Preface

Diagnosis and Treatment in Internal Medicine came about through our experience on the acute medical take. Here, sick patients present in large numbers with a vast range of problems. What all patients need, as the bedrock of management, is a differential diagnosis, and the central aim of our book is to help doctors formulate this. We asked experts in their field to provide succinct and authoritative guidance across the breadth of internal medicine. The assessment of symptoms or presenting problems is a major element of the book, but there is also comprehensive coverage of disorders of the body systems, including psychological aspects and palliative care. Chapters are structured so that key information can rapidly be found. Doctors need a broad perspective on health and its promotion, and there are sections addressing nutrition, lifestyle, and prevention of disease.

This book approaches medicine from the patient's perspective, through the stories that patients tell us about their illness, and provides the knowledge that turns these narratives into diagnoses, treatment, health, and longevity. Throughout, our focus has been on meeting the needs of doctors in the clinic, in the emergency department, or on the ward.

Our eternal thanks go out to our contributors. Some 200 outstanding doctors have produced admirably compact and lucid chapters. Throughout the lengthy gestation of the book, we have been ably supported by the staff at Oxford University Press, who have encouraged us and orchestrated the project. All praise should be directed to the authors, and any mistakes are ours. Please do let us have your suggestions for improvements (you can contact us at david.springs@gmail.com and pftame@gmail.com).

Contents

Normal values *xiii*

Abbreviations *xv*

Contributors *xxiii*

PART 1 THE APPROACH TO THE PATIENT

- 1 Diagnostic reasoning 2
- 2 Dealing with uncertainty 8
- 3 Taking the history 12
- 4 The physical examination 15
- 5 The psychological examination 18
- 6 Confidentiality 22
- 7 Consent 24

PART 2 ASSESSMENT OF SYMPTOMS AND PRESENTING PROBLEMS

- 8 Palpitation 28
- 9 Acute chest pain 31
- 10 Chronic chest pain 37
- 11 Hypotension 43
- 12 Acute breathlessness 47
- 13 Chronic breathlessness 51
- 14 Peripheral oedema 56
- 15 Murmur 58
- 16 Cough 61
- 17 Wheeze 63
- 18 Haemoptysis 65
- 19 Pleural effusion 67
- 20 Chylothorax 70
- 21 Difficulty swallowing 71
- 22 Haematemesis 73
- 23 Acute abdominal pain 75
- 24 Chronic abdominal pain 78
- 25 Dyspepsia 81
- 26 Abdominal mass 83
- 27 Constipation 85
- 28 Acute diarrhoea 87
- 29 Chronic diarrhoea 89
- 30 Rectal bleeding 91
- 31 Jaundice 93
- 32 Ascites 95
- 33 Chylous ascites 98
- 34 Swelling in the neck 99
- 35 Splenomegaly and other disorders of the spleen 101
- 36 Lymphadenopathy 103
- 37 Anaemia 104
- 38 Bruising and bleeding 106
- 39 Transient loss of consciousness 109
- 40 Coma 112
- 41 Delirium (acute confusional state) 116
- 42 Seizures 120
- 43 Difficulty speaking (including dysphasia and dysarthria) 123
- 44 Weakness 126
- 45 Tremor and other abnormal movements 131
- 46 Gait disorders 134
- 47 Sensory loss 137
- 48 Headache 142
- 49 Loss of vision 146
- 50 The red eye 150
- 51 Hearing loss 153
- 52 Facial pain 155
- 53 Dizziness 157
- 54 Disorders of sleep 159
- 55 Haematuria 161
- 56 Oliguria and anuria 163
- 57 Polyuria 165
- 58 Dysuria 167
- 59 Urinary incontinence 170
- 60 Faecal incontinence 173
- 61 Vaginal discharge 175
- 62 Joint pain 178
- 63 Muscle pain 181
- 64 Low back pain 183
- 65 Painful leg 187

- 66 Leg ulcers 191
- 67 Limb ischaemia 193
- 68 Rashes 195
- 69 Blistering rashes 197
- 70 Photosensitive rashes 200
- 71 Itching 203
- 72 Lumps and bumps 205
- 73 Falls 209
- 74 Immobility ('Off legs') 212
- 75 Suspected anaphylaxis 214
- 76 Fever 216
- 77 Hyperthermia 218
- 78 Hypothermia 221
- 79 Fatigue 224
- 80 Unintentional weight loss 226
- 81 Obesity: differential diagnosis 228
- 82 Self-harm 231
- 83 Alcohol intoxication 234
- 84 Intravenous drug use 239

PART 3 CARDIOVASCULAR DISORDERS

- 85 Normal function of the cardiovascular system 244
- 86 Risk factors for cardiovascular disease 248
- 87 Diagnosis and investigation in suspected heart disease 252
- 88 Congenital heart disease in adults 263
- 89 Chronic stable angina 271
- 90 Acute coronary syndromes 275
- 91 Acute heart failure 280
- 92 Chronic heart failure 283
- 93 Aortic stenosis 287
- 94 Aortic regurgitation 290
- 95 Mitral regurgitation 292
- 96 Miscellaneous valvar pathology: Mitral stenosis, pulmonary stenosis, and tricuspid regurgitation 295
- 97 Percutaneous coronary intervention 299
- 98 Heart surgery 302
- 99 Circulatory support therapy 306
- 100 Pulmonary hypertension 308
- 101 Venous thrombosis and pulmonary embolism 312
- 102 Aortic aneurysm 318
- 103 Aortic dissection 320
- 104 Peripheral arterial disease 322
- 105 Raynaud's phenomenon 325
- 106 Heart muscle disease (cardiomyopathy) 327
- 107 Tumours and the heart 332
- 108 Cardiac infection 335
- 109 Pericardial disease 340
- 110 Extrasystoles 342
- 111 Sinus tachycardia 345
- 112 Focal (ectopic) atrial tachycardia 348
- 113 Multifocal atrial tachycardia 351
- 114 Atrioventricular nodal re-entrant tachycardia 354
- 115 Atrioventricular re-entrant tachycardia 357
- 116 Atrial fibrillation 361
- 117 Atrial flutter 366
- 118 Ventricular tachyarrhythmias: Ventricular tachycardia and ventricular fibrillation 369
- 119 Bradyarrhythmias 379
- 120 Sudden cardiac death 384
- 121 Cardiac device therapy 395
- 122 Drug-induced cardiovascular disease 401
- 123 Psychological management of coronary heart disease 403
- 124 Treatment of terminal cardiovascular disease 405

PART 4 RESPIRATORY DISORDERS

- 125 Normal respiratory function 410
- 126 Diagnosis in suspected respiratory disease 412
- 127 Investigation in respiratory disease 415
- 128 Upper respiratory tract infections, including influenza 425
- 129 Pneumonia 427
- 130 Tuberculosis 431
- 131 Pneumothorax 436
- 132 Cystic fibrosis 439
- 133 Asthma 441
- 134 Chronic obstructive pulmonary disease 445
- 135 Respiratory failure 449
- 136 Obstructive sleep apnoea 454
- 137 Bronchiectasis 456

- 138 Sarcoidosis and other granulomatous lung disease 458
- 139 Interstitial lung disease 460
- 140 Pulmonary vasculitis 464
- 141 Lung cancer (including management of an isolated lung lesion) 467
- 142 Occupational lung disease 472
- 143 Pleural infection and malignancy 475
- 144 Drug-induced lung disease 477
- 145 Psychology in respiratory disease, including dysfunctional breathing 480
- 146 Terminal care in respiratory illness 482

PART 5 INTENSIVE CARE MEDICINE

- 147 Critical illness 486
- 148 Role of the intensive care unit 488
- 149 ICU treatment of respiratory failure 490
- 150 ICU treatment of cardiovascular failure 493
- 151 ICU treatment of acute kidney injury 496
- 152 ICU treatment of sepsis and septic shock 498
- 153 Terminal care in the intensive care unit 501
- 154 Brain death 503

PART 6 DISORDERS OF THE KIDNEY AND URINARY TRACT, AND ELECTROLYTE AND METABOLIC DISORDERS

- 155 Normal renal function 506
- 156 Diagnosis in suspected renal disease 509
- 157 Investigation in renal disease 512
- 158 Urinary tract infection 518
- 159 Glomerulonephritis 521
- 160 Interstitial renal disease 527
- 161 Nephrotic syndrome 529
- 162 Acute kidney injury 533
- 163 Chronic kidney disease 536
- 164 Diabetic renal disease 540
- 165 Urinary tract obstruction 543
- 166 Renal calculi 546
- 167 Renal and bladder cancer 549
- 168 Renal replacement therapy 552
- 169 Inherited renal diseases 556
- 170 The kidney in systemic disease 558
- 171 Renal vascular disease 561
- 172 Management of terminal care in renal disease 563
- 173 Disorders of plasma potassium 565
- 174 Disorders of plasma sodium 568
- 175 Disorders of plasma calcium 570
- 176 Disorders of plasma phosphate 573
- 177 Disorders of plasma magnesium 575
- 178 Disorders of acid–base balance 577
- 179 Porphyria 580
- 180 Aminoacidopathies, urea cycle disorders, and organic acidurias 582
- 181 Amyloidosis 584

PART 7 DIABETES MELLITUS AND ENDOCRINE DISORDERS

- 182 Normal function of the endocrine system 588
- 183 Diagnosis and investigation in endocrine disorders 593
- 184 Diabetes mellitus 596
- 185 Hypoglycaemia 601
- 186 Thyroid disease 603
- 187 Primary hyperparathyroidism 610
- 188 Adrenal disease 612
- 189 Cushing syndrome 617
- 190 Short stature 619
- 191 Infertility 621
- 192 Pituitary disorders: Prolactinomas, acromegaly, and pituitary apoplexy 625

PART 8 GASTROINTESTINAL DISORDERS

- 193 Normal gastrointestinal function 632
- 194 Diagnosis in suspected gastrointestinal disease 635
- 195 Investigation in gastrointestinal disease 637
- 196 Immunology and genetics in gastrointestinal and hepatic medicine 641

- 197 Gastrointestinal infections 644
 198 Benign oesophageal disease 648
 199 Peptic ulcer disease 651
 200 Gall bladder disease 653
 201 Pancreatic disease 656
 202 Malabsorption 660
 203 Inflammatory bowel disease 663
 204 Gastrointestinal tumours 667
 205 Functional gastrointestinal diseases 674
 206 Psychiatry in gastrointestinal medicine 676

PART 9 DISORDERS OF THE LIVER

- 207 Normal hepatic function 680
 208 Investigation in liver disease 686
 209 Acute liver failure 690
 210 Chronic liver failure 693
 211 Alcoholic liver disease 697
 212 Viral hepatitis 700
 213 Autoimmune hepatitis 709
 214 Genetic liver disease 713
 215 Drug-induced liver disease 718
 216 Miscellaneous liver diseases 721
 217 The liver in systemic disease 726
 218 Liver cancer 731

PART 10 NEUROLOGICAL DISORDERS

- 219 Normal neurological function 736
 220 Diagnosis in suspected neurological disease 739
 221 Investigation in neurological disease 742
 222 Demographics of neurological disease 752
 223 Neurogenetic disease 755
 224 Neurocutaneous syndromes 760
 225 Congenital neurological disorders 762
 226 Epilepsy 764
 227 Stroke 767
 228 Dementia 777
 229 Neurological infection 781
 230 Disorders of movement 787
 231 Multiple sclerosis 791
 232 Motor neuron disease 794
 233 Spinal cord disease 796
 234 Neuropathy 800
 235 Myopathy 804
 236 Vasculitis in neurology 807
 237 Neurological tumours 812
 238 Non-metastatic neurological manifestations of malignancy 815
 239 Neurosurgery 817
 240 Drug-induced neurological disease 821
 241 Functional and dissociative disorders in neurology 825
 242 Palliative care in neurological disease 828

PART 11 DISORDERS OF THE SKIN

- 243 Normal skin function 832
 244 Approach to diagnosing skin disease 836
 245 Investigation in skin disease 839
 246 Skin infection and infestation 842
 247 Cutaneous vasculitis 845
 248 Acne 847
 249 Psoriasis 850
 250 Eczema 853
 251 Urticaria 855
 252 Bullous disorders 857
 253 Hair disorders 860
 254 Nail disorders 863
 255 Mucosal disease 865
 256 Genital disease 868
 257 Polymorphic light eruption and actinic prurigo 870
 258 Disorders of pigmentation 872
 259 Skin cancer 874
 260 Skin markers of internal medicine 882
 261 Drug-induced skin disease 886
 262 Psychocutaneous medicine 889

PART 12 DISORDERS OF THE MUSCULOSKELETAL SYSTEM

- | | |
|--|---|
| 263 Normal function of the musculoskeletal system 892 | 269 Systemic lupus erythematosus 918 |
| 264 Diagnosis in suspected rheumatological disease 894 | 270 Crystal arthropathy 921 |
| 265 Investigation in rheumatological disease 900 | 271 Infection of joints and bones 925 |
| 266 Osteoarthritis 906 | 272 Vasculitis 927 |
| 267 Rheumatoid arthritis 910 | 273 Osteomalacia 932 |
| 268 Seronegative spondyloarthropathy 914 | 274 Paget's disease of bone 933 |

| 309 Sepsis 1068 | 318 Worm infection (including hydatid disease) 1098 |
| 310 Bacterial infection 1071 | 319 Prion disease 1101 |
| 311 Mycobacterial infection other than tuberculosis 1075 | 320 Sexually transmitted disease (gonorrhoea) 1103 |

PART 16 CANCERS

- 321 Cancers related to infection 1106
322 Principles of oncogenesis 1109
323 Presentations in suspected cancer 1111
324 Diagnosis and staging of cancer 1113
325 Treatment of cancer 1115
326 Prostate cancer 1118
327 Breast cancer 1122
328 Ovarian and testicular cancer 1126
329 Symptom control in cancer 1128
330 Dying from cancer 1131

PART 17 DIETARY, LIFESTYLE, AND ENVIRONMENTAL FACTORS AFFECTING HEALTH

- 331 Normal nutritional function 1134
332 Starvation and malnutrition 1136
333 Vitamin deficiencies 1139
334 Nutritional support in the critically ill 1144
335 Poor diets 1147
336 Obesity: epidemiology, prevention and management 1150
337 Physical activity and its role in disease prevention 1155
338 Smoking 1158
339 Alcohol 1160
340 Environmental radiation 1164
341 Air pollution 1166
342 Non-prescription drugs 1168

PART 18 PREVENTION OF DISEASE

- 343 Prevention of cardiovascular disease 1172
344 Prevention of respiratory disease 1176
345 Prevention of kidney disease 1179
346 Prevention of gastrointestinal disease 1181
347 Prevention of neurological disease 1183
348 Prevention of cerebrovascular disease 1187
349 Prevention of infection 1189
350 Prevention of cancer 1192

PART 19 SCREENING FOR DISEASE

- 351 Screening for cardiovascular disease 1196
352 Screening for respiratory disease 1202
353 Screening for kidney disease 1205
354 Screening for gastrointestinal disease 1206
355 Screening for neurological disease 1209
356 Screening for cancer 1211

