascular disease risk by combining aspirin, a beta blocker, a statin, and an angiotensin-converting enzyme (ACE) inhibitor in varying doses. The polypill could be used in both primary and secondary prevention. It has been hypothesized that a polypill could reduce cardiovascular disease events by 75% in those with vascular disease, which would constitute secondary prevention. If it were used in all those older than 55 years without cardiovascular disease, it is estimated that a polypill would safely reduce ischaemic heart disease events by 88%, and strokes by 80%, which is a primary prevention strategy. Several versions of the polypill are now being trialled by different research groups in different settings involving both primary and secondary prevention.

The polypill, when used in primary prevention, can 'tailor' the intervention to the individual with the aim of maximizing benefits and minimizing risks. However, these factors must be balanced with the disadvantages of high screening costs and imprecise long-term risk prediction in primary prevention. Risk factor thresholds ignore the fact that the relationship between most risk factors (e.g. blood pressure, cholesterol, smoking) and cardiovascular disease is continuous and linear. Therefore, intervening in only those individuals with high risk factor levels excludes the large proportion of cardiovascular events that occur amongst people with 'average' risk factor levels and probably represents the majority of the population (the so-called prevention paradox). Moreover, average risk factor levels seen in Westernized societies and in many urban settings in low-income countries may be biologically abnormal, as highlighted by the Global Burden of Disease Study. Therefore, the individual 'high-risk strategy' may have less overall benefit than a 'population-based strategy' that involves lowering risk factor levels in entire populations.

Importantly, it is unlikely that the long-term use of multiple drugs given separately in 'healthy' asymptomatic individuals to lower multiple risk factor levels will be feasible in whole populations, even in motivated individuals. Advocates of the polypill have suggested that, if the polypill were administered once daily, it could intervene simultaneously across several common risk factors and theoretically reduce cardiovascular disease to a large extent. Amongst people without existing cardiovascular disease, the most discriminatory screening factor is age, because >90% of cardiovascular disease deaths occur in people aged ≥ 55 years, as illustrated by multiple national and international epidemiologic studies of cardiovascular disease, including the Global Burden of Disease Study. The use of the polypill in people aged ≥ 55 years, especially in those with at least one additional risk factor (i.e. those at moderate risk), could therefore prevent the majority of cardiovascular disease events in both high- and low-income countries. However, opponents to widespread use of the polypill in primary prevention cite 'over-medicalization' and 'over-treatment' as major concerns.

The data for the components of the polypill in secondary prevention of cardiovascular disease is much stronger, in the form of high-quality randomized evidence supporting the use of aspirin, statins, beta blockers, and blockers of the renin-angiotensin system (e.g. ACE inhibitors and angiotensin receptor blockers). It has been estimated that 50% of the decline in cardiovascular mortality observed in developed countries during the last 20 years is attributable to medical therapy. However, despite clear evidence of effectiveness, rates of use of secondary prevention therapies and adherence to these therapies are disappointing, even in high-income countries, due to multiple barriers to implementation of secondary prevention, including (i) inadequate prescription of proven therapies in individuals who may benefit; (ii) poor long-term adherence to prescribed medications (often <50%),

Table 351.1 Intervention costs and effects

Intervention	Annual cost per person (£)	Measure of effect	Relative risk
Thiazide diuretic	45	RR CAD; RR stroke	0.86; 0.62
Beta blocker	68	RR CAD; RR stroke	0.89; 0.83
Calcium-channel blocker	140	RR CAD; RR stroke	0.85; 0.66
ACE inhibitor	136	RR CAD; RR stroke	0.83; 0.78
Aspirin	26	RR CAD; RR stroke (ischaemic); RR stroke (haemorrhagic); RR GI bleed	0.82; 0.86; 1.32; 1.54
Statin	440	RR CAD; RR stroke	0.70; 0.81
Phyosterol margarine	165	Total cholesterol	0.925
Dietary advice	Year 1:84 Year 2+:110	Systolic BP; Total cholesterol	0.984; 0.969
Lifestyle programme	Year 1: 164 Year 2+:110	Systolic BP; Total cholesterol	0.974; 0.967
Community heart health programme	Year 1: 1.51 Year 2+:1.02	Systolic BP; Total cholesterol	0.975; 0.995
Mandatory salt reduction	0.52	mg Na/day men; mg Na/day women	0.894; 0.967
Voluntary salt reduction (current practice)	0.31	mg Na/day men; mg Na/day women	0.50; 0.34
Lipid-lowering (current practice)	437	RR CAD; RR stroke	0.70; 0.81
BP-lowering (current practice)	109	RR CAD; RR stroke	0.85; 0.70

Note: All costs are in 2008 GB pounds sterling.

Abbreviations: ACE, angiotensin-converting enzyme; BP, blood pressure; CAD, coronary artery disease; RR, relative risk.

which is caused by sociocultural, psychological, economic, and clinical factors related to patients, healthcare providers, healthcare systems, and their interactions; and (iii) cost and affordability.

Screening for surrogate markers of cardiovascular disease

Risk factors are markers that are statistically related to the risk of developing cardiovascular disease; they do not necessarily identify the disease itself. From the research and trial perspective, surrogate markers do not always correlate with 'hard' disease outcomes (such as cardiovascular disease events) and are therefore not as reliable in 'real-world' clinical practice.

However, surrogate markers of disease make it possible to identify and track disease progression. Reliable markers for the disease might ultimately allow disease progression to replace endpoint events as a guide to the risk of disease and response to therapy, as well as identifying earlier phases of the disease for intervention. Ultimately, the predictive and prognostic accuracy of surrogate markers in screening are weighed against their cost before their use in a given population. However, even relatively new technologies can be introduced into health systems relatively quickly if they are incorporated into consensus clinical guidelines, as illustrated by coronary artery calcium scoring (see 'Coronary artery calcium score').

Carotid intima-media thickness

Carotid intima-media thickness, which is determined via B-mode ultrasound, has been shown to be a safe, non-invasive, and relatively inexpensive means of assessing subclinical atherosclerosis. It correlates with the presence of coronary atherosclerosis and represents an independent risk factor for coronary events as well as stroke and transient ischaemic attacks.

Left ventricular hypertrophy

Left ventricular hypertrophy, which can be detected on echocardiography or ECG, is associated with several disease processes but most commonly hypertension. It is an independent predictor of cardiovascular events: when reductions in left ventricular mass result from antihypertensive therapy, they are associated with reductions in cardiovascular events, independently of blood pressure reduction. There is evidence that echocardiography is more sensitive and more

specific than ECG in the diagnosis of left ventricular hypertrophy; however, the benefits of this increased diagnostic accuracy must be weighed against the increased cost of providing increased access to echocardiography services.

Structural and functional changes in the arterial wall precede and accompany atherosclerotic processes. Therefore, measuring arterial stiffness is another way to assess cardiovascular risk. Large-artery stiffness, as assessed by **pulse pressure** and **pulse wave velocity**, is age dependent and reflects structural alterations that are accelerated by hypertension and atherosclerosis. **Pulse contour analysis** provides information about small-artery stiffness. These techniques provide a way to identify premature disease and to track the progression of disease and the impact of therapy.

Coronary artery calcium score

The coronary artery calcium score is a measure of coronary arterial calcification and is determined by performing CT of the heart. This score is a strong predictor of coronary heart disease events and overall mortality, providing predictive information beyond that of standard risk factors across different racial and age groups. According to the NICE clinical guidelines for chest pain of recent onset (National Institute for Health and Care Excellence, 2010), this score can be used to rule out cardiovascular disease in patients who present with chest pain but, on the basis of traditional risk factors, have a low estimated likelihood of coronary artery disease (10%–29%; see Figure 351.2).

Age- and sex-specific factors

Table 351.2 describes the algorithm recommended by the NICE guidelines for estimating the baseline likelihood of coronary heart disease in an age- and sex-specific manner. In individuals in whom the estimated likelihood of coronary heart disease is $\geq 30\%$, diagnostic testing in the form of non-invasive functional imaging or invasive coronary angiography should be carried out if the estimated likelihood is 30%–60% or 61%–90%, respectively.

Screening for established cardiovascular disease

Screening for symptomatic individuals with coronary heart disease, as discussed in 'Screening for surrogate markers of cardiovascular disease', involves using the coronary artery calcium score, functional