Index 1215

Normal values

Common haematology values	
Haemoglobin	men: 130–180 g/l women: 115–160 g/l
Mean cell volume, MCV	76–96 fl
Platelets	150–400 × 10 ⁹ /l
White cells (total)	4–11 × 10 ⁹ /l
• neutrophils	40%–75%
• lymphocytes	20%–45%
• eosinophils	1%–6%
Blood gases	
pH	7.35–7.45
PaO ₂	>10.6 kPa (75–100 mm Hg)
PaCO ₂	4.7–6 kPa (35–45 mm Hg)
Base excess	±2 mmol/l
U&ES (urea and electrolytes)	
Sodium	135–145 mmol/l
Potassium	3.5–5 mmol/l
Creatinine	70–120 µmol/l
Urea	2.5–6.7 mmol/l
eGFR	>90
LFTs (liver function tests)	
Bilirubin	3–17 µmol/l
Alanine aminotransferase, ALT	5–35 IU/l
Aspartate transaminase, AST	5–35 IU/l
Alkaline phosphatase, ALP	30–150 IU/l (<i>non-pregnant adults</i>)
Albumin	35–50 g/l
Protein (total)	60–80 g/l
Cardiac enzymes	
Troponin T	<0.1 µg/l
Creatine kinase	25–195 IU/l
Lactate dehydrogenase, LDH	70–250 IU/l
Lipids and other biochemical values	
Cholesterol	<5 mmol/l <i>desired</i>
Triglycerides	0.5–1.9 mmol/l
Amylase	0–180 Somogyi U/dl
C-reactive protein, CRP	<10 mg/l
Calcium (total)	2.12–2.65 mmol/l
Glucose, fasting	3.5–5.5 mmol/l
Prostate-specific antigen, PSA	0–4 ng/ml
T4 (total thyroxine)	70–140 mmol/l
Thyroid-stimulating hormone, TSH	0.5–5.7 mU/l

Abbreviations: eGFR, estimated glomerular filtration rate; PaCO₂, partial pressure of carbon dioxide in arterial blood; PaO₂, partial pressure of oxygen in arterial blood. Reproduced from M Longmore and IB Wilkinson et al., *Oxford Handbook of Clinical Medicine, Ninth Edition*, 2014, with permission from Oxford University Press

Abbreviations

γGT	gamma-glutamyl transferase	ALL	acute lymphocytic leukaemia
5-ASA	5-aminosalicylic acid	ALP	alkaline phosphatase
6MP	6-mercaptopurine	ALS	amyotrophic lateral sclerosis
AA	AA protein-related renal amyloidosis	ALT	alanine aminotransferase
AAA	abdominal aortic aneurysm	AMA	anti-mitochondrial antibody
AAFB	acid- and alcohol-fast bacteria	AMD	age-related macular degeneration
AAV	antineutrophil cytoplasmic antibody-associated systemic vasculitis	AMI	acute myocardial infarction
Ab	antibody	AML	acute myeloid leukaemia
ABC	Airway, Breathing, and Circulation	AMP	adenosine monophosphate
ABCDE	Airway, Breathing, Circulation, Disability, and Exposure	ANA	antinuclear antibody
ABG	arterial blood gas	ANC	absolute neutrophil count
ABP	arterial blood pressure	ANCA	antineutrophil cytoplasmic antibody
ABPA	allergic bronchopulmonary aspergillosis	ANS	alcohol nurse specialist
ABPI	ankle-brachial pressure index	anti-dsDNA	anti-double-stranded DNA antibody
ABPM	ambulatory blood-pressure monitoring	anti-HBc	antibody to the hepatitis B core antigen
AC	air conduction	anti-HBe	antibody to the hepatitis B e antigen
ACD	anaemia of chronic disorders	anti-HBs	antibody to the hepatitis B surface antigen
ACE	angiotensin-converting enzyme	anti-LKM	anti-liver kidney microsomal type 1 antibody
ACE-I	angiotensin-converting-enzyme inhibitor	anti-LPA	anti-liver-pancreas antigen antibody
ACPA	anti-citrullinated protein/peptide antibody	anti-SLA	anti-soluble liver antigen antibody
ACR	albumin-creatinine ratio	anti-SMA	smooth muscle antibody
ACS	acute coronary syndrome	anti-TNF	anti-tumour necrosis factor
ACT	activated clotting time	ANZDATA	Australia and New Zealand Dialysis and Transplant Registry
ACTH	adrenocorticotrophic hormone	APACHE	Acute Physiology and Chronic Health Evaluation
AD	autosomal dominant	APC	activated protein C
ADA	adenosine deaminase	APKD	adult polycystic kidney disease
ADC	apparent diffusion coefficient	APS	antiphospholipid syndrome
ADH	antidiuretic hormone	APTT	activated partial thromboplastin time
ADP	adenosine diphosphate	APTT _r	activated partial thromboplastin time ratio
ADT	androgen deprivation therapy	AR	autosomal recessive
AEIPF	acute exacerbation of idiopathic pulmonary fibrosis	ARB	angiotensin II receptor blocker
AF	atrial fibrillation	ARDS	acute respiratory distress syndrome
AFB	acid-fast bacilli	ARF	acute renal failure
AH	atrium-His	ARPKD	autosomal recessive polycystic kidney disease
AHF	acute heart failure	ARR	aldosterone:renin activity ratio
AHI	apnoea hypopnoea index	ARSAC	Administration of Radioactive Substances Advisory Committee
AI	adrenal insufficiency	ART	antiretroviral therapy
AIDS	acquired immune deficiency syndrome	ARVC	arrhythmogenic right ventricular cardiomyopathy
AIH	autoimmune hepatitis	ARVC/D	arrhythmogenic right ventricular cardiomyopathy/dysplasia
AIN	anal intra-epithelial neoplasia	AS	ankylosing spondylitis
AION	anterior ischaemic optic neuropathy	ASAS	Assessment of SpondyloArthritis International Society
AIP	autoimmune pancreatitis	ASD	atrial septal defect
AIVR	accelerated idioventricular rhythm	AST	aspartate aminotransferase
AJCC	American Joint Committee on Cancer	AT	antithrombin
AKI	acute kidney injury	ATG	antithymocyte globulin
AL	amyloid light chain	ATL	adult T-cell leukaemia
ALA	amoebic liver abscess	ATN	acute tubulointerstitial nephritis
ALD	alcoholic liver disease	ATP	adenosine triphosphate
ALERT	Acute Life-threatening Events Recognition and Treatment	AUDIT	Alcohol Use Disorders Identification Test
ALF	acute liver failure		

AV	atrioventricular	CCF	congestive cardiac failure
aVF	augmented voltage unipolar left foot lead	CCP	cyclic citrullinated peptide
AVIR	accelerated idioventricular rhythm	CCS	Canadian Cardiovascular Society
aVL	augmented voltage unipolar left arm lead	CD	Crohn's disease
AVN	atrioventricular node	CDC	Centers for Disease Control
AVNRT	atrioventricular nodal re-entrant tachycardia	CDI	cranial diabetes insipidus
AVP	arginine vasopressin	CF	counting fingers
AVPU	Alert, Voice, Pain, or Unresponsive	CGD	chronic granulomatous disease
AVRT	atrioventricular re-entrant tachycardia	CHD	coronary heart disease
AVSD	atrioventricular septal defect	CHF	congestive heart failure
AZA	azathioprine	CI	confidence interval
BAE	bronchial artery angiography and embolization	CIDP	chronic inflammatory demyelinating polyradiculoneuropathy
BAL	bronchoalveolar lavage		chronic idiopathic pseudo-obstruction
BC	bone conduction	CIPO	carcinoma in situ
BCC	basal cell carcinoma	CIS	Creutzfeldt–Jakob disease
BCLC	Barcelona Clinic Liver Cancer	CJD	creatin kinase
BCNIE	blood culture-negative infective endocarditis	CK	chronic kidney disease
BCP	basic calcium phosphates	CKD	chronic lymphoid leukaemia
BCR	B-cell receptor	CLL	compound muscle action potential
BCT	broad-complex tachycardia	CMAP	carpometacarpal
BD	brain death	CMC	chronic myeloid leukaemia
BDD	body dysmorphic disorder	CML	cardiac magnetic resonance imaging
BI	bacterial index	CMRI	Charcot–Marie–Tooth disease
BIMA	bilateral internal mammary artery	CMT	cytomegalovirus
BIPAP	bi-level positive airway pressure	CMV	central nervous system
BIPSS	bilateral inferior petrosal sinus sampling	CNS	combined oral contraceptive pill
BMD	bone mineral density	COCP	cryptogenic organizing pneumonia
BMI	body mass index	COP	chronic obstructive pulmonary disease
BMRC	British Medical Research Council	COPD	continuous positive airways pressure
BMT	bone marrow transplantation	CPAP	cardiopulmonary bypass
BNP	brain natriuretic peptide	CPB	cardiopulmonary exercise testing
BO	Barrett's oesophagus	CPEX	combined physical and psychological programme
BP	blood pressure	CPP	calcium pyrophosphate dihydrate deposition
BPH	benign prostatic hypertrophy	CPPD	cryptococcal antigen
bpm	beats per minute	CrAG	central retinal artery occlusion
BPPV	benign paroxysmal positional vertigo	CRAO	clinical risk factor for parental hip fracture
BRAO	branch retinal artery occlusion	CRF	corticotrophin-releasing hormone
BRF	bone risk factor	CRH	C-reactive protein
BrS	Brugada syndrome	CRP	cardiac resynchronization therapy
BRVO	branch retinal vein occlusion	CRT	central retinal vein occlusion
BSA	body surface area	CRVO	corticosteroid
BSD	brainstem death	CS	cerebrospinal fluid
BSE	bovine spongiform encephalopathy	CSF	carotid sinus hypersensitivity
BSG	British Society of Gastroenterology	CSH	carotid sinus massage
BTS	British Thoracic Society	CSM	computed tomography
CABG	coronary artery bypass graft surgery	CT	computed tomography angiography
CAD	coronary artery disease	CTA	connective tissues disease
CADASIL	cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy	CTD	chronic thromboembolic pulmonary hypertension
CAH	congenital adrenal hyperplasia	CTEPH	computed tomography pulmonary angiography
CAM	Confusion Assessment Method	CTPA	cerebral vascular accident
cANCA	cytoplasmic antineutrophil cytoplasmic antibody	CVA	cardiovascular disease
CAP	community-acquired pneumonia	CVD	common variable immunodeficiency
CaSR	calcium-sensing receptor	CVID	central venous pressure
CBCD	chronic bullous disease of childhood	CVP	catecholaminergic polymorphic ventricular tachycardia
CBD	common bile duct	CVPT	cotton-wool spot
CBG	cortisol-binding globulin	CWS	chest X-ray
CBT	cognitive behavioural therapy	CXR	cyclophosphamide
CBZ	carbamazole	CYC	dermatitis artefacta
CCB	calcium-channel blocker	DA	

DADS	distal acquired demyelinating symmetrical	ET	essential tremor
DAH	diffuse alveolar haemorrhage	EUA	examination under anaesthesia
DAS	Disease Activity Score	EUS	endoscopic ultrasound
DAT	drug action team	FAP	familial amyloid polyneuropathy
DBS	deep brain stimulation	FAST	Face Arm Speech Test
DCM	dilated cardiomyopathy	FBC	full blood count
DEXA	dual-energy X-ray absorptiometry	FDA	Food and Drug Administration
DF	Maddrey discriminant function	FDG	fluorodeoxyglucose
DHEA	dehydroepiandrosterone	FDP	fibrinogen degradation products
DHEAS	dehydroepiandrosterone sulphate	FEV ₁	forced expiratory volume in 1 second
DI	diabetes incipidus	FFA	free fatty acid
DIC	disseminated intravascular coagulopathy	FFR	fractional flow reserve
DILD	drug-induced lung disease	FFS	five-factor score
DILS	diffuse infiltrative lymphocytosis syndrome	FHH	familial hypocalcaemic hypercalcaemia
DIP	distal interphalangeal	FI	faecal incontinence
DIS	dissemination in space	FiO ₂	inspired fraction of oxygen
DIT	dissemination in time;	FISH	fluorescent in situ hybridization
DLCO	diffusing capacity of the lung for carbon monoxide	FLAIR	fluid attenuated inversion recovery
DLE	discoid lupus erythematosus	FLI	fatty liver index
DM	diabetes mellitus	FNAC	fine-needle aspiration cytology
DMARD	disease-modifying anti-rheumatic drug	FOB	faecal occult blood
DOT	directly observed therapy	FSGS	focal segmental glomerulosclerosis
DPP-4	dipeptidyl peptidase-4	FSH	follicle-stimulating hormone
DRE	digital rectal examination	FTD	frontotemporal dementia
dsDNA	double-stranded DNA	FUO	fever of unknown origin
DSE	dobutamine stress echocardiography	FVC	forced vital capacity
DST	dexamethasone suppression test	FVL	factor V Leiden
DU	duodenal ulcer	FXTAS	fragile X-associated tremor/ataxia syndrome
DVLA	Driver and Vehicle Licensing Agency	G1	Genotype 1
DVP	diastolic blood pressure	G2	Genotype 2
DVT	deep-vein thrombosis	G3	Genotype 3
DWI	diffusion-weighted imaging	G6PD	glucose-6-phosphate dehydrogenase
EBUS-TBNA	endobronchial ultrasound-guided transbronchial needle aspiration	GA	general anaesthesia
EBV	Epstein–Barr virus	GABA	gamma-aminobutyric acid
ECG	electrocardiogram	GAD	glutamic acid decarboxylase
Echo	echocardiography	GAD65	glutamic acid decarboxylase autoantibody
ECOG	Eastern Cooperative Oncology Group	GALT	gut-associated lymphoid tissue
EDTA	ethylenediamine tetra-acetic acid	GAS	Group A streptococcus
EEG	electroencephalogram	GBM	glomerular basement membrane
EGDT	early goal-directed therapy	GBS	Guillain–Barré syndrome
eGFR	estimated glomerular function rate	GCA	giant cell arteritis
EHEC	enterohaemorrhagic <i>Escherichia coli</i>	GCS	Glasgow Coma Scale
EIA	enzyme immunoassay	GFR	glomerular filtration rate
ELISA	enzyme-linked immunosorbent assay	GGO	ground-glass opacity
EMG	electromyography	GH	growth hormone
ENA	extractable nuclear antigen antibody	GI	gastrointestinal
ENT	ear, nose, and throat	GIST	gastrointestinal stromal tumour
EOTR	end-of-treatment response	GMC	General Medical Council
EPAP	expiratory positive airway pressure	GN	glomerulonephritis
EPO	erythropoietin	GnRH	gonadotropin-releasing hormone
EPP	erythropoietic protoporphyria	GOLD	Global Initiative for Chronic Obstructive Lung Disease
ePPi	extracellular pyrophosphate	GORD	gastro-oesophageal reflux disease
EPR	electronic patient record	GOS	Glasgow Outcome Score
EPS	electrophysiological study	GP	general practitioner
ERCP	endoscopic retrograde cholangiopancreatography	GPA	granulomatosis with polyangiitis
EROA	effective regurgitant orifice area	GPI	glycosyl-phosphatidylinositol
ESC	European Society of Cardiology	GRA	glucocorticoid-responsive aldosteronism
ESR	erythrocyte sedimentation rate	GU	gastric ulcer
ESRD	end-stage renal disease	GUM	genito-urinary medicine