Stable chest pain pathway

2. Diagnostic testing for people in whom stable angina cannot be diagnosed or excluded by clinical assessment alone

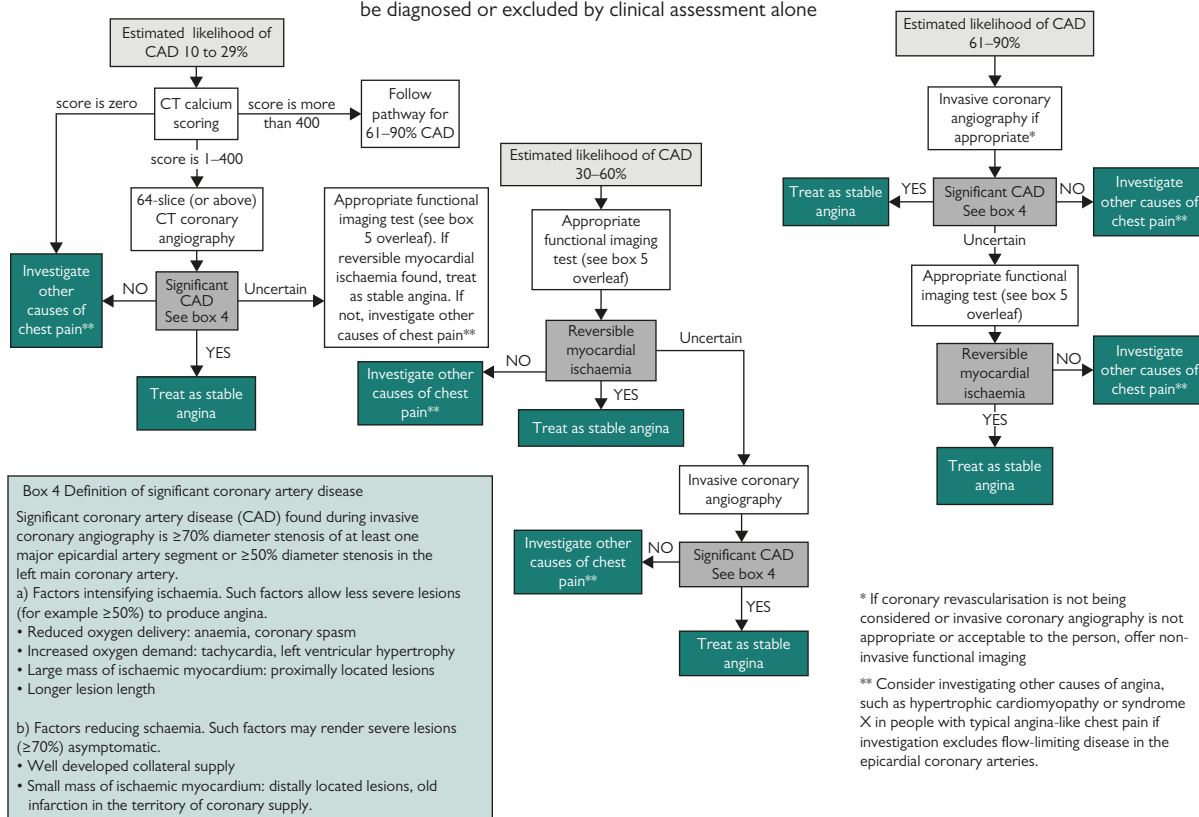

Figure 351.2 NICE stable chest pain pathway.

Pathway from appendix 1 of <https://www.nice.org.uk/guidance/gid-mt252/documents/heartflow-ffrct-for-the-computation-of-fractional-flow-reserve-from-coronary-ct-angiography-final-scope2>.

imaging, or angiography, based on risk stratification and the use of guidelines (such as the algorithm shown in Table 351.2).

Atrial fibrillation

Atrial fibrillation (AF) increases the risk of stroke, thromboembolism, morbidity, and mortality, with huge implications for healthcare expenditure. Demographic transitions and ageing populations are projected to greatly increase the global burden of AF and its sequelae. For stroke and thromboembolism, prevention can be primary (to reduce risk of first stroke) or secondary (preventing recurrent strokes). Prevention can occur at the level of AF itself, with primary prevention restricting the development of AF by reducing the

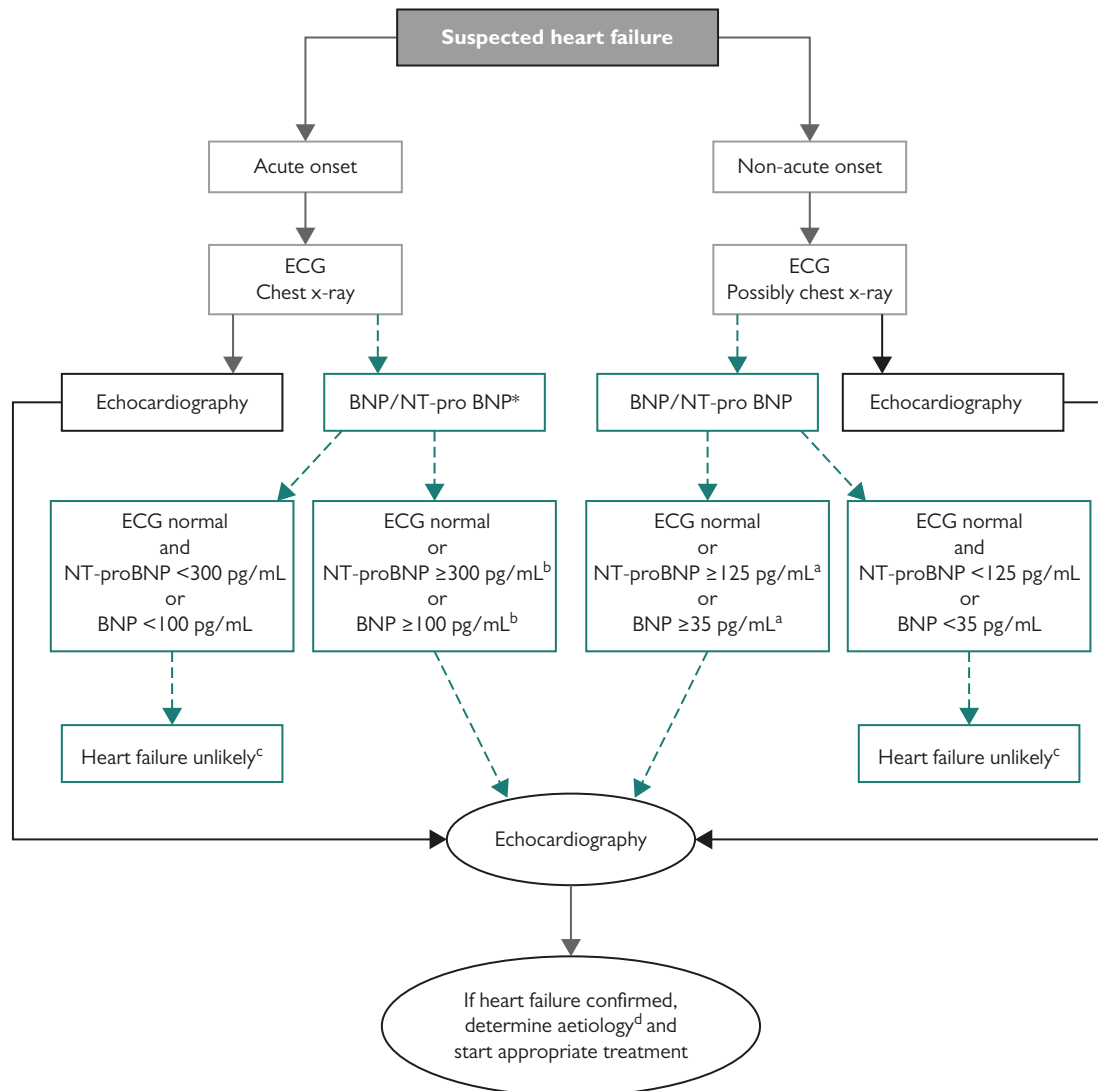

cardiovascular risk factor burden and by the use of upstream therapies, while secondary prevention involves reducing risk factors and the risk of stroke in individuals with established AF. For example, in stroke prevention, a recent analysis has shown that direct-acting anticoagulants (apixaban, rivaroxaban, and dabigatran) have broadly similar efficacies in the secondary prevention of ischaemic stroke, haemorrhagic stroke, vascular death, major bleeding, and intracranial bleeding in AF patients. On the other hand, in the primary prevention of stroke, the three drugs showed some differences in relation to efficacy and bleeding. Thus, it is critical to clarify the level of prevention when considering the impact of different screening and prevention strategies.

Table 351.2 Percentage of people estimated to have coronary artery disease according to typicality of symptoms, age, sex, and risk factors

Age, years	Non-anginal chest pain				Atypical angina				Typical angina			
	Men		Women		Men		Women		Men		Women	
	Low	High	Low	High	Low	High	Low	High	Low	High	Low	High
35	3	35	1	19	8	59	2	39	30	88	10	78
45	9	47	2	22	21	70	5	43	51	92	20	79
55	23	59	4	25	45	79	10	47	80	95	38	82
65	49	69	9	29	71	86	20	51	93	97	56	84

For men older than 70 year with atypical or typical symptoms, assume an estimate $>90\%$. For women older than 70, assume an estimate of 61–90% except women at high risk and with typical symptoms, where a risk of $>90\%$ should be assumed. Values are per cent of people at each mid-decade age with significant coronary artery disease (CAD). High = high risk = diabetes, smoking, and hyperlipidaemia (total cholesterol >6.47 mmol/litre). Low = Low risk = none of these three. The area in bold represents people with symptoms of non-anginal chest pain, who would not be investigated for stable angina routinely. Note: these results are likely to overestimate CAD in primary care populations. If there are resting ECG ST-T changes or Q waves, the likelihood of CAD is higher in each cell of the table.

BNP = B-type natriuretic peptide; ECG = electrocardiogram; HF = heart failure;
MR-proANP = mid-regional pro atrial natriuretic peptide;
NT-proBNP = N-terminal pro B-type natriuretic peptide.

Figure 351.3 European Society of Cardiology guidelines for diagnosis in patients with suspected heart failure, showing alternative 'echocardiography first' (black) or 'natriuretic peptide first' (blue) approaches; BNP, B-type natriuretic peptide; NT-pro BNP, N-terminal pro B-type natriuretic peptide.

Reproduced with permission from John J. V. McMurray et al., ESC Guidelines for the diagnosis and treatment of acute and chronic heart failure 2012, *European Heart Journal*, Volume 33, Issue 14, pp. 1787–1847, Copyright © 2012 Oxford University Press.

A recent consensus statement from the Royal College of Physicians of Edinburgh concluded that 'the most cost-effective method for the detection of AF in primary care is by opportunistic screening of people aged 65 years or older by radial pulse checking followed as soon as practicable by a 12-lead ECG for those with an irregular pulse. ... Diagnostic ECGs should be analysed by a competent individual supported by audit and feedback.' (Stott, Dewar, Garratt, et al., 2012, p. 34). The statement also says, 'Where clinical suspicion of paroxysmal AF exists, including after ischaemic stroke or transient ischaemic attack ... , longer ECG monitoring periods (at least 24 hours) or event recorders should be used' (Stott, Dewar, Garratt, et al., 2012, p. 34). Early recognition of AF is made much more difficult by its often silent nature, with about one-third of patients being unaware of their asymptomatic arrhythmia. The fact that symptoms are unreliable for estimating AF burden and identifying patients with AF has

led to recommendations for the use of longer-term continuous ECG monitoring and even implantable loop recorders, particularly in the setting of cryptogenic stroke, where the role of AF is likely to have been greatly underestimated.

Asymptomatic left ventricular dysfunction

Asymptomatic left ventricular dysfunction progresses to symptomatic heart failure at rates of up to 10% per year, if untreated. Therefore, early detection, if achievable, is important because randomized trials have shown that appropriate drug therapy can significantly improve survival and cardiovascular outcomes. Possible screening strategies may involve ECG, imaging modalities (e.g. echocardiography), biomarkers (e.g. BNP), or a combination of these approaches. Because the signs and symptoms of heart failure are so non-specific, many patients who have suspected heart failure and are

referred for echocardiography are not found to have an important cardiac abnormality.

Where the availability of echocardiography is limited, the European Society of Cardiology guidelines recommend measuring the blood concentration of natriuretic peptides, a family of hormones which are secreted at increased levels when the heart is diseased or the load on any chamber is increased (Figure 351.3). A normal natriuretic peptide level has a high specificity; that is, in an untreated patient, it virtually excludes significant cardiac disease, removing the need for echocardiography. Guidelines have tended to focus on patients with 'suspected heart failure' and not those who are 'asymptomatic'.

Community-based studies have highlighted the high prevalence of heart failure (both systolic and diastolic) in patients with risk factors for cardiovascular disease. For example, the ECHOES study showed that definite systolic dysfunction (defined as an ejection fraction <40%) was found in 22.1% of patients with coronary artery disease, and 5.8% with diabetes, although approximately half of the patients in whom the dysfunction was found were asymptomatic. However, at present, further trials of targeted echocardiography are required before widespread echocardiographic screening is advocated. Testing for BNP levels is likely to provide the most cost-effective method of screening for heart failure in populations, although further prospective trial and cost-effectiveness data are required.

Abdominal aortic aneurysm

Abdominal aortic aneurysm (AAA) rupture is a cause of sudden death. Detection and surveillance are thought to be cost-effective methods for preventing AAA rupture, by ensuring timely AAA surgical repair. AAA screening is gradually being rolled out across the NHS in the UK. Men aged 65 and over are eligible for AAA screening by abdominal ultrasound scanning. The NHS AAA Screening Programme aims to reduce deaths from ruptured AAA amongst men aged 65 and over by up to 50%.

Summary

In this chapter, we have focused on screening for cardiovascular disease via risk factors, surrogate markers, and detecting established disease. The high burden of cardiovascular risk factors and diseases

in all populations in both high- and low-income settings make these considerations of optimal screening strategies universally important. Currently, screening strategies have tended to focus on risk factors rather than established disease, due to many factors, including resource constraints, lack of prospective evidence, and sociocultural factors. In addition, the body of randomized evidence in diagnostic and prognostic studies has lagged behind the exponential growth of trials in the therapeutic arena. Given the importance of screening in both high-risk and population approaches to the prevention of cardiovascular disease, more research is urgently needed.

352 Screening for respiratory disease

Abdul Nasimudeen

Introduction

Routine screening for respiratory diseases is currently not available to the general healthy population, with the exception of screening for cystic fibrosis. In this chapter, we discuss the screening strategies in place for cystic fibrosis, TB, and other conditions, such as COPD, lung cancer, alpha-1 antitrypsin deficiency, pulmonary hypertension, pulmonary arteriovenous malformation, and obstructive sleep apnoea, for which screening can be applied. While screening has the potential to improve quality of life through early diagnosis and management, it is not an easy process and cannot offer a guarantee of protection.

Cystic fibrosis

Neonatal screening has helped early diagnosis of cystic fibrosis before any symptoms may have developed and there is evidence to suggest screening provides better pulmonary outcomes. The UK National Screening Committee currently recommends screening for this condition by testing the blood for immunoreactive trypsinogen (IRT) as part of the Guthrie test on all newborn infants. This is not diagnostic, and further tests are required to confirm the diagnosis. Screening helps affected parents to have genetic counselling to avoid the birth of a second child with cystic fibrosis in a family where the first child may have been undiagnosed.

False-positive levels of IRT are possible in those who are heterozygous for the cystic fibrosis mutation and in those from non-Caucasian origin. These can lead to long-term psychosocial consequences for the families involved in the screening until further diagnostic testing is done. False-negative results are also possible, as ITR levels start to fall variably after the first 4 weeks of birth. A negative IRT test after 8 weeks is no longer informative.

Carrier screening looking for mutation analysis is available for those who have a relative known to have cystic fibrosis and a relative or a partner known to be a carrier of cystic fibrosis. Prenatal screening trials have been done in the past using different approaches in hospital and primary care settings. Stepwise screening and couple screening methods have been used, with the former first testing the pregnant woman and then only testing her partner if she is found to be a carrier. There is now evidence to suggest that prenatal screening of at-risk couples identified by the newborn screening programme has resulted in a reduction in the live-birth prevalence of cystic fibrosis.

TB

Studies have shown that mass screening of general population with chest X-rays (CXR) makes no difference to the number of new cases of TB in that group. The best way of control is preventing the spread from smear-positive cases, and screening contacts. The National Institute of Health Excellence recommends screening the contacts of all cases of active TB, new entrants, healthcare workers, homeless workers, and prisoners.

The Mantoux test is recommended for all close contacts with no evidence of previous BCG, and those under 35 years of age and with previous BCG vaccination. Contacts over 35 years of age and with previous BCG vaccination are screened with a CXR. Further clinical assessments may then be necessary with interferon gamma assays (IGRA) and additional CXRs to determine whether latent disease or active infection is present.

New entrants screening is currently applied only to persons coming from countries with a high incidence of TB (e.g. sub-Saharan Africa or a country with an incidence of >500 in 100 000 population). Patients should be identified from port of arrival reports, registration with primary care, entry to education, and links with voluntary groups. All new immigrants are recommended to have a CXR unless they are <11 years of age or pregnant, in which case they should have a Mantoux test, followed by a clinical assessment for active and latent TB, and risk assessment for HIV.

NHS employee screening is via a pre-employment questionnaire. Asymptomatic individuals with evidence of BCG vaccination are given general advice, whereas vaccination is offered to those with no evidence of active or latent infection. Active case finding in homeless people is recommended using CXRs, based on symptoms, and prisoners should be screened using a health questionnaire on entry followed by a CXR and three sputum samples for TB microscopy.

Screening of contacts in countries such as the UK is not just to identify active cases and initiate treatment but also to identify patients with latent TB who may be able to receive treatment which reduces the risk of acquiring an active infection in the first 2 years after exposure, the time when the risk is considered to be high. In the future, IGRA may replace Mantoux as the first-line screening tool, and trials may show that new entrant screening should ideally include migrants from countries such as India and Pakistan (this population is currently left out, due to having a lower incidence of TB).

Lung cancer

Currently, there is insufficient evidence to recommend for or against screening for lung cancer, even in asymptomatic high-risk individuals, with a low-dose CT (LDCT) scan, a CXR, sputum cytology, or a combination of these tests. The sensitivity and specificity of CXR for diagnosing lung cancer are 26% and 93%, respectively. An LDCT scan is up to four times more sensitive than a CXR but the false-positive rates range from 5% to 41%.

Screening high-risk patients (>50 years of age, >20 pack-year smoking history) using CXRs, with or without sputum cytology, have shown no mortality benefit. The main drawbacks of lung cancer screening trials are lack of control for occupational exposures and family history, possible bias from the screening of healthy individuals, and the lack of completely unscreened control groups. Several cohort studies of LDCT have shown that an LDCT is significantly more sensitive than a CXR for identifying lung cancer and also identifies a significantly higher proportion of small (early stage, resectable) lung cancers than a CXR does. However, the effectiveness of an LDCT in decreasing lung cancer mortality cannot be evaluated from these studies because of the absence of randomization and the lack of an unscreened control group for which mortality was an outcome. International Early Lung Cancer Action Program investigators looking at the survival of patients with Stage 1 lung cancer detected on CT screening concluded that annual spiral CT screening can detect curable lung cancer but the main drawbacks were that the study had no control group; it lacked an unbiased outcome measure and did not mention the harms of screening.

Screening smokers via CT can show other incidental non-malignant conditions needing further investigation and high-risk procedures such as lung biopsies. This can sometimes lead to over-diagnosis and to patients having to deal with the psychological issues arising from stress and anxiety. The National Lung Cancer Screening Trial launched in 2002 is currently comparing the utility of CT scans and

CXRs for screening. More than 50 000 patients have been enrolled and the results will not be available until later this year. This study has also tried to address some important issues, such as all causes of death in groups screened for lung cancer, the cost-effectiveness of screening, the quality of life for those who test positive, and the influence of screening on smoking behaviour and beliefs.

The identification of biomarkers has led to a greater understanding of the molecular pathways of lung cancer. Mutations in K-ras and p53, and proteins such as carcinoembryonic antigen, CYFRA21-1, plasma kallikrein B1, neuron-specific enolase, and so on, have been proposed as potential biomarkers for lung cancer. However, despite extensive studies thus far, few have turned out to be useful and, even those used do not show enough sensitivity, specificity, and reproducibility for general use.

COPD

Most individuals with airflow limitation do not recognize or report symptoms, and spirometry forms the mainstay in screening for COPD, although, currently, there are no recommendations to screen asymptomatic high-risk healthy adults. In individuals who present with respiratory symptoms, spirometry would be indicated as part of a diagnostic test for COPD, asthma, or other pulmonary diseases. Screening and early detection for those with mild or moderate airflow obstruction could benefit from smoking cessation advice and annual influenza vaccination.

Pharmacological therapy to these individuals may help prevent exacerbations but may not change hospitalization rates in those with severe disease. It is not known whether pharmacological therapy in patients who are asymptomatic but meet spirometric criteria for moderate-to-severe disease would have the same benefit as in those who are symptomatic with severe airflow obstruction. The costs associated with screening for COPD are large, even in those considered as high risk. There is a risk of false-positive diagnosis in those over 70 years of age, due to the natural decline of lung function.