GvHD	graft-vs-host disease	IBD	inflammatory bowel disease
HAART	highly active antiretroviral therapy	IBS	irritable bowel syndrome
HAP	hospital-acquired pneumonia	IC	intermittent claudication
HAS	human albumin solution	ICA	islet cell autoantibody
HAV	hepatitis A virus	I_{CaL}	L-type calcium current
Hb A	adult haemoglobin	ICD	implantable cardioverter defibrillator
Hb A1c	haemoglobin A1c (glycosylated haemoglobin)	ICH	intracranial haemorrhage
Hb F	fetal haemoglobin	ICP	intracranial pressure
Hb	haemoglobin	ICU	intensive care unit
HBc	hepatitis B core protein	ID	infectious disease
HBeAg	hepatitis B e antigen	IDL	intermediate-density lipoprotein
HBPM	home blood-pressure monitoring	IDU	intravenous drug users
HBsAg	hepatitis B surface antigen	IE	infective endocarditis
HBV	hepatitis B virus	IFD	invasive fungal disease
HCC	hepatocellular carcinoma	IFN	interferon
HCM	hypertrophic cardiomyopathy	IFN-alpha	interferon alpha
HCV	hepatitis C virus	IgA	immunoglobulin A
HD	Huntington's disease	IgE	immunoglobulin E
HDL	high-density lipoprotein	IgG	immunoglobulin G
HDU	high-dependency units	IgM	immunoglobulin M
HDV	hepatitis D virus	IGRA	interferon gamma release assays
HER2	human epidermal growth factor receptor 2	IHD	ischaemic heart disease
HEV	hepatitis E virus	I_{K1}	inward rectifier potassium current
HF	heart failure	I_{Kr}	rapidly activating component of the delayed rectifier potassium current
HFmrEF	heart failure with mid-range ejection fraction	I_{Ks}	slowly activating component of the delayed rectifier potassium channel
HFpEF	heart failure with preserved ejection fraction	IL	interleukin
HFrEF	heart failure with reduced ejection fraction	IL-6	interleukin 6
HHT	hereditary haemorrhagic telangiectasia	ILD	interstitial lung disease
HHV6	human herpes virus 6	IM	intramuscular
HHV7	human herpes virus 7	IMD	inherited metabolic disease
HHV8	human herpes virus 8	IMiG	intramuscular immunoglobulin
HIFU	high-intensity focused ultrasound	IMPACT	Ill Medical Patients' Acute Care and Treatment
HIGM	hyperimmunoglobulin M	I_{Na}	sodium current
HIT	heparin-induced thrombocytopenia	$I_{Na,K}$	sodium-potassium pump current
HIV	human immunodeficiency virus	I_{NCX}	sodium-calcium exchanger current
HLA	human leukocyte antigen	INR	international normalized ratio
HM	hand movements	IPAP	inspiratory positive airway pressure
HMW	high molecular weight	IPD	idiopathic Parkinson's disease
HNPCC	hereditary non-polyposis colorectal cancer	IPF	idiopathic pulmonary fibrosis
HNPP	hereditary neuropathy with liability to pressure palsies	IPG	implantable pulse generator
HPA	hypothalamic-pituitary-adrenal	IPI	International Prognostic Index
HPIV	human parainfluenza virus	IPJ	interphalangeal joint
HPV	human papilloma virus	IRIS	immune reconstitution inflammatory syndrome
HRA	Human Rights Act 1998	IRRT	intermittent renal replacement therapy
HRCT	high-resolution computed tomography	IRT	immunoreactive trypsinogen
HRS	hepatorenal syndrome	ISS	International Staging System
HS	hereditary spherocytosis	IST	inappropriate sinus tachycardia
HSCT	haemopoietic stem cell transplantation	ITP	immune thrombocytopenia
HSP	Henoch-Schönlein purpura	ITT	insulin tolerance test
HSV	herpes simplex virus	ITU	intensive therapy unit
HTLV1	human T-lymphotrophic virus 1	IUD	intrauterine device
HUS	haemolytic-uraemic syndrome	IV	intravenous
HUV	hypocomplementaemic urticarial vasculitis	IVC	inferior vena cava
HV	His-ventricle	IVDU	intravenous drug use
IA2	islet antigen 2 autoantibody	IVF	in vitro fertilization
IAA	insulin autoantibody	IVIg	intravenous immunoglobulin
IABP	intra-aortic balloon pump	IVUS	intravascular ultrasound
IAH	intra-abdominal hypertension	JVP	jugular venous pulse
IAP	intra-abdominal pressure		
IBA	identification and brief advice		

KCO	carbon monoxide transfer coefficient	MDS	myelodysplasia
KDIGO	Kidney Disease: Improving Global Outcomes	MDT	multidisciplinary team
KEEP	Kidney Early Evaluation Program	MELAS	mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes
KS	Kaposi's sarcoma	MELD	Model for End-Stage Liver Disease
KSHV	Kaposi's sarcoma-associated herpesvirus	MEN	multiple endocrine neoplasia
LACS	lacunar stroke	MERRF	myoclonic epilepsy with ragged red fibres
LAD	left anterior descending	MG	myasthenia gravis
LAE	left atrial enlargement	MGUS	monoclonal gammopathy of unknown significance
LAVAT	local anaesthetic video-assisted thoracoscopy	MHC	major histocompatibility complex
LBBB	left bundle branch block	MHRA	Medicines and Healthcare Products Regulatory Agency
LBC	liquid-based cytology	MI	myocardial infarction
LBD	Lewy body dementia	MIC	minimum inhibitory concentration
LBP	low back pain	MM	malignant melanoma
LCIS	lobular carcinoma in situ	MMA	methylmalonic acidaemia
LCSD	left cervicothoracic sympathetic denervation	MMR	measles, mumps, rubella
LCX	left circumflex artery	MMSE	Mini-Mental State Examination
LDCT	low-dose computed tomography	MND	motor neuron disease
LDH	lactate dehydrogenase	MOAI	monoamine oxidase inhibitor
LDL	low-density lipoprotein	MODY	maturity-onset diabetes of the young
LEMS	Lambert–Eaton myasthenia syndrome	MOF	multi-organ failure
LET	linear-energy transfer	MPO	myeloperoxidase
LFT	liver function test	MPS	myocardial perfusion scan
LH	luteinizing hormone	MR	mitral regurgitation
LIMA	left internal mammary artery	MRA	magnetic resonance angiography
LMN	lower motor neuron	MRA	magnetic resonance angiography
LMWH	low-molecular-weight heparin	MRC	Medical Research Council
LN	lymph node	MRC	magnetic resonance cholangiopancreatography
LOS	lower oesophageal sphincter	MRI	magnetic resonance imaging
LP	lumbar puncture	MRSA	meticillin-resistant <i>Staphylococcus aureus</i>
LPA	Lasting Power of Attorney	MRV	magnetic resonance venography
LPP	lichen planopilaris	MS	multiple sclerosis
LQTS	long-QT syndrome	MSE	mental state examination
LR	likelihood ratio	MSF	Mediterranean spotted fever
LSMDT	local skin cancer multidisciplinary team	MSM	men who have sex with men
LT	leukotriene	MSU	monosodium urate
LTBI	latent infection with <i>Mycobacterium tuberculosis</i>	MSUD	maple syrup urine disease
LTNP	long-term non-progressor	MTP	metatarsophalangeal
LV	left ventricular	MTX	methotrexate
LVAD	left ventricular assist device	MUP	minimum unit price
LVEF	left ventricular ejection fraction	MuSK	muscle-specific kinase
LVESD	left ventricular end-systolic diameter	MUST	Malnutrition Universal Screening Tool
LVH	left ventricular hypertrophy	NAAT	nucleic acid amplification test
LVNC	left ventricular non-compaction	NAC	N-acetylcysteine
LVOT	left ventricular outflow tract	NAD	nicotinamide adenine dinucleotide
LVRS	lung volume reduction surgery	NADPH	nicotinamide adenine dinucleotide phosphate
MAC	<i>Mycobacterium avium</i> complex	NAFLD	non-alcoholic fatty liver disease
MALT	mucosa-associated lymphoid tissue	NAPQI	N-acetyl-p-benzoquinone imine
MAP	mean arterial pressure	NASH	non-alcoholic steatohepatitis
MAT	multifocal atrial tachycardia	NCRN	National Cancer Research Network
MBL	mannan-binding-lectin	NCS	nerve conduction study
MCA	middle cerebral artery	NEWS	National Early Warning Score
MCandS	microscopy, culture, and sensitivities	NFD	nephrogenic fibrosing dermopathy
MCBT	mindfulness-based cognitive therapy	NGT	nasogastric tube
MCH	mean cell haemoglobin	NHL	non-Hodgkin's lymphoma
MCHC	mean cell haemoglobin concentration	NICE	National Institute for Health and Care Excellence
MCI	mild cognitive impairment	NIHL	noise-induced hearing loss
MCP	metacarpophalangeal	NIHSS	National Institutes of Health Stroke Scale
MCV	mean corpuscular volume	NIPPV	nasal intermittent positive pressure ventilation
MDM	multidisciplinary meeting		
MDR	multidrug-resistant		

NIV	non-invasive ventilation	PET	positron emission tomography
NK	natural killer	PEX	plasma exchange
NMO	neuromyelitis optica	PFT	pulmonary function testing
NMS	neuroleptic malignant syndrome	PG	prostaglandin
NP	nosocomial pneumonia	PH	pulmonary hypertension
NPL	no perception of light	PHT	pressure half-time
NRH	nodular regenerative hyperplasia	PI	pancreatic insufficiency
NRT	nicotine replacement therapy	PIP	proximal interphalangeal
NS	nephrotic syndrome	PISA	proximal isovelocity surface area
NSAID	non-steroidal anti-inflammatory drug	PJP	<i>Pneumocystis jiroveci</i> pneumonia
NSCLC	non-small cell lung carcinoma	PJRT	persistent junctional reciprocating tachycardia
NSLBP	non-specific low back pain	PK	pyruvate kinase
NSTEMI	non-ST-elevation myocardial infarction	PKU	phenylketonuria
NSVT	non-sustained ventricular tachycardia	PL	perception of light
NTA	National Treatment Authority	PLAX	parasternal long-axis view
NTG	glyceryl trinitrate (nitroglycerin)	PLE	polymorphic light eruption
NTM	non-tuberculous mycobacteria	PLMS	periodic leg movements during sleep
NT-pro-BNP	N-terminal brain natriuretic peptide	PLS	primary lateral sclerosis
NYHA	New York Heart Association	PML	progressive multifocal leucoencephalopathy
OA	osteoarthritis	PML	progressive multifocal leucoencephalopathy
OAC	oral anticoagulation	PMN	polymorphonuclear
OCP	oral contraceptive pill	PMT	pacemaker-mediated tachycardia
OCSF	Oxfordshire Community Stroke Project	PNH	paroxysmal nocturnal haemoglobinuria
ODI	oxygen desaturation index	PNS	peripheral nervous system
OGD	oesophagogastroduodenoscopy	POF	premature ovarian failure
OHS	obesity hypoventilation syndrome	POI	premature ovarian insufficiency
OLM	ocular larva migrans	POTS	postural tachycardia syndrome
ONJ	osteonecrosis of the jaw	PPH	primary pulmonary hypertension
OPSI	overwhelming post-splenectomy infection	PPI	proton-pump inhibitor
OSA	obstructive sleep apnoea	PPM	permanent pacemaker
PABA	para-aminobenzoic acid	PPMS	primary progressive multiple sclerosis
PACNS	primary angitis of the central nervous system	PPV	polysaccharide pneumococcal vaccine
PaCO ₂	partial pressure of carbon dioxide in arterial blood	pred.	predicted
PAH	pulmonary arterial hypertension	PRES	posterior reversible encephalopathy syndrome
PAI	primary adrenal insufficiency	PRR	pattern recognition receptors
PAMP	pathogen-associated molecular patterns	PS	performance status
pANCA	perinuclear antineutrophil cytoplasmic antibody	PSA	prostate-specific antigen
PAO ₂	partial pressure of alveolar oxygen	PsA	psoriatic arthritis
PaO ₂	partial pressure of oxygen in arterial blood	PSAX	parasternal short-axis view
PAT	Paddington Alcohol Test	PSC	primary sclerosing cholangitis
PBC	primary biliary cholangitis	PSP	primary spontaneous pneumothorax
PC ₂₀	the provocative concentration required to cause a 20% fall in the forced expiratory volume in 1 second	PT	prothrombin time
PCI	percutaneous coronary intervention	PTA	pure tone audiogram
PCO ₂	partial pressure of carbon dioxide	PTCA	percutaneous transluminal coronary angioplasty
PCOS	polycystic ovary syndrome	PTH	parathyroid hormone
PCP	pneumocystis pneumonia	PTU	propylthiouracil
PCR	polymerase chain reaction	PUD	peptic ulcer disease
PCT	porphyria cutanea tarda	PUJ	pelvic–ureteric junction
PCV	pneumococcal conjugate vaccine	PUO	pyrexia of unknown origin
PD	Parkinson's disease	PUVA	psoralen plus ultraviolet light A
PDA	patent ductus arteriosus	PVC	premature ventricular complex
PE	pulmonary embolus	PVE	prosthetic valve endocarditis
PEA	pulseless electrical activity	PVL	Panton–Valentine leukocidin
PEEP	positive end-expiratory pressure	PVT	portal vein thrombosis
PEFR	peak expiratory flow rate	RA	rheumatoid arthritis
PEG	percutaneous endoscopic gastrostomy	RAPD	relative afferent pupillary defect
PEG-IFN α	pegylated interferon alpha	RAS	reticular activating system
PEI	percutaneous ethanol injection	RAST	radioallergosorbent testing
PEM	protein-energy malnutrition	RBBB	right bundle branch block
		RBC	red blood cell