Although influenza vaccination may reduce exacerbations, there is not much evidence to indicate that spirometry screening improves influenza vaccination rates or promotes smoking cessation. In the future, screening programmes should aim to prevent disease progression, exacerbations, and COPD-related complications. It should also aim to improve exercise tolerance and health status and provide a reduction in mortality.

Alpha-1 antitrypsin deficiency

Despite its prevalence, alpha-1 antitrypsin deficiency remains grossly under-diagnosed, the reason being its highly variable symptom development, as it can present with symptoms similar to COPD or asthma, or have no symptoms at all. Initially, a blood test is done to measure alpha-1 antitrypsin concentrations; patients found to have suboptimal or low levels of alpha-1 antitrypsin should then undergo DNA testing to identify which of the various alpha-1 antitrypsin deficiency genotypes they have.

Current European Respiratory Society and American Thoracic Society guidelines recommend a high level of suspicion for:

- symptomatic individuals with early onset (<45 years of age) emphysema, regardless of smoking history
- individuals with emphysema in the absence of a recognized risk factor
- individuals with predominantly basal emphysema on a CT scan
- individuals who have asthma with incomplete reversibility of airflow obstruction after aggressive treatment with bronchodilators
- asymptomatic individuals with airflow obstruction on lung function testing and with identifiable risk factors such as smoking or occupational exposure
- individuals with unexplained liver disease
- adults with necrotizing panniculitis
- individuals with bronchiectasis with no obvious cause
- siblings of individuals with alpha-1 antitrypsin deficiency

They also recommend that such individuals undergo diagnostic testing for alpha-1 antitrypsin deficiency.

Recognition of alpha-1 antitrypsin deficiency can prompt specific interventions such as genetic counselling, screening of family members, smoking cessation advice, and consideration of augmentation therapy. Evidence from previous studies suggests that targeted detection has generally produced a higher rate of detecting disease than large-scale population-based screening has. In the future, improved awareness campaigns and easy and cheaper sampling techniques may improve the detection rates, resulting in better treatment options such as augmentation therapy, which may well help preserve lung function in asymptomatic individuals.

Pulmonary hypertension

Heritable pulmonary arterial hypertension (PAH) is an autosomal dominant condition with incomplete penetrance. Mutations in *BMPR2*, which resides in the chromosomal region 2q32, have been identified in up to 70% of patients when PAH occurs within families. The same mutations have been identified in patients with idiopathic (sporadic) forms of PAH as well. Mutations in *ALK1* and *ENG* have been identified in patients with a family history of hereditary haemorrhagic telangiectasia (HHT). Individuals can still end up transmitting the mutations to their children but may never acquire the disease due to variable penetrance. One way of screening would be to do genetic testing and counselling of these individuals, with detailed explanation of the limitations and risks involved. Linkage analysis of at-risk relatives, in the absence of any identified mutations or gene sequencing, is another way of identifying patients at risk of developing heritable PAH.

Echocardiography should always be performed in cases of suspected pulmonary hypertension. Pulmonary hypertension is defined as a mean pulmonary arterial pressure ≥ 25 mm Hg on Doppler measurements but these values can be inaccurate in some individuals. Underestimation of pulmonary hypertension can happen in patients with severe tricuspid regurgitation, and overestimation by >10 mm Hg is also common; hence, Doppler echo is not ideal for screening asymptomatic or patients with mild pulmonary hypertension. One study by Grünig et al. (2000) looking at asymptomatic carriers of a mutated primary pulmonary hypertension (PPH) gene did suggest that stress echocardiographic measurements of pulmonary artery systolic pressure may be useful for identify persons at risk of PPH even before the pulmonary arterial pressure at rest is elevated.

ECG may provide supportive evidence for pulmonary hypertension. In patients with idiopathic PAH, right ventricular hypertrophy and right axis deviation is present in 87% and 79% of patients, respectively, but the sensitivity and specificity rates of 55% and 70% makes ECG a poor screening tool. The CXR may be abnormal in up to 90% of patients with idiopathic PAH, but the degree of pulmonary hypertension does not correlate with the extent of radiographic abnormalities.

Patients suspected of or diagnosed with pulmonary hypertension may well need further tests such as a CT scan, a lung function test, a V/Q scan, and so on, but none of these tests provide a useful screening tool at present. Prenatal testing for heritable PAH is a possibility in future, given the genetic background, but this is controversial, as the intellect of PAH patients is normal, and effective treatments are available.

Pulmonary arteriovenous malformation

Due to the high incidence of unsuspected pulmonary and cerebral arteriovenous malformation in family members of patients with HHT, it is recommended that family members carrying the mutation for this disease should be screened for pulmonary arteriovenous malformation via chest radiography and/or measurement of shunt fraction. Contrast echocardiography or V/Q scanning could also be used as first-line screening in patients with a high index of suspicion.

Although screening with CT is very sensitive, it does carry a risk of radiation exposure and cost issues. Contrast echocardiography carries a risk of diagnosing microvascular shunts which may not need

intervention. Routine genetic screening of HHT family members may play an increasingly important role in future but is currently limited by the lack of a predominant mutation.

Obstructive sleep apnoea

Obstructive sleep apnoea (OSA), if undiagnosed, does carry a significant cardiovascular mortality and morbidity, with a high risk of automobile and workplace accidents. Although polysomnography remains the gold standard for diagnosis, currently in UK hospital settings, the Epworth Sleep Score and nocturnal oximetry are widely used as a screening tool for the diagnosis of OSA.

A recent study concluded that simple variables such as sex, blood pressure, BMI, and self-reported snoring could all provide valid tools for the assessment of sleep disordered breathing.

In the future, due to increasing number of patients with obesity, conditions such as OSA are likely to increase and screening programmes using the tools described in this section should be used in primary care settings to improve the diagnosis and outcome measures.

353 Screening for kidney disease

Aron Chakera, William G. Herrington, and Christopher A. O’Callaghan

What kidney diseases can we screen for?

Renal disease is common and, with routine reporting of estimated glomerular filtration rates, impairment of renal function is increasingly being recognized.

As renal impairment is usually asymptomatic until very advanced, chronic kidney disease (CKD) guidelines have been developed to improve the identification and screening of at-risk populations.

Target groups include patients with vascular risk factors (e.g. diabetes mellitus and hypertension); patients with certain multisystem diseases which can cause renal impairment; patients with urological conditions; patients on nephrotoxic medication; and immediate relatives of patients with established renal disease (see Table 353.1).

Kidney function should also be checked during intercurrent illness and perioperatively in all patients with CKD or suspected CKD. The frequency of screening is dictated by the CKD stage (see Table 353.2).

How do we screen for kidney disease?

Screening for kidney disease should include a serum creatinine measurement and, in most circumstances, a urine dipstick. Diabetic patients should also have an albumin-to-creatinine ratio or an Albustix® measurement to identify microalbuminuria, which will not be detected on standard urine dipsticks.

What is the impact of kidney disease screening in the real world?

The costs of a serum creatinine test and a urine dipstick are low. The tests are simple to perform, minimally invasive, and readily available.

Table 353.1 Target groups for renal screening

Vascular	Multisystem diseases	Urological conditions	Nephrotoxic drugs
Hypertension	Diabetes mellitus	Bladder outflow obstruction	Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers
Heart failure	SLE	Neurogenic bladder	NSAIDs
Coronary artery disease	Vasculitis	Urinary diversion surgery	Lithium
Cerebrovascular disease	Myeloma	Urinary anatomical abnormalities	Mesalazine
Peripheral vascular disease	Rheumatoid arthritis	Recurrent stone formers	Calcineurin inhibitors (ciclosporin, tacrolimus)
	Scleroderma	Stone disease due to primary hyperoxaluria, cystinuria, Dent’s disease, or infections	Proton-pump inhibitors

Table 353.2 Current Renal Association guidelines for screening frequency

eGFR	Screening frequency
>90	annual
60–89	annual
30–59 (known to be stable*)	annual
30–59 (newly diagnosed or progressive [†])	6-monthly
15–29 (known to be stable*)	6-monthly
15–29 (newly diagnosed or progressive [†])	3-monthly
<15	3-monthly

Abbreviations: eGFR, estimated glomerular filtration rate; GFR, glomerular filtration rate.

*Stable kidney function defined as change of GFR of <2 ml/min/1.73 m² over 6 months or more.

[†]Progressive kidney damage defined as change of GFR of >2 ml/min/1.73 m² over 6 months or more.

Reproduced with permission of the Renal Association.

The introduction of national guidelines is raising the awareness and detection of CKD in the community. Earlier detection of kidney disease may allow treatment to prevent the progression of renal impairment. For example, there is increasing evidence that starting angiotensin-converting-enzyme inhibitors or angiotensin receptor blockers in diabetics with microalbuminuria slows progression to overt nephropathy.

Screening programmes can also identify patients at risk of end-stage disease, in time to allow the patient and physician to prepare for renal replacement therapy or to ensure that appropriate advanced directives are in place.

Issues and the future of kidney disease screening programmes

The impact of the new CKD screening guidelines on patient outcomes still needs to be validated. There is ongoing debate about which patients need referral for specialist opinions and which can be managed safely in primary care. This will potentially have significant impact on resource allocation and workload.

As the serum creatinine test is acknowledged to be an imperfect measure of renal function, particularly when the estimated glomerular filtration rate is above 60 ml/min 1.73 m⁻², there is a need for new markers to be developed. One promising measure is the serum cystatin C level.

354 Screening for gastrointestinal disease

Satish Keshav and Alexandra Kent

Barrett's oesophagus

Barrett's oesophagus (BO) is where the normal squamous epithelium in the oesophagus has been replaced by metaplastic columnar epithelium. This is generally diagnosed endoscopically and requires histological confirmation. Chronic heartburn affects a large number of the population, and BO is found in approximately 10% of those undergoing endoscopy for reflux symptoms. However, the risk of adenocarcinoma in patients with gastro-oesophageal reflux is <1 in 1000 per year; therefore, performing BO screening in patients presenting with heartburn is not appropriate. In patients with BO, approximately 5% will develop dysplasia, and 10%–50% of the low-grade dysplasias will progress to high-grade dysplasia or adenocarcinoma within 2–5 years. In addition, a high-grade dysplasia contains a focus of adenocarcinoma in 30%–40% of cases. Screening has been developed to reduce the development of adenocarcinoma via the early detection of high-grade dysplasias or cancer in situ.

How do we screen for BO?

Current guidelines from the British Society of Gastroenterology (BSG) advocate the following screening programme:

- symptomatic therapy with a proton-pump inhibitor should be offered to those with BO, and the dose escalated to control symptoms; however, it must be recognized that studies have shown that symptom control does not necessarily correlate with prevention of acid reflux
- quadrantic biopsies should be taken every 2 cm from the segment of BO, and from any visible lesion
- BO with no dysplasia should undergo a surveillance endoscopy after 2 years
- biopsies which are 'indefinite for dysplasia' should lead to a repeat endoscopy with further multiple biopsies; if the second set of biopsies plus a third set at 6 months continue to show no definite dysplasia, the patient can return to 2-yearly surveillance
- low-grade dysplasia should be treated with high-dose acid suppression for 8–12 weeks and then be re-biopsied; persistent low-grade dysplasia requires 6-monthly surveillance
- if high-grade dysplasia persists after acid suppression and re-biopsy, the patient should be offered treatment; treatment options include mucosal resection, photodynamic therapy, radiofrequency ablation, and oesophagectomy

This advice should be purely used as a guideline, with each patient being assessed individually as to their suitability for undergoing routine endoscopies. Factors associated with a higher risk of developing cancer include age >45 years, male gender, extended segment BO (>8 cm), mucosal damage (oesophagitis, ulceration), family history of cancer, long duration of reflux, and early age of reflux symptoms.

What is the impact of screening for BO?

Currently, survival rates for patients with BO are identical to those for age- and sex-matched populations, with most patients dying from causes unrelated to their BO. However, adenocarcinoma of the oesophagus and gastro-oesophageal junction is the fastest growing cancer of the Western world; thus, screening has been implemented in an attempt to curb this growth. Currently, there is little evidence to confirm or refute the evidence for screening of BO.

The future of BO screening programmes

The real impact of BO screening programmes will become more evident as the screening program continues. The Barrett's Oesophagus

Surveillance Study and other such studies will eventually give evidence as to the actual benefit to patients (in increased life-years) and the NHS (in cost-effectiveness).

Colorectal cancer

Colorectal cancer is the third most common cancer in the UK, and the second commonest cause of cancer-related death. Approximately 1 in 20 people will develop colorectal cancer in their lifetime. The main aim of colorectal cancer screening is the early detection of polyps and cancers, at a time when treatment is likely to be more effective.

How do we screen for colorectal cancer?

The NHS National Bowel Cancer Screening Programme was introduced in 2006 and offers faecal occult blood (FOB) testing every 2 years to all men and women aged 60–69. Patients who are ≥70 and want FOB testing can obtain screening kits via a telephone helpline. Patients with positive FOB tests are subsequently offered a colonoscopy.

What is the impact of screening for colorectal cancer?

The screening programme has estimated the costs in 2008–9 to be £55 000 000. It has been estimated that, if 1000 people undergo FOB testing, approximately 20 will have positive results. Of those with positive results, ~10% will have an underlying colorectal cancer. This equates to 2 of the original 1000 patients (i.e. 0.2% of those screened). Furthermore ~6 (0.6%) will have colonic polyps, which can be removed at colonoscopy and dictate the need for further surveillance (see 'Screening in patients with adenomatous colorectal polyps'). Studies have shown that screening reduces the risk of death from colorectal cancer by ~16%.

The future of colorectal screening programmes

The colorectal cancer screening programme is still in its early days; the full extent of cancer prevention it provides will be recognized over the next few years. Despite the fact that changing lifestyle measures have reduced the rate of colorectal cancer, it is expected that population growth, alongside screening programmes and increased public awareness, will lead to a higher number of cases over the next 20 years.

Screening for gastrointestinal cancer in specific groups

Various groups have been shown to have an increased risk of gastrointestinal (GI) cancer, including those with inflammatory bowel disease, acromegaly, or a family history of colorectal cancer, amongst others. Guidelines have been put in place to ensure these patients are monitored regularly, aiming to reduce their risk of GI cancer to that of the general population.

Screening for GI cancer in patients who have had a colorectal cancer resection

There is no evidence that screening for GI cancer after colorectal cancer resection improves survival. However, the BSG advise that a colonoscopy should be performed 5 years after a colorectal cancer resection, and 5-yearly thereafter, up to the age of 70 years. In addition, it is reasonable to offer liver imaging within 2 years of the surgery to those ≤70 years, to identify operable liver metastases early.

Studies are ongoing in order to detect the benefit of more aggressive surveillance in this patient group.

Screening for GI cancer in patients with adenomatous colorectal polyps

It is widely accepted that most colorectal cancers develop from asymptomatic adenomatous polyps. The National Polyp Study in the US showed a reduction in incidence of colorectal cancer by 70%–90% in patients undergoing polyp surveillance. If polyps are seen at the time of colonoscopy, they should be removed. BSG guidelines advocate follow-up of these patients, as follows:

- 1–2 small (<1 cm) polyps: no follow-up or colonoscopy for 5 years
- 3–4 polyps, or one polyp which is ≥ 1 cm in diameter: 3-yearly colonoscopy, until two consecutive negative colonoscopies
- ≥ 5 or ≥ 3 polyps, with one of them being ≥ 1 cm: 12-monthly colonoscopy
- large lesions: these should be re-examined at 3 months

The degree of dysplasia also affects time between colonoscopies, with high-grade dysplasia requiring rapid re-examination of the polyp site. Surveillance is usually ceased at 75 years, when the life expectancy is seen to be shorter than the average time taken for adenomas to become malignant.

Screening for GI cancer in patients with inflammatory bowel disease

Patients with inflammatory bowel disease affecting their colon are at an increased risk of colorectal cancer, and colonoscopy has been advocated to increase detection of dysplasia. The following guidelines have been provided:

- surveillance colonoscopies should be performed when the disease is in remission, as differentiating between inflamed and dysplastic tissue is difficult
- colonoscopy should be performed 8–10 years after diagnosis, to assess the extent of the disease
- surveillance colonoscopy should be commenced 8–10 years after symptom onset in patients with extensive colitis
- surveillance colonoscopy should be commenced 15–20 years after symptom onset in patients with left-sided disease
- patients with associated primary sclerosing cholangitis have an even greater risk of colorectal cancer, and should undergo an annual colonoscopy

The BSG recommends that, during the colonoscopy, two to four biopsies should be taken every 10 cm and from suspicious areas. More recent advances in endoscopic procedures (chromoendoscopy, narrow-band imaging) are more effective at identifying abnormal mucosa. Subsequent studies suggest surveillance is more effective if these modalities are used, with biopsies targeting abnormal tissue.

Screening for GI cancer in patients with acromegaly

Screening of acromegalic patient for colorectal cancer commences at the age of 40 years, and is influenced by the activity of underlying acromegaly. Patients found to have adenomatous polyps at the index endoscopy, or those with IGF-1 levels above the maximum normal range, should undergo 3-yearly surveillance. Those with a negative initial endoscopy or normal IGF-1 levels require 5-yearly surveillance.

Screening for GI cancer in patients who have undergone a ureterosigmoidostomy

Patients who have undergone a ureterosigmoidostomy are at risk of developing adenomas and subsequent adenocarcinomas at the anastomosis. The earliest recorded case of a ureterosigmoidostomy-related adenoma occurred 10 years post-operatively. Therefore, screening in these patients, via flexible sigmoidoscopy, should commence 10 years post-operatively. This screening should only be stopped if the patient undergoes a further procedure with an alternative diversion and removal of the ureteric anastomosis.

Screening for GI cancer in patients with a family history of colorectal cancer

Patients are considered to have a significant family history of colorectal cancer and thus require colonoscopic surveillance if they have either one first-degree relative who has colorectal cancer and is <45 years old, or two first-degree relatives affected by colorectal cancer. The lifetime risk of dying from colorectal cancer is as follows: 1:50 for those in the general population, 1:17 for those with any family history, 1:10 for those with one affected relative <45 years old, and 1:6 for those with two affected relatives. Patients with a significant family history of colorectal cancer should be offered a colonoscopy at 35–40 years, with a repeat at 50 years of age.

Screening for GI cancer in patients with hereditary non-polyposis colorectal cancer

Patients with hereditary non-polyposis colorectal cancer (HNPCC) should be referred to a regional genetics centre in order to undergo formal assessment, with genetic mutation analysis. Thereafter, the specialist centre can organize family screening as required. In patients with HNPCC, there is a lifetime risk of colorectal cancer of ~80%, and 13%–20% for gastric cancer. Colonoscopic cancer surveillance in these patients should start at age 25, and gastroscopic surveillance at age 50 (in families affected by gastric cancer), or 5 years earlier than the first case within the family. Surveillance should continue with colonoscopies every 2 years until the age of 75. Surveillance is not required in family members who do not carry the genetic mutation shown to be the cause of colorectal cancer in other members of their family.

Screening for GI cancer in patients with familial adenomatous polyposis

Patients with familial adenomatous polyposis should be referred to a regional genetics centre in order to undergo formal assessment, with genetic mutation analysis. Thereafter, the specialist centre can organize family screening as required. Patients with familial adenomatous polyposis will almost universally develop colorectal cancer, with gastroduodenal cancers occurring in ~7%. Surgery in these patients is strongly recommended before age 25, preferably with a proctocolectomy and ileo-anal pouch. Patients deferring surgery should be offered annual colonoscopies and 6-monthly sigmoidoscopies. If the anorectum is retained the patient should have annual surveillance, due to the risk of cancer in the remaining bowel.