RBV	ribavirin	SPECT	single-photon emission computed tomography
RCC	red-cell count	SQTS	short-QT syndrome
RCM	restrictive cardiomyopathy	SRH	stigmata of recent haemorrhage
RCT	randomized control trial	SSP	secondary spontaneous pneumothorax
RDT	rapid diagnostic test	SSRI	selective serotonin reuptake inhibitor
REM	rapid-eye-movement	ssRNA	single-stranded RNA
RF	rheumatoid factor	SSSS	staphylococcal scalded skin syndrome
RFA	radiofrequency ablation	STD	sexually transmitted disease
RIP	Riyadh Intensive Care Programme	STEMI	ST-elevation myocardial infarction
RIPA	ristocetin-induced platelet aggregation	STI	sexually transmitted infection
RNP	ribonucleoprotein	STIR	short T1 inversion recovery
RNS	repetitive nerve stimulation	SUA	serum uric acid
ROSIER	Recognition of Stroke In the Emergency Room	SUDEP	sudden unexpected death in epilepsy
RPGN	rapidly progressive glomerulonephritis	SUNCT	short-lasting neuralgiform headache with conjunctival injection and tearing
RR	relative risk	SV40	simian virus 40
RRT	renal replacement therapy	SVC	superior vena cava
RS	reactive site	SVR	sustained virologic response
RSV	respiratory syncytial virus	SVT	supraventricular tachycardia
RTA	road traffic accident	SWEDD	subjects without evidence of dopaminergic deficits
RUQ	right upper quadrant	T3	triiodothyronine
RV	right ventricular	T4	thyroxine
RVAD	right ventricular assist device	TAA	thoracic aortic aneurysm
RVOT	right ventricular outflow tract	TACE	trans-arterial chemo-embolization
RVOTO	right ventricular outflow tract obstruction	TB	tuberculosis
SAA	serum amyloid A protein	TBG	thyroxine-binding globulin
SAAG	serum-ascites albumin gradient	TBNA	transbronchial needle aspiration
SAB	<i>Staphylococcus aureus</i> bacteraemia	TCA	tricyclic antidepressant
SAECG	signal-averaged electrocardiogram	TCR	T-cell receptor
SAH	subarachnoid haemorrhage	TdP	torsades de pointes
SAI	secondary adrenal insufficiency	TE	thromboembolism
SALT	speech and language therapists	TFPI	tissue factor pathway inhibitor
SaO ₂	arterial oxygen saturation	TFT	thyroid function test
SAPS	Simplified Acute Physiology Score	TGA	transposition of the great arteries
SARS	severe acute respiratory syndrome	Th	T helper
SBP	systolic blood pressure	Th2	T-helper type 2
SCA	sudden cardiac arrest	TIA	transient ischaemic attack
SCC	squamous cell carcinoma	TIN	tubulointerstitial nephritis
SCD	sudden cardiac death	TINU	tubulointerstitial disease with uveitis
SCID	severe combined immune deficiency	TIPS	transjugular intra-hepatic portosystemic shunt
SCLC	small cell lung carcinoma	TK	tyrosine kinase
SCLE	subacute cutaneous lupus erythematosus	TKI	tyrosine kinase inhibitor
ScvO ₂	central venous oxygen saturation	TLC	total lung capacity
SD	standard deviation	TLCO	transfer factor for carbon monoxide
SF	synovial fluid	TLoC	transient loss of consciousness
SHBG	sex hormone-binding globulin	TLR	Toll-like receptor
SIADH	syndrome of inappropriate antidiuretic hormone excretion	TLS	tumour lysis syndrome
SIRS	systemic inflammatory response syndrome	TM	tympanic membrane
SIV	simian immunodeficiency virus	TNF α	tumour necrosis factor alpha
SLE	systemic lupus erythematosus	TNM	tumour, node, and metastases
SLNB	sentinel lymph node biopsy	TOE	transoesophageal echocardiography
SMA	smooth muscle antibody	TPMT	thiopurine methyltransferase
SMART	Specific, Measurable, Achievable, Realistic, and Timed	TPO	thyroid peroxidase
SMR	standard mortality ratio	TPR	total peripheral resistance
SNHL	sensorineural hearing loss	TRH	thyrotropin-releasing hormone
SNRT	sinus node re-entrant tachycardia	TRUS	trans-rectal ultrasound
SOD	sphincter of Oddi dysfunction	TSE	transmissible spongiform encephalopathy
SOFA	Sequential Organ Failure Assessment	TSH	thyroid-stimulating hormone
SOV	single-organ vasculitis	TT	thrombin time
		TTE	transthoracic echocardiography

TTP	thrombotic thrombocytopenic purpura	VC	vital capacity
TURBT	trans-urethral resection of bladder tumour	VCD	vocal cord dysfunction
TURP	trans-urethral resection of the prostate	VCLAD	very long-chain acyl-coenzyme A dehydrogenase deficiency
TWI	T-wave inversion	VDRL	Venereal Disease Research Laboratory
UA	undifferentiated arthritis	VEGF	vascular endothelial growth factor
U&E	urea and electrolytes	VF	ventricular fibrillation
UC	ulcerative colitis	VGCC	voltage-gated calcium channel
UCD	urea cycle disorder	VGKC	voltage-gated potassium channel complex
UDCA	ursodeoxycholic acid	VKA	vitamin K antagonist
UGIH	upper gastrointestinal haemorrhage	VLDL	very-low-density lipoprotein
UKPDS	UK Prospective Diabetes Study	VLM	visceral larva migrans
UKRR	UK Research Reserve	VOC	volatile organic compound
ULN	upper limit of normal	VPC	premature ventricular complex
ULT	urate-lowering therapy	VQ	ventilation–perfusion
UMN	upper motor neuron	VSD	ventricular septal defect
UNSCEAR	United Nations Scientific Committee on the Effects of Atomic Radiation	VT	ventricular tachycardia
URTI	upper respiratory tract infection	VTE	venous thromboembolism
USRDS	United States Renal Data System	VUJ	vesicoureteric junction
USS	ultrasound scan	VZV	varicella zoster virus
UTI	urinary tract infection	WBC	white blood cell
UUN	urinary urea nitrogen	WCC	white-cell count
UV	ultraviolet	WG	Wegener's granulomatosis (granulomatosis with polyangiitis)
UVA	ultraviolet light A	WG–MPA	Wegener's granulomatosis–microscopic polyangiitis
UVB	ultraviolet light B	WHO	World Health Organization
V _A	effective alveolar volume	WPW	Wolff–Parkinson–White syndrome
VaD	vascular dementia	XO	xanthine oxidase
VAD	ventricular assist devices	XP	xeroderma pigmentosum
VAP	ventilator-associated pneumonia		
VATS	video-assisted thoracoscopic surgery		

Contributors

Richard Abbott

Consultant Neurologist, Leicester Royal Infirmary, Leicester, UK

Yasir Abu-Omar

Consultant Cardiothoracic and Transplant Surgeon, Papworth Hospital, Papworth Everard, UK

Bhavyang Acharya

Consultant in Palliative Medicine, Cynthia Spencer Hospice, Northamptonshire Healthcare NHS Foundation Trust, Northampton, UK

David Adlam

Senior Lecturer in Acute and Interventional Cardiology and Honorary Consultant Cardiologist, University of Leicester, Leicester, UK

Joshua Agbetile

Consultant Respiratory Physician, Homerton University Hospital, London, UK

Daniel Ajzensztejn

Consultant Clinical Oncologist, Oxford University Hospitals NHS Foundation Trust, Oxford, UK

Raza Alikhan

Consultant Haematologist, University Hospital of Wales, Cardiff, UK

Rob Andrews

Associate Professor of Diabetes University of Exeter, Exeter, UK

Tim Anstiss

Member, British Psychological Society, and Fellow, Royal Society of Arts

Charles M. G. Archer

Specialist Registrar in Dermatology, Churchill Hospital Oxford, UK

Clive B. Archer

Consultant Dermatologist, Guy's and St Thomas' NHS Foundation Trust, London, UK

Richard Armstrong

Consultant Neurologist, Royal Berkshire NHS Foundation Trust, Reading, UK, and Oxford University Hospitals NHS Foundation Trust, Oxford, UK

Kaleab Asress

St Thomas' Hospital, London, King's College London; Royal North Shore Hospital, University of Sydney, Australia

Stephen Aston

National Institute for Health Research Academic Clinical Lecturer in Infectious Diseases, University of Liverpool, Liverpool, UK

Mona Bafadhel

Consultant Respiratory Physician, Oxford University Hospitals NHS Foundation Trust, and Senior Clinical Researcher, University of Oxford, Oxford, UK

Fahd Baig

Clinical Research Fellow, University of Oxford, Oxford, UK

Peter G. Bain

Reader and Honorary Consultant in Clinical Neurology, Charing Cross Hospital, London, UK

Amitava Banerjee

Senior Clinical Lecturer in Clinical Data Science and Honorary Consultant Cardiologist, University College London, London, UK

Phil Barber

Consultant Respiratory Physician, University Hospital of South Manchester, Manchester, UK

Simon Barry

Consultant in Respiratory Medicine, University Hospital Llandough, Penarth, UK

Dirk Bäumer

Consultant Neurologist, Peterborough and Stamford Hospitals NHS Foundation Trust, Peterborough, UK

Mike Beadsworth

Consultant in Infectious Diseases and General Medicine, Royal Liverpool University Hospital, Liverpool, UK

Nick Beeching

Senior Lecturer and Honorary Consultant in Infectious Diseases, Liverpool School of Tropical Medicine and Royal Liverpool University Hospital, Liverpool, UK

Tony Bentley

Consultant Microbiologist, Northampton General Hospital NHS Trust, Northampton, UK

Anthony Bewley

Consultant Dermatologist, Barts Health NHS Trust, London, UK, and Honorary Senior Lecturer, University of London, London, UK

Kailash P. Bhatia

Professor of Clinical Neurology, University College London, London, UK, and Honorary Consultant Neurologist, National Hospital for Neurology and Neurosurgery, London, UK

Malini Bhole

Consultant Immunologist, The Dudley Group NHS Foundation Trust, Dudley, UK

Benjamin Bloch

Consultant Orthopaedic Surgeon, Nottingham University Hospitals NHS Trust, Nottingham, UK

James Bonnington

Consultant Intensivist, Nottingham University Hospital NHS Trust, Nottingham, UK

Ian Bowler

Consultant and Deputy Clinical Lead in Microbiology, John Radcliffe Hospital, Oxford, UK

Marilyn Bradley

Consultant Physician in Genitourinary Medicine, Royal Liverpool and Broadgreen University Hospitals NHS Trust, Liverpool, UK

Rowland J. Bright-Thomas

Consultant Respiratory Physician, University Hospital of South Manchester, Manchester, UK

Elaine Buchanan

Consultant Physiotherapist, Oxford University Hospitals NHS Foundation Trust, Oxford, UK

Chris Bunch

Consultant Physician and Clinical Haematologist, John Radcliffe Hospital, Oxford, UK

Sarah Cader

Consultant Neurologist, Basingstoke and North Hampshire Hospital, Basingstoke, UK

Caroline Cardy

Consultant Rheumatologist, Worcestershire Royal Hospital, Worcester, UK

Alan Carson

Consultant Neuropsychiatrist, NHS Lothian, Edinburgh, UK, and Reader, University of Edinburgh, Edinburgh, UK

Matteo Cella

Lecturer in Clinical Psychology, King's College London, London, UK

Aron Chakera

Consultant Nephrologist, Sir Charles Gairdner Hospital, Perth, Australia

Trudie Chalder

Professor of Cognitive Behavioural Psychotherapy, King's College London, London, UK

John Chambers

Professor of Clinical Cardiology and Consultant Cardiologist, Guy's and St Thomas' NHS Foundation Trust, London UK

Hannah Chapman

Specialist Registrar in Clinical Oncology, Mount Vernon Cancer Centre, Northwood, UK

Mas Chaponda

Consultant in Infectious Diseases and General Medicine, Royal Liverpool University Hospital, Liverpool, UK

Mimi Chen

Consultant Endocrinologist, St. George's University Hospitals Foundation NHS Trust, London, UK

Nigel Clayton

Senior Chief Clinical Physiologist, Wythenshawe Hospital, Manchester, UK

Sian Coggle

Consultant in Infectious Diseases and Acute Internal Medicine, Cambridge University Hospitals NHS Foundation Trust, Cambridge, UK

Graham Collins

Clinician Scientist, Imperial College, London, UK

Cris S. Constantinescu

Professor of Neurology and Consultant Neurologist, Nottingham University Hospital NHS Trust, Nottingham, UK

Graham Cooke

Reader Infectious Diseases, Imperial College, London, UK

Susan Cooper

Consultant Dermatologist and Honorary Senior Clinical Lecturer, Oxford University Hospitals NHS Foundation Trust, Oxford, UK

Lucy Cottle

Consultant Physician in Infectious Diseases, Leeds Teaching Hospitals NHS Trust, Leeds, UK

Anthony Cox

Senior Lecturer in Clinical Pharmacy and Drug Safety, University of Birmingham, Birmingham, UK

Sonya Craig

Consultant Respiratory and Sleep Physician, Aintree University Hospital, Liverpool, UK

Anjali Crawshaw

Consultant Respiratory Physician, Queen Elizabeth Hospital, University Hospitals Birmingham NHS Foundation Trust, Birmingham, UK

Paul Cullinan

Professor of Occupational and Environmental Respiratory Disease, National Heart and Lung Institute, Imperial College, London, UK

Nicola Curry

Consultant Haematologist, Churchill Hospital, Oxford, UK

David Cutter

Consultant Clinical Oncologist, Oxford University Hospitals NHS Foundation Trust, Oxford, UK

Adam Darowski

Consultant Physician, John Radcliffe Hospital, Oxford, UK, and Honorary Senior Lecturer, Oxford University, Oxford, UK

Parthajit Das

Consultant Rheumatologist, Kettering General Hospital NHS Foundation Trust, Kettering, UK

Patrick Davey

Consultant Cardiologist, Northampton General Hospital NHS Trust, Northampton, UK

Emily Davies

Consultant Dermatologist, Gloucestershire Royal Hospital, Gloucester, UK

Geraint Davies

Reader in Infection Pharmacology and Consultant in Infectious Diseases, University of Liverpool, Liverpool, UK

Paul Davies

Consultant Neurologist, Northampton General Hospital NHS Trust, Northampton, UK

Sam Dawkins

Specialist Registrar in Cardiology, John Radcliffe Hospital, Oxford, UK

David de Berker

Consultant Dermatologist and Honorary Senior Lecturer, University Hospitals Bristol NHS Foundation Trust, Bristol, UK

Aminda De Silva

Consultant Gastroenterologist, Royal Berkshire NHS Foundation Trust, Reading UK

Sarah Deacon

Consultant Respiratory Physician, Worcestershire Royal Hospital, Worcester, UK

Miguel Debono

Consultant Endocrinologist and Honorary Senior Lecturer, Royal Hallamshire Hospital, Sheffield, UK

Patrick Deegan

Metabolic Physician, Addenbrooke's Hospital, Cambridge, UK

Alastair Denniston

Consultant Ophthalmologist, University Hospitals Birmingham NHSFT & Hon Professor, University of Birmingham, Birmingham, UK

Dhananjay Desai

Consultant Respiratory Physician, University Hospital Coventry, Coventry, UK

Michael Doherty

Professor of Rheumatology and Head of Division of Academic Rheumatology, School of Medicine, University of Nottingham, Nottingham, UK

Moutaz El-Kadri

Consultant Cardiologist and Electrophysiologist, Sheikh Khalifa Medical City, Abu Dhabi, UAE

Michelle Ellinson

Freelance Dietitian, London, UK

Christine Elwell

Consultant Oncologist, Northampton General Hospital NHS Trust, Northampton, UK

Clare England

Senior Research Associate, University of Bristol, Bristol, UK

Ben Esdaile

Consultant Dermatologist, Whittington Hospital, London, UK

Robin Ferner

Honorary Professor of Clinical Pharmacology, University of Birmingham, Birmingham, UK

Tom Fletcher

Wellcome Trust/Ministry of Defence Research Training Fellow and Speciality Registrar in Infectious Diseases, Liverpool School of Tropical Medicine, and Royal Liverpool University Hospital, Liverpool, UK