Upper GI endoscopy should be performed 3-yearly from the age of 30, although patients with large numbers of polyps should have more frequent endoscopies.

Screening for GI cancer in patients with juvenile polyposis

Patients with juvenile polyposis should be referred to a regional genetics centre in order to undergo formal assessment, with genetic mutation analysis. Thereafter, the specialist centre can organize family screening as required. Of those with this disease, 10%–38% develop colorectal cancer, and ~21% develop gastric cancer. Patients with juvenile polyposis should be offered colonoscopic screening from ages 15–18, and upper GI endoscopy from age 25, on an annual or biannual basis.

Screening for GI cancer in patients with Peutz–Jeghers syndrome

Patients with Peutz–Jeghers syndrome should be referred to a regional genetics centre in order to undergo formal assessment, with genetic mutation analysis. Thereafter, the specialist centre can organize family screening as required. Of those with this disease, 10%–20% will develop colorectal cancer; therefore, patients with Peutz–Jeghers syndrome should undergo colonoscopic surveillance from age 18, with upper GI endoscopy 3-yearly from age 25.

Hepatocellular cancer

Cirrhosis is a risk factor for the development of hepatocellular cancer (HCC), with an annual risk of 1%–6%.

How do we screen for HCC?

Currently, the strategies involved in HCC screening are 6-monthly liver ultrasounds, and alpha-fetoprotein levels. This should, in theory, be offered to all patients with evidence of cirrhosis. However, in general, screening is reserved for patients who are suitable for active treatment should a small HCC be found (e.g. those with Child–Pugh Class A or B liver disease). Many patients with cirrhosis have decompensated disease with poor synthetic function, resulting in a poor prognosis. As with all screening programmes, thought should be given to whether the patient will benefit from early detection of an underlying cancer.

What is the impact of HCC screening?

The evidence for screening for HCC in cirrhotic patients is limited, with few controlled studies. Small studies have shown improved early detection and overall survival in patients with hepatitis B cirrhosis. Early detection of HCC is advantageous, as the prognosis in advanced

disease is very poor. Unfortunately, a large percentage of HCCs are found in patients with undiagnosed cirrhosis, meaning that screening will fail to pick up these patients. Each centre should develop its own surveillance programme, based on the available expertise; but, in general, 6-monthly alpha-fetoprotein tests and ultrasound scans are advocated.

355 Screening for neurological disease

Sarah Cader

What neurological diseases can we screen for?

Given the nature of some neurological diseases to become progressively disabling, early detection and treatment would be very welcome. However, screening for neurological illnesses in the general population has a number of problems. There are only a few neurological conditions that exist in a detectable asymptomatic state prior to development of clinical disease, and a small number of other conditions have early symptomatic stages before the full impact of the disease manifests. In addition, in many neurological conditions, there are no definitive treatments available. There are, of course, many genetic conditions that have neurological manifestations and could be screened for, and early access to neurological assessment for some progressive conditions may enable early intervention.

Potential target groups include patients with neurogenetic disorders, patients with neurodegenerative disorders, patients with inflammatory disorders, and patients with metabolic disorders (see Table 355.1)

Table 355.1 lists the more common neurological conditions for which there may be a potential role for screening and intervention. Acute neurological conditions, such as infections and acute inflammatory disorders, would not merit screening as they are rapid in onset, and many have good treatments. There are also a number of relatively benign chronic conditions, such as migraine and epilepsy, that are readily treatable and do not typically progress.

How can we screen for neurological diseases?

A full neurological examination should be undertaken for all patients presenting to hospital. This may allow early detection of subtle neurological defects that the patient has not yet become aware of or had ignored. It can provide clues to systemic conditions or be an indicator of an emerging neurological diagnosis.

For the most part, it is not appropriate to screen the general asymptomatic population for these conditions, as they are not common conditions. However, it would be worthwhile being aware of the conditions in Table 355.1 so that they are considered in all patients.

Screening for neurogenetic disorders

Screening for patients with genetic disorders is potentially exciting as it is likely that there will be a specific and sensitive test for the condition that can be used before the emergence of any clinical symptoms.

Many of these patients will have a family history that will indicate the risk. Certainly, in the case of Huntington's disease, genetic screening is done for predictive testing in relatives of affected individuals. In Huntington's disease, there is an unstable CAG trinucleotide repeat in Chromosome 4. If there are >40 repeats, then the individuals will develop the disease, although the onset is earlier in those with longer segments. Charcot-Marie-Tooth disease, or hereditary motor and sensory neuropathy, is caused by a number of different mutations. Testing is usually for the commoner mutations in PMP22 and MPZ, and is confined usually to patients presenting with a neuropathy following supportive nerve conduction studies or with affected family members. There have been many mutations that have been shown to cause mitochondrial disorders, and these can occur in both mitochondrial DNA and the nuclear DNA encoding for mitochondria. Initial screening is, therefore, usually for evidence of an underlying mitochondrial defect, and this will be evident on electromyography, from a muscle biopsy, or in blood lactate levels. If the clinical signs and bedside testing indicate that a mitochondrial diagnosis is possible, then the patient's tissue and blood can be sent for screening of the genome or more targeted mutation analysis. Muscular dystrophies comprise a large group of muscle disorders that are caused by an underlying defect in the genes encoding muscle development. Genetic testing usually provides a definite diagnosis, but it needs to be targeted according to the clinical picture and whether any family members are affected. There may be additional clues from testing for creatine kinase, a muscle enzyme.

Screening for neurodegenerative disorders

The incentive to screen for neurodegenerative conditions is large, given the potential to interrupt the disease early in its course before progression has been established. Unfortunately, screening for these conditions is not easy, and they are rather insidious in onset. There are familial variants that could be screened with genetic testing, but they tend to be rare in comparison. Early onset Alzheimer's disease can be caused by mutations in PSEN1, PSEN2, and APP. Sporadic and late-onset Alzheimer's does not have any specific genetic test. Early stage of dementia can be difficult to diagnose accurately, so diagnosis is often not made until cognitive impairment is established. Brain biopsy might detect early pathological changes but taking a brain biopsy is not practical in most patients. In Parkinson's disease, diagnosis is based on a triad of bradykinesia, rigidity, and tremor. However, radioisotope imaging for the dopamine transporter can demonstrate evidence of dopamine depletion even relatively early in the condition, when the only symptom may be a tremor. The test will not reliably distinguish Parkinson's disease from other causes of parkinsonism, such as multisystem atrophy or progressive supranuclear palsy. Genetic mutations have been identified for some familial, early onset cases in a number of genes, such as PARK2. Genetic mutations have only been identified in a small proportion of patients with motor neuron disease, most commonly in SOD1; diagnosis is usually made late, progression is rapid, and there is currently no method to screen patients for the risk of developing this disease. Spongiform encephalopathies, on the other hand, have a typically long latency. Familial Creutzfeldt-Jakob disease, Gerstmann-Sträussler-Schlenker disease, and familial fatal insomnia are hereditary spongiform encephalopathies that are due to mutations in PRNP, the gene that codes for the human prion protein. Genetic screening can be done in those with affected family members. Sporadic forms of these diseases may be due to post-translational structural protein changes or spontaneous somatic gene mutations. These changes may be present for some time before any symptoms emerge. Homozygosity for methionine at codon 129 of PRNP gene appears to confer susceptibility to Creutzfeldt-Jakob disease.

Table 355.1 Neurological conditions for which there may be a potential role for screening and intervention

Neurogenetic disorders	Neurodegenerative disorders	Inflammatory and autoimmune disorders	Metabolic disorders
Huntington's disease	Alzheimer's disease	Multiple sclerosis	Vitamin B ₁₂ deficiency
Charcot-Marie-Tooth disease	Parkinson's disease	SLE	Wilson's disease
Mitochondrial disease	Motor neuron disease	Sarcoidosis	Copper deficiency
Muscular dystrophy	Spongiform encephalopathies	Vasculitis	Lead neuropathy
		Temporal arteritis	Iron overload
			Thyroid disease
			Drug-induced myopathy
			Diabetes

Screening for inflammatory and autoimmune disorders

Inflammatory disorders are often multisystem and may be detectable before any significant symptoms appear. Temporal arteritis can lead to blindness, but testing the erythrocyte sedimentation rate (ESR) in older patients presenting with headache is a useful screening tool that may prevent any problems. Similarly, patients with other vasculitides, as well as with SLE and many other autoimmune conditions, may have a raised ESR, or be positive for autoimmune antibodies (e.g. antineutrophil cytoplasmic antibodies). If this is the case, then immunosuppressive treatment can be instigated early to prevent more serious clinical problems. Sarcoidosis can be more troublesome to screen, as angiotensin-converting enzyme is neither particularly sensitive nor specific. A chest radiograph may show hilar lymphadenopathy, and there may be abnormalities in liver enzymes. However, these will only be present during a flare, and have no predictive value as to the onset of neurosarcoid. Evidence of multiple sclerosis may be found on MRI in patients that have minimal symptoms. It may be possible to treat these patients before a definite diagnosis of the disease is made or any progression occurs.

Screening for metabolic disorders

Some neurological disorders are due to deficiencies or toxic levels of certain substances. Most of the tests in these cases are simple to perform and involve a simple blood test. Testing for vitamin B₁₂ and thyroid hormone levels is widespread, since there is considerable awareness of the problems their deficiencies can cause. Testing for trace metals and less common conditions tends to be reserved for patients that present to the neurologist with consistent symptoms, and so are not screened as such. Paediatric specialists will, however, often do an extended spectrum of screening tests for the common inborn errors of metabolism.

What is the impact of screening for neurological diseases in the real world?

Neither the genetic or neurodegenerative conditions have many effective treatments. Management is largely supportive,

and widespread screening for relatively rare conditions is not cost-effective.

In multiple sclerosis, there is some evidence that early intervention may prevent the onset of clinically definite disease, but this is limited. In other inflammatory disorders, early immunosuppression will prevent progression and accumulation of disability. In practice, patients do not get such treatment until they have symptoms that would necessitate the use of potentially strong drugs.

Most metabolic disorders are rare and so do not justify routine screening. Screening for vitamin deficiencies, diabetes, and thyroid disease is routinely done, and early detection has no doubt prevented the onset of a considerable degree of neurological morbidity. These are common conditions that are easily tested.

Issues and the future of neurological screening programmes

There are no screening programmes in neurology. As studies emerge, it may become apparent that early intervention in some conditions does indeed prevent development of the disease. This is may be first available for multiple sclerosis, which is one of the commonest neurological conditions, and MRI is safe and sensitive, albeit relatively expensive.

The main issues remain across neurology. There are often inadequate treatments for many diseases and there is difficulty in early diagnosis when symptoms may only show subtle differences at early stages. In neurology, there is a wide range of relatively rare conditions, and screening in these circumstances is very difficult.

356 Screening for cancer

Warren Grant and Martin Scott-Brown

Aims of screening for cancer

Many of us spend a lot of time wanting not to contract diseases! We are likely to alter our lifestyles as a result. Physicians, particularly in primary care, are challenged on a daily basis by worried people who feel they may not be able to avoid conditions such as cancer. These individuals often believe they should at least have it 'caught early' before it causes them any harm. The physician then enters the world of preventive care. It incorporates medical traditions such as 'the annual medical' and is the motivation behind the GP that takes your blood pressure when you attend with an infected toenail.

Preventive care encompasses immunization, screening, lifestyle change, and chemoprevention (i.e. using medicine to prevent disease). Each of these aspects involves active participation by the patient. In cancer, screening is a key method of preventing symptomatic disease, but is subtly different from the patient-led preventive care consultation. The aim in cancer screening is not just to prevent the incidence of disease or diagnose it in an early stage but, most importantly, to reduce mortality. Designing screening programmes leads to challenging questions such as:

- is it worth diagnosing the cancer before symptoms develop?
- will screening reduce mortality or just create more people living with the disease?
- who should be screened?
- what form should the screening test take?
- is screening cheaper than treating symptomatic disease?
- how will screening affect individuals without the diagnosis?

Effective cancer screening programmes require a centralized organization to coordinate implementation, robust statistical evidence of benefit, and extensive cost and resource planning for the inevitable increase in use of diagnostic and treatment services. This chapter will outline the three UK population cancer screening programmes and highlight the key issues considered in their design.

The history of screening for cancer

Cancer screening began with the Pap smear. George Papanicolaou published his seminal paper 'The diagnostic value of vaginal smears in carcinoma of the uterus' in *American Journal of Obstetrics and Gynaecology* in 1941. He had first announced his ideas based on exfoliative cytology back in 1928 but, at this time, his colleagues held such strong doubts about the validity of such a test that he laid his ideas to rest for the forthcoming decade.

Since then, the only evidence-based programmes to have been developed are in breast, cervical, and bowel cancers. This reflects not only the challenging and lengthy process of assessing potential screening tests, but also how certain cancers are more suitable for screening than others.

Which cancers are suitable for screening?

In 1968 Wilson and Junger of the WHO outlined a series of principles that should lie behind the development of a screening programme:

- the condition to be screened should be an important public health problem in terms of frequency and severity
- its natural history should be well understood
- it should be recognizable at an early stage
- treatment outcomes should be better at an early stage of the disease

- a suitable test exists (i.e. one that can reliably detect the disease)
- an acceptable test exists (i.e. one that is cost-effective and safe for patients)
- adequate facilities should exist to cope with the abnormalities detected
- screening should be done at repeated intervals when the onset of the disease is insidious
- the chance of harm should be less than the chance of benefit
- the financial cost should be balanced against the benefit

These ten principles clarify the aims and objectives of disease screening. They also highlight key problems in the development of such a programme for cancer. For example, the incidence of prostate cancer has increased over recent years, and many countries are looking for ways of preventing an increase in prostate cancer deaths. However, the design of a suitable screening programme falls at the second principle. Prostate cancer's indolent natural history makes decisions about when to screen very complicated. Should all men over 18 be screened because we know early diagnosis of organ-confined disease offers more treatment options and that disease in younger men is more likely to be fatal? Or should we just screen men aged over 50 once a year to save cost? What about screening the symptomatic? Maybe this is enough to reduce mortality. But what about the onset of symptoms in young men? These individuals are more likely to have aggressive disease, and symptomatic treatment may be too late to prevent mortality. The issues with prostate cancer screening highlight themes common to screening in many other less prevalent cancers (e.g. ovarian or gastric cancers).

Screening for breast cancer

In the UK, breast cancer screening was set up by the Department of Health in 1988, in response to the report of a working group led by Professor Sir Patrick Forrest. The Forrest Report, as it became known, was published in 1986 and set out ideas about population screening in the UK for breast cancer. It concluded that screening by mammography could lead to prolongation of life for women aged 50 and over.

Women were first invited for screening in 1988 and by 1990 national coverage had been achieved. The programme is currently costed at around £75 million per year, which works out at around £37.50 per woman invited, or £45.50 per woman screened.

Recent developments in the programme mean that women between the ages of 47 and 73 will be invited to attend for two-view mammographic assessment every 3 years. After the age of 73, women can attend for screening by open invitation, but are no longer routinely invited. Some screening does occur in the high-risk population under 47. This is often instigated by the local genetic counselling team, oncologists, or GPs. The idea of the screening programme is to detect radiological changes of cancer at a very early stage. Those who are found to have abnormal tests go on to have further diagnostic investigations, including a core biopsy. This has been shown to reduce mortality and, by 2010, saved 1250 lives each year. But breast screening will also cause some women to undergo invasive biopsy tests for benign breast lesions.

Screening for cervical cancer

In some cancers, there is a biological window of opportunity where precancerous abnormalities can be reliably detected. In these cases, screening can lead to treatment to prevent the onset of invasive cancer. This is the basis for cervical cancer screening.

In the UK, a liquid-based cytology (LBC) test is used to screen all women between the ages of 25 and 64 at 3–5 year intervals. It involves obtaining a specimen via a speculum examination and taking a 'smear' of the cells on the cervical surface. This specimen is then added to a fluid solution for preservation before it is sent to a laboratory for analysis.

In recent years, both the interval between screening invitations and the nature of the assessment test used have undergone extensive review and development to improve the quality of the programme. Initially, all women were screened every 3 years. Since 2003, those aged 50 or over have been offered 5-yearly invitations. This has obvious cost benefits by reducing the number of tests carried out, and may increase the specificity of the testing programme. But it will also increase the chance of length time bias and more aggressive cancers may be missed.

Smear testing began in the 1960s but initially was only used by those who presented to a doctor. As a result, those women thought to be at highest risk were likely not to have the test, and those who did have it and had a positive result had no formal framework to ensure that their condition was managed in a standard way. The computerized national screening programme was rolled out in 1988.

In September 2008 the HPV vaccine was introduced in the UK for girls aged 12–13. This virus is a key etiological factor in cervical cancer and, inevitably, the vaccine will reduce its incidence, but it will take many years to do so. As a result, the LBC screening programme is likely to continue for the foreseeable future.

Screening for bowel cancer

A bowel cancer screening programme was initiated across the UK, with national coverage achieved by the end of 2009. It is aimed at diagnosing cancer at an early stage by using faecal occult blood (FOB) testing. This technique was tested in a successful pilot based in Coventry and North Warwickshire in 2007. A kit is sent to the homes of all men and women aged 60–69 with instructions about how to use it. The sample is then sent to a hub laboratory, and the results are communicated to the patient within 2 weeks. Those with a positive test will see a specialist nurse and are likely to undergo colonoscopy, the gold-standard diagnostic test for bowel cancer. The total cost of the programme will be around £55 million per year. One of the major issues in designing the programme was establishing a reliable screening test. Although, due to its high sensitivity and specificity, colonoscopy is the gold-standard diagnostic test for bowel cancer, it is relatively expensive. Other radiological investigations have similar problems. FOB tests are cheap, easy to mass-produce, and have been shown to have a high sensitivity for bowel cancer. But what about reliability? If a major feasibility study for bowel cancer screening involved the Haemocult tester (Beckman Coulter Inc., Fullerton, California) and you wish to use a tester of a different brand, should you run another major randomized control trial? In practice, this has not been done.

Ensuring a useful cancer screening test

The accuracy of a screening test, that is, its ability to differentiate diseased from non-diseased individuals, is measured by its **sensitivity** and **specificity** (see Table 356.1).

Sensitivity is the proportion of individuals **with** the disease who are correctly identified by the test. Specificity is proportion

of individuals **without** the disease who are correctly identified by the test. Ideally, a screening test would score 100% sensitivity and specificity, but no test currently does this. This results in some individuals being diagnosed as having the screened condition when they do not, and some individuals with the screened condition not being diagnosed. In a quest to reduce the numbers of these unfortunate individuals, every effort is made to increase sensitivity and specificity; however, in practice, they are inversely related. If, for example, the value of a positive result for a blood test such as the PSA test in prostate cancer is reduced (e.g. from 4 ng/ml to 3 ng/ml), more cases of prostate cancer are likely to be diagnosed and thus the sensitivity would rise. At the same time, some individuals who do not have prostate cancer are likely to be diagnosed as having the condition because they have benignly elevated PSA levels (e.g. because of prostatitis). Balancing these two factors is key to a successful cancer screening programme.