Colin Forfar

Consultant Cardiologist, Oxford University Hospitals NHS Foundation Trust, Oxford, UK

Martin Fotherby

Consultant Stroke Physician, Leicester Royal Infirmary Leicester, UK

Anthony Frew

Professor of Allergy and Respiratory Medicine, Royal Sussex County Hospital, Brighton, UK

Paul Frost

Consultant in Intensive Care Medicine, University Hospital of Wales, Cardiff, UK

Hill Gaston

Emeritus Professor of Rheumatology, University of Cambridge, Cambridge, UK

David J. Gawkrödger

Professor Emeritus in Dermatology, University of Sheffield, Sheffield, UK

Sir Ian Gilmore

Honorary Consultant, Royal Liverpool University Hospital, and Honorary Professor, University of Liverpool, Liverpool, UK

William Gilmore

Research Fellow, National Drug Research Institute, Curtin University, Perth, Australia

Sherif Gonem

National Institute for Health Research Clinical Lecturer in Respiratory Medicine, University of Leicester, Leicester, UK

Lynsey Goodwin

Specialist Trainee in Infectious Diseases and General Medicine, Royal Liverpool University Hospital, Liverpool and North Manchester General Hospital, Manchester, UK

Warren Grant

Consultant Clinical Oncologist, Cheltenham General Hospital, Cheltenham, UK

Tracey Graves

Consultant Neurologist, Addenbrooke's Hospital, Cambridge, UK, and Hinchingbrooke Hospital, Huntingdon, UK

Alexander L. Green

Spalding Associate Professor and Consultant Neurosurgeon, John Radcliffe Hospital, Oxford, UK

Seamus Grundy

Consultant Respiratory Physician, Aintree University Hospital, Liverpool, UK

Pranabashis Haldar

Senior Clinical Lecturer in Respiratory Medicine, University of Leicester, Leicester, UK

George Hart

Honorary Research Professor, University of Manchester, Manchester, UK

Yvonne Hart

Consultant Neurologist, Newcastle Upon Tyne NHS Foundation Trust, Newcastle, UK

Catherine Harwood

Professor in Dermatology and Honorary Consultant Dermatologist, Queen Mary University of London, London, UK

Victoria Haunton

Consultant and Honorary Senior Lecturer in Geriatric Medicine, University Hospitals of Leicester NHS Trust, Leicester, UK

Neil Herring

Associate Professor of Cardiovascular Physiology, University of Oxford, Oxford, UK, and Consultant Cardiologist, Oxford University Hospitals NHS Trust, Oxford, UK

William G. Herrington

Honorary Consultant Nephrologist, Churchill Hospital, Oxford, UK

Melvyn Hillsdon

Associate Professor of Exercise and Health Behaviour, University of Exeter, Exeter, UK

Stephan Hinze

Consultant Neurologist, Great Western Hospital, Swindon, UK

Sandeep Hothi

Bye Fellow, University of Cambridge, Cambridge, UK, and Specialist Registrar in Cardiology and General Internal Medicine, Glenfield Hospital, Leicester, UK

Jonathan A. Hyam

Consultant Brain and Comprehensive Spinal Neurosurgeon, National Hospital for Neurology and Neurosurgery, London, UK, and Honorary Senior Lecturer in Neurosurgery, University College London, London, UK

Sarosh Irani

Honorary Consultant Neurologist and Senior Clinical Fellow, John Radcliffe Hospital, Oxford, UK

Simon Jackson

Consultant Urogynaecologist, Oxford University Hospitals NHS Foundation Trust, Oxford, UK

Kassim Javaid

Honorary Consultant Rheumatologist, University of Oxford, Oxford, UK

Rachel Jeffery

Consultant Rheumatologist, Northampton General Hospital NHS Trust, Northampton, UK

Andrew A. Jeffrey

Consultant Respiratory Physician and Director of Medical Education, Northampton General Hospital NHS Trust, Northampton, UK, and Honorary Senior Lecturer, University of Oxford, Oxford, UK

Liberty Jenkins

Fellow in Neuromuscular Medicine, Stanford University Hospital, Palo Alto, CA, USA

Andrew M. Jones

Consultant Respiratory Physician, University Hospital of South Manchester, Manchester, UK

Michael Jones

Clinical Fellow in Cardiology, Oxford University Hospitals NHS Foundation Trust, Oxford, UK

Nerissa Jordan

Consultant Neurologist, Fiona Stanley Hospital, Perth, Australia

Elizabeth Justice

Consultant Rheumatologist, Queen Elizabeth Hospital Birmingham, Birmingham, UK

Manish Kalla

Lecturer in Medicine and Clinical Research Fellow, University of Oxford, Oxford, UK

Alexandra Kent

Research Fellow, John Radcliffe Hospital, Oxford, UK

Satish Keshav

Gastroenterologist and Honorary Senior Lecturer, John Radcliffe Hospital, Oxford, UK

Saifudin Khalid

Consultant Respiratory Physician, Royal Blackburn Hospital, Blackburn, UK

Richard Knight

Professor of Clinical Neurology, National CJD Research And Surveillance Unit, Edinburgh, UK

Robin Lachmann

Consultant in Metabolic Medicine, National Hospital for Neurology and Neurosurgery, London, UK

Ajit Lalvani

Chair of Infectious Diseases, Director of the National Institute of Health Research Health Protection Research Unit, Director of the Tuberculosis Research Centre, and Head of Respiratory Infections, National Heart and Lung Institute, Imperial College London, London, UK

Chris Lavy

Professor of Orthopaedic and Tropical Surgery, and Consultant Orthopaedic and Spine Surgeon, University of Oxford, Oxford, UK

Richard Lessells

Senior Infectious Diseases Specialist, University of KwaZulu-Natal, Durban, South Africa

Andrew Lever

Professor of Infectious Diseases, University of Cambridge, Cambridge, UK, and Honorary Consultant Physician, Addenbrooke's Hospital, Cambridge, UK

Keir Lewis

Professor of Respiratory Medicine, University of Swansea, Swansea, UK

Su-Yin Lim

Specialist Registrar in Neurology, Leicester General Hospital, Leicester, UK

Mark P. Little

Senior Investigator, National Cancer Institute, Bethesda, MD, USA

Yoon Loke

Professor of Medicine and Pharmacology, University of East Anglia, Norwich, UK

Melanie Lord

Speech and Language Therapist, Fen House, Ely, UK

Raashid Luqmani

Professor of Rheumatology, University of Oxford, Oxford, UK

Linda Luxon

Professor Emeritus of Audiovestibular Medicine and Honorary Consultant Physician in Neuro-otology, University College London and University College Hospitals NHS Trust, London, UK

Graz Luzzi

Consultant in Genitourinary Medicine, Wycombe General Hospital, High Wycombe, UK, and Honorary Senior Clinical Lecturer, University of Oxford, Oxford, UK

Robert MacKenzie-Ross

Respiratory Consultant, Royal United Hospital, Bath, UK

Rubeta Matin

Consultant Dermatologist, Churchill Hospital, Oxford, UK

Jane McGregor

Consultant Dermatologist, Barts Health NHS Trust, London, UK

Tess McPherson

Consultant Dermatologist, Churchill Hospital, Oxford, UK

Benedict Michael

National Institute for Health Research Senior Clinician Scientist Fellow University of Liverpool, Liverpool, UK, and Post-Doctoral Researcher/Lecturer, Massachusetts General Hospital/Harvard Medical School Boston, MA, USA

Siraj Misbah

Consultant Clinical Immunologist, John Radcliffe Hospital, Oxford, UK, and Honorary Senior Clinical Lecturer, Oxford University, Oxford, UK

Amit Mistri

Consultant in Stroke Medicine, Leicester Royal Infirmary, Leicester, UK

Sajjan Mittal

Consultant Haematologist, Northampton General Hospital NHS Trust, Northampton, UK

Susan Mollan

Consultant Ophthalmologist, University Hospitals Birmingham NHSFT & Clinical Fellow, University of Birmingham, Birmingham, UK

Rhiain Morris

Clinical Psychologist, Oxfordshire Counselling and Psychology Practice, Oxford, UK

Karen Morrison

Associate Dean for Education and Student Experience, Director of Medical Education, and Professor of Neurology, University of Southampton, Southampton, UK, and Honorary Consultant Neurologist, University Hospital Southampton, Southampton, UK

Alia Munir

Consultant Endocrinologist, Royal Hallamshire Hospital, Sheffield, UK

Louisa Murdin

Consultant Audiovestibular Physician, Guy's and St Thomas' NHS Foundation Trust, London, UK

Elaine Murphy

Consultant in Inherited Metabolic Disease, National Hospital for Neurology and Neurosurgery, London, UK

Chandramouli Nagarajan

Consultant Haematologist and Adj. Assistant Professor, DUKE-NUS Medical School, Singapore General Hospital, Singapore

Pradip Nandi

Consultant Rheumatologist, Northampton General Hospital NHS Trust, Northampton, UK

Abdul Nasimudeen

Consultant Chest Physician, Northampton General Hospital NHS Trust, Northampton, UK

Pavithra Natarajan

Consultant in Infectious Diseases, North Manchester General Hospital, Manchester, UK

John Newell-Price

Professor of Endocrinology and Consultant Endocrinologist, University of Sheffield, Sheffield, UK

Jim Newton

Consultant Cardiologist, Oxford University Hospitals NHS Foundation Trust, Oxford, UK

Pippa Newton

Consultant in Infectious Diseases, Manchester University NHS Foundation Trust, Manchester, UK

Kannan Nithi

Consultant Neurologist and Neurophysiologist, Northampton General Hospital NHS Trust, Northampton, UK

Christopher A. O'Callaghan

Professor of Medicine and Honorary Consultant Physician and Nephrologist, University of Oxford, Oxford, UK

Liz Orchard

Consultant Cardiologist, John Radcliffe Hospital, Oxford, UK

Rakesh Panchal

Consultant Respiratory Physician, Glenfield Hospital, Leicester, UK

Manish Pareek

Senior Clinical Lecturer in Infectious Diseases, University of Leicester, Leicester, UK, and Honorary Consultant in Infectious Diseases, Leicester Royal Infirmary, Leicester, UK

Joanna Pepke-Zaba

Consultant Respiratory Physician, Papworth Hospital, Papworth Everard, UK

Erlick A. C. Pereira

Senior Lecturer in Neurosurgery, St George's, University of London, London, UK, and Consultant Neurosurgeon, St George's Hospital, London, UK

Jeremy Perkins

Consultant Vascular Surgeon, John Radcliffe Hospital, Oxford, UK

Joanna Peters

Locum Consultant in Infectious Diseases and Medical Microbiology, Royal Sussex County Hospital, Brighton, Sussex, UK

Katrina Pollock

National Institute for Health Research Clinical Lecturer in Genitourinary Medicine, Imperial College London, London, UK

Jenny Powell

Consultant Dermatologist, Basingstoke and North Hampshire Hospital, Basingstoke, UK

Jonathan Price

Clinical Tutor in Psychiatry, University of Oxford, Oxford, UK

Natalia Price

Consultant Urogynaecologist, John Radcliffe Hospital, Oxford, UK

Susan Price

Consultant in Clinical Genetics, Oxford Regional Genetics Service, Oxford, UK

Norman Qureshi

Consultant Cardiologist and Electrophysiologist, Imperial College Healthcare NHS Trust, London, UK

Kazem Rahimi

Professor of Medicine, University of Oxford, Oxford, UK

Kim Rajappan

Consultant Cardiologist, John Radcliffe Hospital, Oxford, UK

Tommy Rampling

Academic Clinical Fellow, University College London, London, UK

James Ramsden

Consultant ENT Surgeon, John Radcliffe Hospital, Oxford, UK

Anna Rathmell

Medical Manager, Takeda UK Ltd, Wooburn Green, UK, and Lay Member, South Central-Oxford C Research Ethics Committee, Bristol, UK

David Ratliff

Consultant Vascular Surgeon, Northampton General Hospital NHS Trust, Northampton, UK

Karim Raza

Professor of Clinical Rheumatology, University of Birmingham, Birmingham, UK

Dave Riley

Palliative Medicine Consultant and Clinical Director, Northamptonshire Healthcare NHS Foundation Trust, Northampton, UK

Simon Rinaldi

MRC Clinician Scientist and Honorary Consultant Neurologist, University of Oxford, Oxford, UK

Joanna Robson

Consultant Senior Lecturer in Rheumatology, University of the West of England, Bristol, UK

Kufre Sampson

Consultant Clinical Oncologist, Leicester Royal Infirmary, Leicester, UK

John Saunders

Consultant Gastroenterologist, Royal United Hospital, Bath, UK

Alys Scadding

Consultant in Respiratory Medicine, Glenfield Hospital, Leicester, UK

Matthew Scarborough

Consultant in Clinical Infection, John Radcliffe Hospital, Oxford, UK

Alexander Schmidt

Director, Professor of Musicians' Medicine, and Consultant Neurologist, Kurt Singer Institute for Music Physiology and Musicians' Health, Berlin, Germany

Susanne Schneider

Consultant Neurologist, Ludwig-Maximilians-Universität München, München, Germany

Martin Scott-Brown

Consultant Oncologist, University Hospital Coventry, Coventry, UK

Aung Sett

Consultant Stroke Physician, Fairfield General Hospital, Bury, UK

Shireen Shaffu

Consultant Rheumatologist, Leicester Royal Infirmary, Leicester, UK

Karen K. K. Sheares

Respiratory Consultant, Papworth Hospital, Papworth Everard, Cambridge

Jackie Sherrard

Consultant Physician, Department of Sexual Health, Churchill Hospital, Oxford, UK

Cheerag Shirodaria

Honorary Consultant Cardiologist, John Radcliffe Hospital, Oxford, UK

Ehoud Shmueli

Consultant Gastroenterologist, Northampton General Hospital, NHS Trust, Northampton, UK

Kevin Shotliff

Consultant Diabetologist, Chelsea and Westminster Hospital, London, UK

Salman Siddiqui

Clinical Senior Lecturer, Glenfield Hospital, Leicester, UK

Muthu Sivaramakrishnan

Consultant Dermatologist, Ninewells Hospital and Medical School, Dundee, UK

Jacky Smith

Professor of Respiratory Medicine, University of Manchester, Manchester, UK, and Honorary Consultant, University Hospital of South Manchester, Manchester, UK

Roger Smyth

Consultant Psychiatrist, Royal Infirmary of Edinburgh, Edinburgh, UK

Tom Solomon

Professor of Neurology, University of Liverpool, Liverpool, UK

Christine Soon

Consultant Dermatologist, Northampton General Hospital NHS Trust, Northampton, UK

David Sprigings

Formerly Consultant Physician, Northampton General Hospital NHS Trust, Northampton, UK

Robert Stevens

Consultant Rheumatologist, Doncaster Royal Infirmary, Doncaster, UK

Jon Stone

Consultant Neurologist and Honorary Reader in Neurology, University of Edinburgh, Edinburgh, UK

Sarah Stoneley

Consultant Geriatrician, Leicester Royal Infirmary, Leicester, UK

Michael Stroud

Consultant Gastroenterologist and Professor of Clinical Nutrition, Southampton University Hospital, Southampton, UK

Kenny Sunmboye

Consultant Rheumatologist and UKNIHR CRN East Midlands Musculoskeletal Disorders Specialty Lead, University Hospitals of Leicester, Leicester, UK

Ravi Suppiah,

Consultant Rheumatologist, Auckland District Health Board, Auckland, New Zealand

Joanna Szram

Consultant Respiratory Physician, Royal Brompton and Harefield NHS Foundation Trust, London, UK

David Taggart

Professor of Cardiovascular Surgery, John Radcliffe Hospital, Oxford, UK

Kathy Taghipour

Consultant Dermatologist, Whittington Health NHS Trust, London, UK

James Taylor

Consultant Rheumatologist, Northampton General Hospital NHS Trust, Northampton, UK

Sherine Thomas

Consultant in Infectious Diseases and General Medicine, Barts Health NHS Trust, London, UK

Bryan Timmins

Consultant Neuropsychiatrist, Northamptonshire Healthcare NHS Trust, Northampton, UK

Jonathan Timperley

Consultant Cardiologist, Northampton General Hospital NHS Trust, Northampton, UK

Stacy Todd

Consultant in Infectious Diseases and General Medicine, Royal Liverpool University Hospital, Liverpool, UK

Palak Trivedi

Academic Clinical Lecturer and Specialist Registrar in Hepatology and Gastroenterology, University of Birmingham, Birmingham, UK

Martin R. Turner

Professor of Clinical Neurology and Neuroscience, John Radcliffe Hospital, Oxford, UK

Jaime Vera,

Clinical Senior Lecturer, Brighton and Sussex Medical School,
Brighton, UK

Raman Verma

Specialist Registrar in Respiratory Medicine and Honorary National
Institute for Health Research Lecturer, Glenfield Hospital University,
Leicester, UK

Sarah Wakelin

Consultant Dermatologist and Honorary Senior Lecturer, Imperial
College Healthcare NHS Trust, London, UK

Ben Wakerley

Consultant Neurologist, Gloucestershire Royal Hospital,
Gloucester, UK

Emma Wall

Academic Clinical Lecturer, University College London,
London, UK

Pippa Watson

Consultant Rheumatologist, University Hospital of South
Manchester, Manchester, UK

Andrew Weir

Consultant Neurologist, Royal Berkshire Hospital, Reading, UK,
and John Radcliffe Hospital, Oxford, UK

Sophie West

Consultant Physician, Freeman Hospital, Newcastle, UK

Matt Wise

Physician, University Hospital of Wales, Cardiff, UK

Martyn Wood

Consultant in Sexual Health and HIV Medicine, Royal Liverpool
and Broadgreen University Hospitals NHS Trust, Liverpool, UK

Chee-Seng Yee

Consultant Rheumatologist, Doncaster Royal Infirmary,
Doncaster, UK

Figure 87.8 Myocardial perfusion imaging with single-photon emission computed tomography (SPECT): An example of inducible hypoperfusion in the anterior wall and apex. Panels, from left to right, show representative vertical long-axis (VLA), horizontal long-axis (HLA), and mid short-axis (SAX) slices, with stress above rest. The white arrows show a perfusion defect which is present on the stress slices but which resolves at rest. Figure 87.9 CT coronary angiography showing a critical soft plaque stenosis in the left main stem. Reproduced with permission from Warrell, Cox and Firth, *Oxford Textbook of Medicine*, fifth edition, Oxford University Press, Oxford, UK, Copyright © 2010

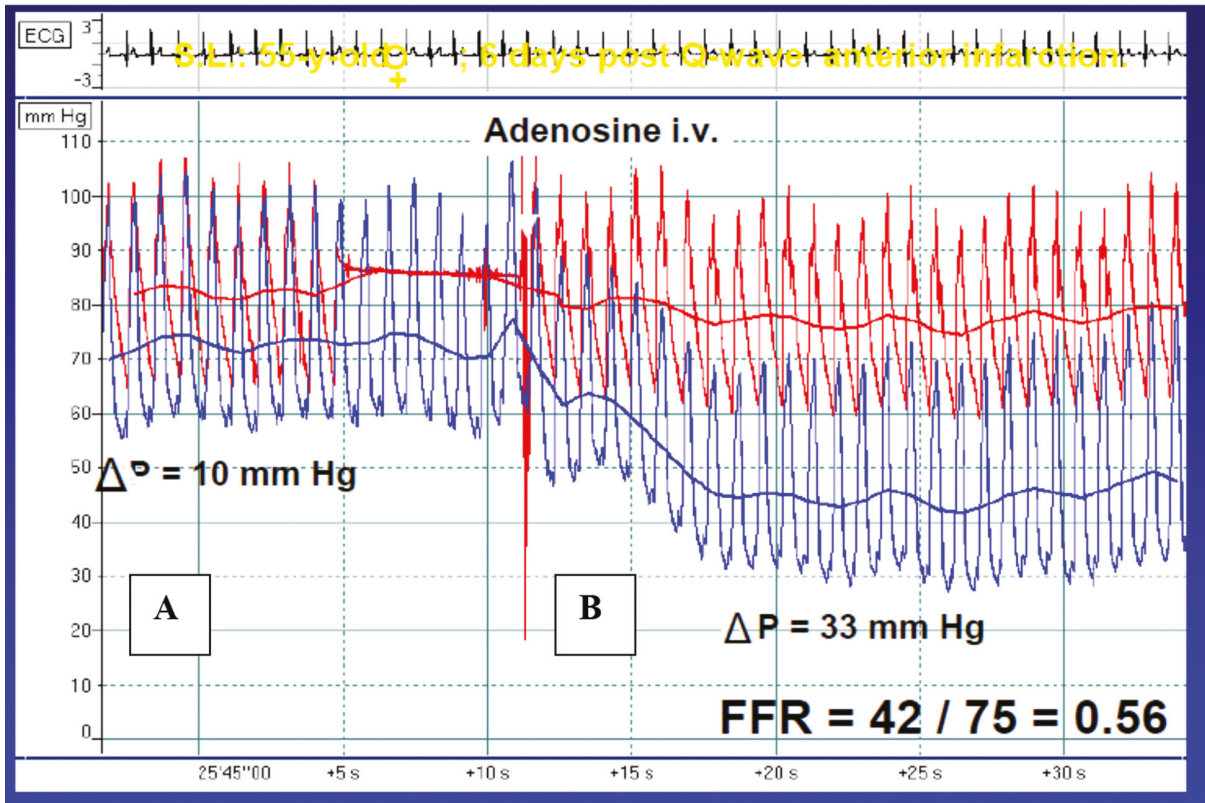

Figure 87.11 To assess the fractional flow reserve, which is the ratio of the pressures distal to and proximal to a stenosis, a small flexible wire with two separate pressure sensors is placed across a candidate coronary artery stenosis. Under resting conditions (A), there is only a 10 mm Hg gradient (ΔP) across the lesion but, under maximal hyperaemia ('adenosine i.v.': B), the gradient increases markedly to 33 mm Hg, with a mean distal-to-proximal pressure ratio of 0.56. Thus, in this case, the fractional flow reserve indicates the presence of a functionally significant stenosis, and coronary angioplasty is indicated; FFR, fractional flow reserve; i.v., intravenous.

Figure 267.1 Hands of a patient with rheumatoid arthritis. Synovitis of the wrists and metacarpophalangeal joints is apparent. Rheumatoid nodules (present here over the right middle finger proximal interphalangeal joint) and fixed deformity (present here at the right little finger proximal interphalangeal joint) are unusual in early disease.

PART 1

The approach to the patient

1 Diagnostic reasoning

David Sprigings

Introduction

It was an ordinary medical outpatient clinic. I was seeing a ward follow-up, a 25-year-old woman who had been admitted a couple of months earlier with a non-specific febrile illness, anaemia, and raised inflammatory markers. She was now feeling well. I began the examination by taking her blood pressure. But for some reason I couldn't feel her brachial pulse. What was going on?

Diagnostic reasoning is the mental process by which we turn such information about the patient into the name of a disease. In the patient above, this proved to be Takayasu arteritis. To do this we must gather and evaluate evidence relevant to the clinical problem, and then choose a diagnosis or make a decision about management. Like detective work, with which it has many similarities, we have to reason from observed effects to their possible causes. In this chapter we will explore the thinking behind diagnostic reasoning, drawing on insights from cognitive psychology, philosophy, and the design of computer programs. If we have a deeper understanding of the reasoning that underpins making a diagnosis, we may be more astute diagnosticians, and better able to teach the skill to novices. And, however we arrive at a diagnosis, we need to be able to articulate our reasoning to the patient and our colleagues. But first, let's clarify what we mean by a diagnosis.

Patients with diseases exist in the real world. A diagnosis, however, is a mental construct with which we reason about disease. In essence, it is an explanation for what is happening to the patient.

It resembles a scientific hypothesis, but differs in that there are agreed criteria for its confirmation or exclusion. It is often the name of a disease, but can be much broader than this: for example, it could be a syndrome—a cluster of clinical features—such as heart failure or malabsorption, or a category of disease like cancer or sepsis. A diagnosis summarizes our thoughts about what is happening to the patient, guides our actions, and helps us foretell the future. It need only be as precise as is required by the circumstances and the next step to be taken. This may be at the level of investigation (if we diagnose heart failure, we order an echocardiogram), or treatment (if we diagnose cardiac arrest, we start life support).

Like other human reasoning, diagnostic reasoning is fallible. Ten per cent or more of diagnoses are wrong, and for certain diseases (such as rare diseases) the rate of misdiagnosis (failure or delay in diagnosis) is often higher. Because so much of our management hinges on the diagnosis, errors in diagnosis typically lead to poor outcomes. Perhaps unfairly, patients regard misdiagnosis as more negligent than technical errors or complications. Many factors contribute to misdiagnosis (Table 1.1), amongst which errors in diagnostic reasoning are prominent. The single most common failing we need to guard against is 'premature closure', that is too readily accepting a diagnosis which seems to fit the facts, without considering better alternatives. Formulating a **differential diagnosis** (asking yourself 'What else could this be?') helps avoid this trap.

Table 1.1 Factors contributing to diagnostic error

Factor	Comment
<i>Doctor related</i>	
Lack of knowledge of specific diseases	Diseases such as subdural empyema, cerebral venous sinus thrombosis, oesophageal rupture, and mesenteric ischaemia are sufficiently rare to mean that we may not have encountered them in our training, and so do not consider them in the relevant setting.
Failure to appreciate the spectrum of clinical presentations of diseases we know	Many diseases have a broad range of clinical manifestations. Examples include pulmonary embolism, aortic dissection, infective endocarditis, and pheochromocytoma, as well as multisystem diseases such as vasculitis or amyloidosis.
Inadequate data collection	Failure to take an adequate history, perform an appropriate examination, or order relevant investigations inevitably increases the risk of misdiagnosis.
Errors in diagnostic reasoning	We may ignore, misunderstand, or misinterpret relevant clinical data. We may put too much store by 'normal' results in ruling out disease (e.g. we may wrongly believe that a normal ECG excludes acute coronary syndrome). We may accept a working diagnosis without subjecting it to proper scrutiny, or considering better alternatives.
Other human factors	Biases, fatigue, distraction, and lapses of memory may lead us astray.
<i>Patient/setting related</i>	
Older patients	Older patients are more likely to have more than one disease. The presentation of diseases may be modified with age.
Patients with psychiatric symptoms or disease	Diagnostic error is more common in patients with both physical and psychiatric symptoms. Psychiatric symptoms may in fact be due to physical disease. Psychiatric disease and its treatment may affect the response to physical disease (e.g. reduced pain perception in schizophrenia).
Patients in intensive care	Information from the history is reduced, and physical examination may be more difficult. The spectrum of disease is different, and patients often have multiple, interrelated diseases.
<i>System related</i>	
Management of healthcare records	Access to previous paper and electronic healthcare records may be difficult; as a consequence, key facts about the patient may not be known when diagnoses are being made.
Management of test results	Doctors may not be alerted to abnormal test results (e.g. of patients who have been discharged from hospital or who are outpatients) and so these results go unrecognized.
Communication across healthcare interfaces	Diagnostic information may not be passed between primary and secondary care, or between hospitals.

Defining characteristics (present in all patients)	Consistent features (present in >75% of patients)	Variable features (present in <75% of patients)
Cultured dermal fibroblasts synthesize abnormal type III procollagen molecules Identification of a mutation in the gene for type III procollagen (<i>COL3A1</i>)	Autosomal dominant inheritance Easy bruising Thin skin with visible veins Characteristic facial features	Hypermobility of large joints Hyperextensibility of skin Arterial rupture, dissection, or aneurysm formation Uterine rupture Gastrointestinal perforation

Diagnosis, disease, and clinical features

The exact number of diseases is uncertain, but likely to be in excess of 30 000 (the current International Classification of Diseases (ICD-10) has 12 420 codes; online *Mendelian Inheritance in Man* (OMIM™), which focuses primarily on inherited genetic disorders, has just under 20 000 entries). We recognize diseases by their clinical features—the symptoms, signs, imaging, and other data they are associated with. For a given disease, there are **defining characteristics**—those abnormalities which confirm the presence of the disease and distinguish it from other diseases; **consistent features**, seen (arbitrarily) in >75% of patients with the disease; and **variable features**, seen in <75% of patients. Defining characteristics may change over time, with advances in understanding of the genetic and molecular mechanisms of the disease. There is of course substantial overlap between diseases as regards their consistent and variable features but, by definition, the defining characteristics are unique to a single disease. Table 1.2 illustrates this for the collagen disorder, Ehlers–Danlos syndrome type IV (EDS IV).

In EDS IV, as in many other diseases, the defining characteristics relate to the results of laboratory investigations. The **clinical diagnosis** is the diagnosis based on the presence of clinical features most

consistently associated with the disease. A patient presenting with easy bruising and who has typical facial features and thin skin could be given the clinical diagnosis of EDS IV. The **working diagnosis**—which we will return to in ‘Making a diagnosis’—is the diagnosis about which we are sufficiently certain to use as the basis for action. If the patient with easy bruising had joint hypermobility but no other abnormal signs (and no other cause for easy bruising apparent), EDS IV might be our working diagnosis, leading us to request collagen and DNA studies. If these tests were both positive, EDS IV would be the **final (or confirmed) diagnosis**. A comprehensive final diagnosis should provide answers to three questions: which tissue, organ, region, or system of the body is diseased; what is the pathophysiological process causing the disease; and why has this process happened in this patient?

Making a diagnosis

The knowledge base of medicine is largely structured by disease, as reflected in the contents list of this book, but patients come to us with problems. A schematic description of the process through which we transform a clinical problem into a final diagnosis is shown in Figure 1.1.