When evaluating a screening programme, it is also important to understand the **positive predictive value** of the test involved. The positive predictive value is the proportion of individuals who actually have the disease, having had a positive test result. It is based on the sensitivity and specificity of the screening test and also, importantly, on the prevalence of the disease. To put it another way, if the positive predictive value of a test is only 10%, this could be because the test is not accurate in detecting the disease (low sensitivity), inaccurate in defining people who do not have the disease (low specificity), or it could be that the population screened are of low risk for the disease. Therefore, factors that increase the positive predictive value include increasing the sensitivity and the specificity of the test, as well as focusing on high-risk individuals. A high positive predictive value may not always correlate with a good screening test. It may be that only large, advanced tumours are detected, and screening them is likely to be of no benefit to patient survival. A test with a low positive predictive value may reflect screening in a low-prevalence population but with a greater cancer detection rate (increased sensitivity) diagnosing a broader selection of tumours. These patients will benefit from screening.

Bias in screening for cancer

As mentioned earlier, screening for cancer is designed to increase survival in those who have the disease and who have been screened, compared to those who have not been screened. Assessing survival in this context raises some statistical challenges and is subject to two types of bias—**length time and lead time** (see 'Bias in screening for cancer'). Generally, randomized control trials (RCTs) are thought of as the gold standard when it comes to evaluating a screening programme. Case-control studies are a cheaper, smaller alternative to RCTs but are prone to selection bias. In the ideal trial, large numbers of individuals would be allocated randomly to either have the screening test or not. This selected population would then be followed up until enough data on the key outcome have been collated. In cancer screening, this outcome is survival. This type of trial is expensive, can take many years to complete (depending on the biology of the cancer), and requires many thousands of participants to give statistically significant results. As an example, four RCTs evaluating screening for bowel cancer have involved over 300 000 people and taken around 15 years to complete. When analysing such trials, it is important to note that the relevant outcome is a change in **disease-specific** survival. Trials that present data on overall survival can often be misinterpreted.

Results of trials that suggest there is a survival advantage in those who have had the screening test may be reflecting **lead time bias**. Lead time is, in essence, what a screening programme is trying to promote, that is, an extension in the period of time before an individual would have normally presented with symptoms from the disease being screened. However, an apparent increase in length of survival, without taking account of mortality rate, can merely reflect an earlier diagnosis of a condition that individuals then live with for longer, before dying at the same rate and at the same age as the population without screening. As mentioned, prospective RCTs that take account of disease-specific mortality rates help to get round problems of lead time bias.

Table 356.1 Determining the sensitivity, specificity, and negative/positive predictive value of a test

Test result	Disease	No disease	Total
Positive	A	B	A + B
Negative	C	D	C + D
Total	A + C	B + D	A + B + C + D

Note: sensitivity = $A/(A + C)$; specificity = $D/(B + D)$; positive predictive value = $A/(A + B)$; negative predictive value = $D/(C + D)$.

Length time bias suggests that aggressive, fast-growing cancers are less common after a screening programme is introduced, and results in the phenomenon of slower-growing, less aggressive cancers being more common in the screened population. It occurs because of the interval between screening invitations. During this time, some individuals will develop aggressive, fast-growing tumours and may go on to develop symptoms or even die from them before their next screening invitation. Those individuals who develop slower-growing tumours are more likely to be picked up at screening. The ideal screening interval, therefore, will be short enough to detect the onset of new disease, at a time when it can successfully be treated, without putting too large a resource burden

on the organizing agency or inconveniencing the population to be screened and encouraging them not to attend (e.g. breast cancer screening every 3 years).

 neurological disease prevention 1186
 use disorder 697
 withdrawal syndrome 234, 235, 236, 237, 697
Alcohol Use Disorders Identification Test
 (AUDIT) 236, 697, 1163
alcoholic cirrhosis 95
alcoholic fatty liver (steatosis) 697, 698, 721, 722
alcoholic hallucinosis 235
alcoholic hepatitis 78, 94, 690–1, 697, 698
alcoholic liver disease (ALD) 94, 697–9
aldosterone 588, 591, 594, 613–14
aldosterone–renin ratio 594
aldosteronism, primary 613–14
alemtuzumab 1040*t*, 1117
Alexander disease 758*t*
algorithms, use of 4, 5, 6*f*
alkalaemia 577–9
alkaline phosphatase (ALP) 686, 694, 715, 933
allergic bronchopulmonary aspergillosis (ABPA) 457,
 1086, 1087
allergic contact dermatitis 198, 204
allergies/allergens 1013, 1014–15, 1016
 asthma 443, 472, 473
 history taking 13
 itching 203
 skin testing 840–1, 840*f*
 vaginal discharge 176
allodynia 138
alloimmune haemolysis 965
allopurinol 718
alopecia areata 860, 861*t*, 861
alopecia totalis 860
alopecia universalis 860
alpha-1 antitrypsin 447
 deficiency 641*t*, 716–17, 1203
alpha-2 antiplasmin 978
alpha-2-macroglobulin 978
alpha-fetoprotein (αFP) 686–7, 732–3
alpha granules 968
alpha thalassaemia 962
Alport's syndrome 161, 522
altered consciousness 742
alveolar gas equation 416
alveolar hydatid disease 1098, 1100
alveolar-to-arterial (A–a) gradient 416, 449, 450, 491
alveolar ventilation 410
alveolocapillary membrane diffusion 410–11
Alzheimer's disease 757*t*, 777, 778, 779, 780
 demographics 753
 polygenic inheritance 751
 prevention 1184
 screening 1209
amantadine 1067*t*
amaurosis fugax 322, 323
ambulatory ECG recording 258
American College of Rheumatology classification,
 rheumatoid arthritis 911*t*
amine hormones 588
amino acids 682, 1134–5
aminoacidopathies 582–3
amiodarone 477, 478, 606–7, 823, 823*t*
ammonia 749, 1135
amoebiasis 645, 1092
amoebic liver abscess (ALA) 723, 724, 1092
Amor criteria, spondyloarthropathy 914*t*
amphetamines 1168
Amsler grid 148

- amylase 494, 654
 amyloid light-chain (AL) amyloidosis 558, 559, 584–5
 amyloidosis 510, 558, 559, 584–5
 amyotrophic lateral sclerosis (ALS) 794
 anabolic steroids 1168
 anaemia 104–5, 948, 951
 aplastic 948, 949–50
 chronic breathlessness 54
 of chronic disease (ACD) 900, 953t, 957
 chronic renal failure 884
 deficiency 955–7
 folate deficiency 955–6, 957
 haematological investigations 952
 haemolytic 958–66
 hypotension 44
 infection 1050t
 iron-deficiency see iron-deficiency anaemia
 macrocytic 104, 900, 955
 malabsorption 660
 megaloblastic 955–6, 957, 960
 microcytic 104, 953t
 normocytic 104, 953t
 oxygen dissociation curve 945f
 pernicious 952, 955, 956, 957
 red cells and haemoglobin 945
 renal 538, 539
 sideroblastic 953t
 suspected gastrointestinal disease, diagnosis in 635
 vitamin B₁₂ deficiency 955, 956, 957
 anaesthesia (sensory loss) 138
 anal cancer 672, 1116
 anal sphincter damage 174
 analgesic ladder 1128t
 analgesic nephropathy 528
 anaphylactic shock 215t
 anaphylaxis
 hypotension 44, 46

 unstable 32t, 39, 275
 angiogenesis, sustained (oncogenesis) 1110
 angiogenic switch 1110
 angioedema 855, 886t, 888, 1032, 1033
 angioplasty 562
 angiotensin-converting enzyme (ACE) 459
 angiotensin-converting enzyme (ACE) inhibitors 477, 478
 angiotensin II 588
 animal reservoir 1048
 anion gap 578, 582
 anisocytosis 944t
 ankle–brachial pressure index (ABPI) 191, 193, 194f, 323
 ankle pain 189
 ankylosing spondylitis (AS) 915, 917
 extra-articular manifestations 916f
 joint pain 178
 low back pain 183–4
 rheumatoid arthritis 912
 anorexia nervosa 204, 676, 1138
 anterior circulation strokes 768–9, 769b
 anterior pituitary gland 592
 anti-C1q vasculitis (hypocomplementaemic urticarial vasculitis) 928t, 1033
 anti-CCP2 912
 anti-cyclic citrullinated peptide antibodies (ACPA) 900, 910, 912
 anti-double-stranded DNA antibodies 919
 anti-glomerular basement membrane (anti-GBM) disease (Goodpasture's disease) 466, 927, 928t, 521, 522, 524, 525
 haemoptysis 66
 histology of renal biopsy 523f
 immunofluorescence of renal biopsy 524f
 test 516
 anti-growth signals, insensitivity to (oncogenesis) 1109–10
 anti-Scl-70 antibody 901
 anti-Sm antibodies 919
 anti-U3-ribonucleoprotein antibodies 901
 antibody deficiencies 1025–7, 1038
 anticomere antibodies 901
 anticipatory prescribing for end-of-life medication 406t
 anticoagulation 363–4, 365f, 771, 774
 antidiuretic hormone (vasopressin) 588, 592
 antidromic atrioventricular re-entrant tachycardia (aAVRT) 357, 358, 359
 antigen detection tests 1059
 antigen presentation 1012, 1044b
 antihypertensives 772, 774
 antimicrobials 1061–2, 1063
 resistance 1063
 stewardship 1063
 antineutrophil cytoplasmic antibody (ANCA) 516, 901, 902t
 antineutrophil cytoplasmic antibody (ANCA)-associated systemic vasculitis (AASV) 464–6, 465t
 antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis (AAV) 523f, 927, 928t
 antineutrophil cytoplasmic antibody (ANCA)-negative vasculitis 810
 antineutrophil cytoplasmic antibody (ANCA)-positive vasculitis 521, 522, 523, 524, 525, 558, 810
 antinuclear antibodies (ANAs) 516, 900, 901t, 919
 antiphospholipid antibodies 516
 antiphospholipid syndrome (APS) 559, 810, 986
 antiplatelet agents 771, 774
 antithrombin (AT) 975, 984
 antithrombotic therapy 771–2
 antithymocyte globulin (ATG) 949
 anuria 163–4