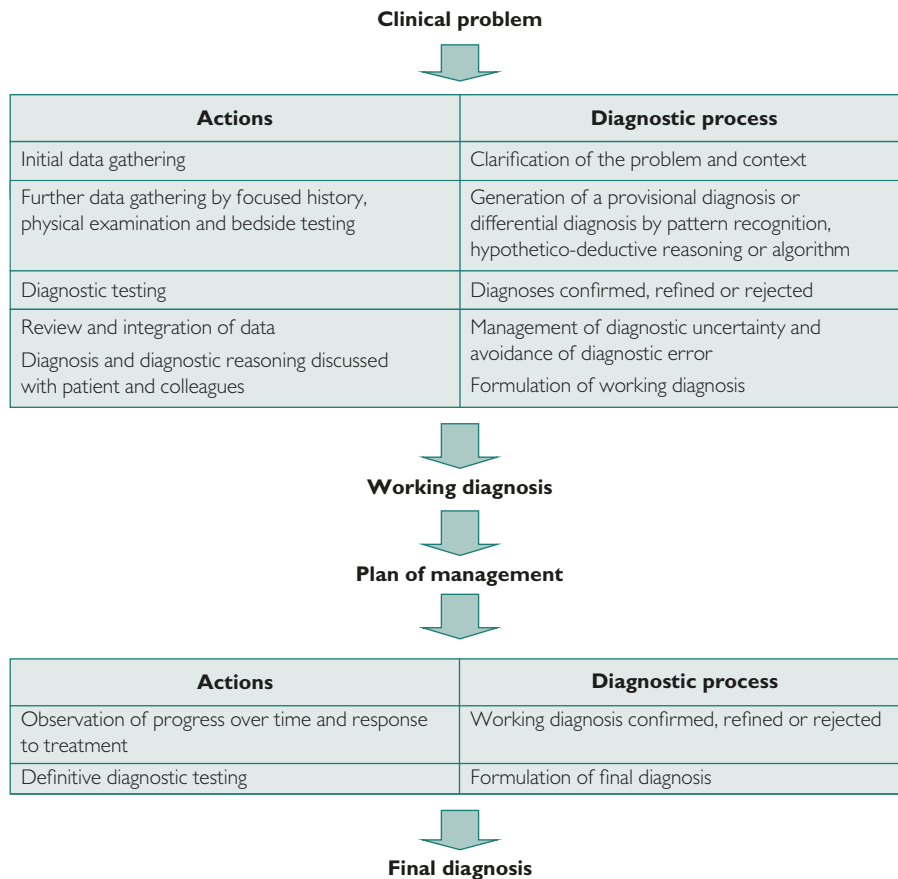

Figure 1.1 Diagnostic reasoning.

Table 1.3 Common causes of thrombocytopenia by clinical context, illustrating the powerful influence of context on the differential diagnosis

Context	Common causes (after exclusion of pseudothrombocytopenia due to platelet clumping)
Acute hospital admission	Sepsis Acute alcohol toxicity Disseminated intravascular coagulation Drug-induced thrombocytopenia Immune thrombocytopenic purpura Thrombotic thrombocytopenic purpura
Inpatient	Sepsis Disseminated intravascular coagulation Drug-induced thrombocytopenia Dilutional thrombocytopenia from transfusion of plasma-reduced red cells Post-transfusion purpura
Pregnancy and peripartum	Gestational thrombocytopenia Immune thrombocytopenic purpura HELLP syndrome (haemolysis, elevated liver enzymes, low platelet count) Disseminated intravascular coagulation Thrombotic thrombocytopenic purpura
Outpatient	Myelodysplasia Hypersplenism Immune thrombocytopenic purpura Antiphospholipid-antibody syndrome

Clarification of the problem and context

Over the first minute or two of the clinical encounter, we gather data to clarify the nature of the problem and its context. The opening remarks or appearance of the patient, the physiological observations, the contents of the referral letter, or the comments of the nurse—all may help define the problem. The context—which will include the age and sex of the patient, and the clinical setting (e.g. primary/secondary care)—exercises a powerful constraint on diagnostic possibilities. This influence of context is particularly important when dealing with clinical problems with a wide differential diagnosis. Thrombocytopenia, for example, has over 30 causes, when considered by mechanism. However, classification by context yields groups of 4–6 causes (Table 1.3), allowing us to focus on a much more manageable shortlist. We may need to cast our net wider if the shortlist does not contain a diagnosis which meets the standards of a good working diagnosis, but narrowing the field in this way makes the diagnostic process more efficient.

Generation of a provisional diagnosis or differential diagnosis

Our initial data gathering is followed by a more systematic process of focused history taking, physical examination, and bedside testing. By focused we mean that our thoughts about what might be the diagnosis drive our search for further information. We use three distinct methods to generate a provisional diagnosis or differential diagnosis: pattern recognition, hypothetico-deductive reasoning, and the use of algorithms. Broadly speaking, we solve easy cases by pattern recognition, and difficult cases by hypothetico-deductive reasoning. What counts as easy or difficult depends on our knowledge and experience: experts playing on their home ground will tend to use pattern recognition but, when faced with an unusual problem which does not yield to this, switch to hypothetico-deductive reasoning. Algorithms are helpful when the clinical picture is dominated by one feature with a relatively narrow differential diagnosis.

Pattern recognition

Consider the case of a 52-year-old woman who presented to the Emergency Department with headache. This is her account:

I was towel-drying my hair yesterday evening when I got a blinding headache. I think I blacked out for a few seconds.

I went to bed. The headache was still there. It was worse when I moved my head around and when I coughed. I could sometimes find a comfortable position. I've still got the headache now. I took a painkiller this morning which helped a bit. It's worse if I bend my head down.

Pattern recognition transforms clusters of clinical features—patterns—into diagnoses, based on their match with previously classified patterns in memory. In this case, the characteristics of the headache (its abrupt onset, association with syncope, and exacerbation by head movement and coughing) and the ensuing neck stiffness allow a pattern-recognition diagnosis of subarachnoid haemorrhage. The case is typical: all the features are consistent with subarachnoid haemorrhage, and none is discordant. The diagnosis can be made in a minute or two.

Of course, we soon learn that not all cases are typical. As we gain experience, we become familiar with unusual presentations—also called disease polymorphisms—such as the presentation of subarachnoid haemorrhage with pulmonary oedema or confusional state. These patterns can be thought of as ‘illness scripts’—narratives of the features of the case. The more patients we see (or hear or read about), the more illness scripts we have in our memory and the better we become at recognizing patients with the same disease, even when the clinical features don't match those of the typical case. Pattern recognition is a fast and economical method of making a diagnosis, but has an Achilles heel: we have a tendency to assess less critically the diagnoses we make by pattern recognition.

Hypothetico-deductive reasoning

Hypothetico-deductive reasoning means thinking of possible explanations for the problem and testing them. We use hypothetico-deductive reasoning when we don't have all the relevant clinical information immediately to hand, and diagnosis by pattern recognition is not possible. Typically, we start with a tentative initial diagnosis ('Has he had a pulmonary embolism?', 'Could this be meningitis?'). As we progress with the case, seeking and organizing further information, we mentally adjust the probabilities of the diagnoses we are actively considering. We are particularly interested in those clinical features that are **defining characteristics** of a disease or syndrome (e.g. regional ST elevation in a patient with acute chest pain) or allow discrimination between different diseases. **Discriminatory features** are those whose presence or absence significantly increases or decreases the probability of a given diagnosis. In a patient presenting with exertional syncope, hair colour is of no discriminatory value, but the presence of a loud mid-systolic murmur is highly relevant, given its association with aortic stenosis and hypertrophic obstructive cardiomyopathy. Discriminatory features may be a combination of several signs. For example, the presence of an elevated jugular venous pressure together with pulsus paradoxus of >10 mm Hg and a large cardiac silhouette on the chest X-ray make cardiac tamponade the likely diagnosis in the breathless patient. Conversely, the absence of fever, or neck stiffness, or altered mental state—one or more of which are present in 99% of patients with meningitis—effectively excludes this diagnosis in the patient with headache. In general, the **presence** of features (single or composite) with a **low false-positive rate** rules in a diagnosis, and the **absence** of features with a **low false-negative rate** rules out a diagnosis. False-positive and false-negative rates are discussed further in 'Diagnostic testing'.

Red flags and worst-case scenarios

Many symptoms have a broad differential diagnosis ranging from self-limiting diseases such as minor viral infection to life-threatening disorders. When considering the cause of a patient's problem, we need to be mindful of the consequences of failure to diagnose rare but potentially lethal diseases. Various strategies have been proposed to force consideration of diagnoses which carry a high penalty if missed. 'Red flags' are the name given to symptoms or signs whose presence mandates further testing to exclude serious disease. The limitation of this focus on 'red flags' is that many patients with serious disorders do not have red-flag symptoms (in other words, these symptoms have a high false-negative rate), so their absence does not allow you to rule out the diagnosis. For example, subarachnoid haemorrhage may not

cause abrupt-onset or severe headache. Nevertheless, it is a strategy that is helpful, especially when the prevalence of life-threatening disease is low.

A related strategy is to force consideration of life-threatening diseases in a given situation—a 'rule out worst-case scenario' strategy. In patients with acute chest pain, for example, it is useful always to consider acute coronary syndrome, pulmonary embolism, aortic dissection, and oesophageal rupture, and test the features of the case against these diagnoses. Many clinical aphorisms are of this sort ('In patients with abdominal pain, always consider acute appendicitis in the very young, the very old, and the pregnant.', 'Positive blood cultures are due to infective endocarditis until proven otherwise.').

The use of pivots

Often, the sheer volume of clinical features—most of which are not going to be relevant to the diagnosis—can make it difficult to know where to start with hypothetico-deductive reasoning. When faced with this situation, one fruitful approach is to focus on pivotal features. Pivotal clinical features are features which have to be explained—that is, they are rarely if ever seen in the absence of disease and, importantly, have a manageable differential diagnosis. Examples include pleuritic chest pain, finger clubbing, splenomegaly, extensor plantar response, and heavy proteinuria.

The use of a pivot can be illustrated by analysis of this case from the *British Medical Journal*:

A 70-year-old man presented with a 30-minute history of throbbing left-sided headache that woke him from sleep. He had no history of headache or recent head injury. He also described a four-day history of breathlessness when climbing one flight of stairs. He was taking tablets for type 2 diabetes mellitus, hypertension, and congestive cardiac failure. He did not smoke and drank seven units of alcohol a week. The patient was alert and oriented, with a heart rate of 100 beats/minute and a blood pressure of 150/90 mm Hg. Respiratory rate was 16 breaths per minute, oxygen saturation was 98% on air, and his lungs were clear to auscultation. An early diastolic murmur was heard at the base of the heart. He had no temporal artery tenderness or neck stiffness. Haemoglobin was 13.2 g/L; white blood cell count was $7 \times 10^9/L$; urea and electrolytes, liver function, and renal function were normal, and the erythrocyte sedimentation rate was 30 mm/hour (normal <20 mm/hour in men over 50). Electrocardiography showed sinus tachycardia. The results of chest radiography and computed tomography of the brain were normal.

Where to start? Well, amongst all the clinical features mentioned, only two stand out as clearly abnormal: the unilateral throbbing headache and the early diastolic murmur. An early diastolic murmur is usually due to aortic regurgitation, the causes of which can be divided into acute or chronic (see Table 1.4).

If we presume that aortic regurgitation started suddenly, which would account for the patient's breathlessness, then there are really only two diagnoses we need to consider: infective endocarditis and aortic dissection. Use of this pivot has simplified the problem—for the moment—to making a judgement as to which of these two diagnoses could explain the clinical features and, if both could, which is the more likely.

Both disorders are famous for their varied clinical presentation. Against a diagnosis of aortic dissection is the absence of chest pain, and the normal chest X-ray. However, in patients with proven aortic dissection, chest pain is absent in 15%, and the chest X-ray normal in a similar percentage. Against a diagnosis of infective endocarditis

is the absence of fever, the normal full blood count and only mildly raised ESR.

So both are possible. Aortic dissection is perhaps the more likely. But how to account for the headache? A unilateral throbbing headache suggests a local vascular cause, rather than a systemic cause related to infection. But can aortic dissection and headache be linked? At this point, most of us would need help. Fortunately, Google is usually to hand, and googling 'headache' and 'aortic dissection' returns several case reports of aortic dissection extending into the carotid artery and thus causing headache.

So we can now adopt a **working diagnosis** of painless proximal aortic dissection complicated by acute aortic regurgitation (resulting in breathlessness) and extension into the left carotid artery (causing unilateral headache). We don't yet have a **final or confirmed diagnosis**: this requires imaging to demonstrate an aortic dissection flap, the defining characteristic of aortic dissection. CT with contrast was done and this was found.

Pivots are useful because they reduce the diagnostic possibilities to a number we can hold in short-term memory (around five at a time), and take advantage of the fact that, although we are generally poor at estimating absolute probabilities of diseases, we are much better at comparing and ranking the relative probabilities of diseases.

Use of algorithms

An algorithm is defined as a set of rules designed to solve a specific problem by proceeding through a sequence of logical steps. Diagnostic algorithms are typically written by experts for non-experts, with reference to the evidence base, and follow an approach considered the most expeditious in the analysis of a clinical problem. They prompt us to seek specific information which discriminates between the choices at the branch points of the flowchart. For example, in relation to hypokalaemia (Figure 1.2), whether the urinary potassium-to-creatinine excretion is low or high and, if high, whether there is a metabolic alkalosis or acidosis. The diagnostic process of an algorithm is explicit, but its output still needs to be validated, as we would any provisional diagnosis.

Diagnostic support systems

We often find ourselves needing help with diagnoses, which usually comes from colleagues or a review of the relevant medical literature. Web-based diagnostic support (Table 1.5) is increasingly available where we see patients, and is underused. Google, as previously demonstrated, is a powerful tool, particularly when we have a cluster of definite abnormalities (i.e. findings that are unquestionably pathological) for which we are seeking a unifying diagnosis. For example, a middle-aged woman presented with breathlessness and was found to have hypoxia and a 9 cm diameter aortic root aneurysm, without significant aortic regurgitation. Extensive respiratory investigation drew a blank as to the cause of hypoxia. However, googling these two features gives the answer: distortion of the right atrium by the aortic root aneurysm allowing a right-to-left shunt across a patent foramen ovale (confirmed as the diagnosis by bubble-contrast echocardiography). With further development of the electronic patient record (EPR), automatic diagnostic support may be possible, using information taken directly from the EPR.

Diagnostic testing

We do diagnostic testing to confirm, refine, or reject possible diagnoses. A diagnosis is confirmed if its defining characteristics are found, and rejected if these are absent. Some tests are used to determine if a particular disease is present (e.g. measurement of urinary copper excretion for Wilson's disease), while others provide information relevant to a range of diseases (e.g. chest X-ray in acute breathlessness). Testing may also enable us to refine a diagnosis (e.g. echocardiography in cardiac valve disease, or staging CT in carcinoma of the bronchus).

A perfect diagnostic test is abnormal or positive in every patient with the disease, and normal or negative in every patient without the disease. Most tests are less than perfect, and gold-standard tests of high accuracy may be invasive or costly. Bayes' theorem tells us explicitly how much we should adjust our assessment of the probability of disease in the light of a positive or negative result on a test that is not 100% accurate. There are several introductions to Bayes' theorem available on the web (e.g. <http://yudkowsky.net/rational/bayes>).

Table 1.4 Causes of aortic regurgitation

Acute aortic regurgitation	Chronic aortic regurgitation
Infective endocarditis	Bicuspid aortic valve
Aortic dissection	Calcification of a morphologically normal aortic valve
	Aortic root dilatation

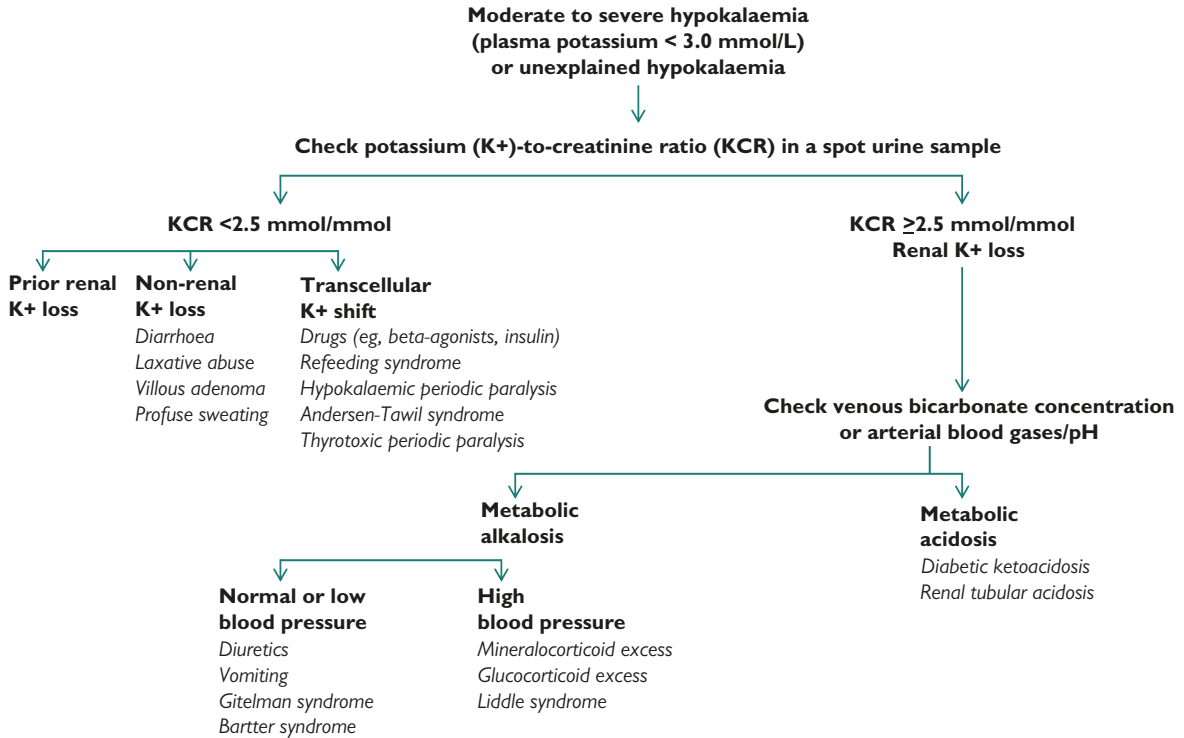

Figure 1.2 Algorithm for the differential diagnosis of hypokalaemia.

A key insight from the theorem is that we must consider the probability of disease before we did the test (the pretest probability) when interpreting a test result.

To illustrate the practical application of Bayes' theorem, consider two patients you've seen in clinic: one is a 30-year-old woman, the other a 57-year-old man. Both have been referred because of a 6-month history of episodic retrosternal chest discomfort which may come on at rest (with no relation to meals) but sometimes occurs when they run up two flights of stairs at work. Both are smokers of ten cigarettes daily, with no other coronary risk factors. There is no other relevant past or family history. Examination and resting ECG are normal. You wonder about the possibility of coronary disease and arrange an exercise ECG. The test is positive in both patients, that is, exercise provokes ST depression of 2 mm (but no symptoms). Does this mean that both have coronary disease?

To answer this question, we need two pieces of information: first, how likely was coronary disease before we had the test result; and, second, how good is exercise ECG as a test for coronary disease?

We can estimate the probability of coronary disease from the age, sex, symptoms, and coronary risk factor profile of a patient. For a 30-year-old female smoker with atypical angina, the probability of coronary disease is <10%. It is substantially higher in a 57-year-old male smoker with atypical angina, at around 60%.

The relation between disease and test result can be depicted in a 2 × 2 table. Data on coronary disease and ST depression on exercise

ECG are shown in Table 1.6. This table tells us how likely a positive test result is in patients with coronary disease (70%, the true-positive rate (or sensitivity)). But we want to know the obverse: how likely is coronary disease in a patient with a positive test result?

From the data in the 2 × 2 table, we can calculate this likelihood. The likelihood ratio is the percentage of patients **with** coronary disease who show ST depression on exercise ECG (70%), divided by the percentage **without** coronary disease who also have a positive test (20%), that is, 3.5. So, a positive exercise test increases the likelihood of coronary disease by a factor of 3.5. The negative likelihood ratio is the percentage of patients **with** coronary disease who have a **negative** test (30%), divided by the percentage **without** coronary disease who have a negative test (80%), that is, 0.4. Likelihood ratios for positive and negative tests can be translated into approximate changes in the probability of disease (Table 1.7): a positive exercise test increases the probability of coronary disease by 20%–25%, while a negative test decreases it by a similar amount.

Table 1.5 Some web-based diagnostic support services

Returning to our patients, the positive exercise test therefore increases the likelihood of coronary disease to around 30% in the woman, and around 80% in the man. The same test result is associated with very different probabilities of disease, driven by the different pretest probabilities. We would now need to make a clinical judgement as to how to manage these patients, in the light of their individual probabilities of coronary disease. The limited diagnostic accuracy of exercise testing, as revealed in the relatively modest positive and negative likelihood ratios, is the principal reason why its use as a diagnostic test is declining in favour of other, more accurate tests such as CT coronary angiography and myocardial perfusion imaging.

The likelihood ratios of some commonly used diagnostic tests in acute medicine are given in Table 1.8. A positive finding on a test with a positive likelihood ratio >10 effectively rules in the disease in question, while a negative finding on a test with a negative likelihood ratio <0.1 effectively rules it out. Likelihood ratios have some important advantages over other measures of test performance, such as sensitivity and specificity (from which they can be calculated): they incorporate all the information in the 2×2 table of the test, and can be applied to individual patients, across the full range of pretest probabilities of disease. If we regard elements in the history and clinical examination as biomarkers of disease (e.g. abrupt-onset chest pain, pulse deficit, and aortic regurgitation in aortic dissection), we can use the likelihood ratios of these features to adjust our estimate of the probability of the disease as we assess the patient: we deal with this in more detail in the chapters on history taking (Chapter 3) and physical examination (Chapter 4).

Table 1.8 Likelihood ratios of selected diagnostic tests

Disease	Test	Positive LR	Negative LR
Coronary artery disease	Exercise electrocardiography	3.5	0.4
Coronary artery disease	CT coronary angiography	9.0	0.03
Pulmonary embolism	CT pulmonary angiography	5.9	0.18
Aortic dissection	Plasma D-dimer	2.6	0.06
Heart failure as the cause of acute dyspnoea	Plasma brain natriuretic peptide	3.8	0.14
Subarachnoid haemorrhage	Cranial CT and examination of CSF	3.0	0

Abbreviations: LR, likelihood ratio.
Data from several sources.

Box 1.1 Questions to ask yourself before you accept a working diagnosis

- Can I trust my working diagnosis? Are there discordant features which it doesn't explain?
- Let's assume my working diagnosis is wrong: what would be the next most likely diagnosis?
- Have I considered and excluded the most serious causes of this clinical problem?
- Am I relying on a normal test result to rule out a serious diagnosis? Do I know how much I can trust this test to do so?

Formulation of a working diagnosis

Formulation of a working diagnosis is a crucial step in diagnostic reasoning and misdiagnosis often stems from too readily accepting a diagnosis which seems to fit the facts, without considering better alternatives. Always starting with a differential diagnosis (e.g. the obvious cause, the less obvious cause and the cause we don't want to miss) defends against this. When considering the causes in our differential diagnosis, we need to subject these to intellectual as well as diagnostic testing. How well does each explain the significant positive and negative findings? Does it provide a plausible anatomical or physiological mechanism to link them, and account for the time course of events? Are there any significant findings not explained by the diagnosis (or another confirmed diagnosis)? Are any expected findings absent? Some questions we should ask ourselves before accepting a working diagnosis are given in Box 1.1.

Deciding between competing diagnoses may be difficult. In essence, one diagnosis is better than another if it explains more, that is, provides a more plausible mechanism and more convincing narrative, and unifies more findings, with fewer loose ends. Although we should prefer the more probable over the less probable diagnosis, other things being equal, the fine detail of the individual case may make a rare diagnosis more likely than a common one. As the cause of acute chest pain with minor ST/T-wave abnormalities, acute coronary syndrome is more common than oesophageal rupture (by a factor of >100); however, if the patient was weightlifting before the onset of pain, and has evidence of pneumomediastinum on chest X-ray, oesophageal rupture will be our diagnosis.

We may not be able to make a definite diagnosis after our first encounter with the patient. Often, this uncertainty can be resolved by further diagnostic testing. Alternatives are the use of tests of time and treatment. For example, in a young patient with non-specific chest pain and whose clinical features make serious disease unlikely, we may decide to observe progress over an appropriate period, without intervention. Or we may opt for a test of treatment, such as a course of proton-pump inhibitor, as an alternative to diagnostic testing. Whichever course we take, the progress of the patient is a crucial test of the correctness of our diagnosis. Each time we review patients, in clinic or on the ward, we should ask ourselves how well their progress matches what would be expected from our working diagnosis.

Diagnostic reasoning is a serious business, but also absorbing, satisfying, and often exhilarating. We can enjoy learning from our colleagues when a stunning diagnosis is made which transforms the care of a patient, and we should also learn from our mistakes. However good we are, we can always be better diagnosticians.

2 Dealing with uncertainty

David Sprigings

Introduction

Uncertainty is a frequent and often uncomfortable element in our professional lives. Its many overlapping sources range from biological variation in patients and diseases, to the inherent unpredictability of the future (Table 2.1). In this chapter, we focus on dealing with uncertainty in diagnosis, prognosis, and management. How can we make better judgements and take wiser decisions, even though the information on which they are based is incomplete?

Dealing with diagnostic uncertainty

We can mismanage a patient even when we've got the right diagnosis but, given the central importance of the diagnosis to our choice of actions, if our diagnosis is wrong, our management will almost certainly be wrong as well. The strategies that may help us deal with diagnostic uncertainty can be illustrated by an analysis of this case:

A 58-year-old man, with a background of type 2 diabetes and hypertension, comes to the Emergency Department following an episode of central chest pain, without radiation, which came on abruptly while he was in a stressful meeting at work. He graded the pain 9/10 in severity. It was associated with sweating and faintness, was not affected by breathing or posture, and lasted for over an hour, settling after he was given morphine. When you see him, 2 hours following the onset of symptoms, he is free of pain, with normal findings on cardiovascular and general examination. His pulse is 80 beats per minute, and blood pressure 150/90 mm Hg. Oxygen saturation breathing air is 95%. ECG on admission showed sinus rhythm with no ST/T-wave abnormalities. His chest X-ray is normal.

Rule out worst-case scenario

The diagnostic process is a journey with certainty as its sometimes unattainable goal: from a problem which may have a dozen possible

causes to the exact cause in our patient. For many presenting symptoms, the range of diagnoses extends from benign disorders to life-threatening diseases. 'Rule out worst-case scenario' is a useful approach which reminds us to consider life-threatening diseases (Table 2.2) before we accept a diagnosis of a benign disorder as the cause of acute chest pain. Does the patient have major risk factors for or typical clinical features of one of these diseases? Coronary disease is common in a middle-aged man with type 2 diabetes and hypertension, but of course this doesn't necessarily make acute coronary syndrome the diagnosis. The abrupt onset of non-pleuritic chest pain raises the question of aortic dissection, particularly given the normal ECG. There's nothing pointing strongly to pulmonary embolism or oesophageal rupture, but neither are there features allowing a positive diagnosis of an alternative benign disorder.

The clinical features of aortic dissection are notoriously diverse, but 'aortic pain'—defined as acute chest or back pain of onset within less than 2 minutes, tearing or ripping in quality—is the most common. Other features independently predictive of aortic dissection are pulse or blood pressure differences between the limbs, and mediastinal or aortic widening on chest X-ray. In a study of 250 patients with suspicion of aortic dissection, the absence of all three features made the probability of dissection low (<10%). However, 1 in 25 of patients who proved to have aortic dissection were in this group, making the point that low risk does not mean no risk of the disease. Conversely, any combination of the three features or isolated pulse/blood pressure differences indicated a high likelihood of dissection (>80%).

With one of the three features, abrupt-onset chest pain, this patient is at intermediate risk of dissection (around 30%). We must bear in mind, of course, that abrupt-onset chest pain is not exclusive to aortic dissection: it may be a feature of other aortic diseases (e.g. intramural haematoma), as well as acute coronary syndrome and oesophageal diseases (such as oesophageal rupture).

Table 2.1 Sources of uncertainty in medicine

Source	Comment
Biological variation in patients and diseases	Patients with the same disease may have very different clinical manifestations, prognoses, and responses to treatment. Our understanding of the genetic and molecular differences which underlie this variation—the promise of personalized medicine—is still rudimentary.
Stochastic mechanisms of disease	The same initial conditions may result in a range of outcomes which can only be described by probability distributions and cannot be predicted with certainty for the individual patient (e.g. acute myocardial ischaemia may or may not result in ventricular fibrillation).
Limits of clinical data	We work with data which may be incomplete, inaccurate, unreliable, or missing. Elements in the history may be forgotten by the patient, or not elicited by the doctor. Examination findings may be overlooked or misinterpreted. Many diagnostic tests have limited accuracy.
Limits of the medical literature	The medical literature is vast, but of varying quality, with gaps, inaccuracies, and bias. Many clinical questions are not specifically addressed. It is often difficult to consult the literature at the point of care.
Limits of diagnostic and prognostic models	Models are imperfect: they may predict what proportion of patients have a diagnosis or will suffer an event, but cannot specify the outcome of individuals.
Limits of personal knowledge	Because of limited or faulty knowledge, our differential diagnosis may be too narrow and not contain the true diagnosis; even if it does contain the true diagnosis, we may wrongly reject this. Distinguishing between the limits of personal knowledge and the limits of medical knowledge may be difficult, especially early in one's career.
Limits of our ability to assess and interpret data	Experience generally improves our ability to interpret data; factors such as fatigue and distraction can reduce it. Heuristics (rules of thumb) and biases may lead us to make wrong judgements. We may respond to missing data with assumptions which prove to be unfounded.
The inherent unpredictability of the future	Predictions are necessarily provisional. The unexpected may happen. We cannot quantify unknown risks.

Table 2.2 Life-threatening causes of acute chest pain

	Acute coronary syndrome	Pulmonary embolism	Aortic dissection	Oesophageal rupture
Approximate incidence per 10 ⁵ population per year	~300	~30	~3	~1

Data averaged from several sources.

Using clinical decision rules

Pulmonary embolism seems unlikely, but how confidently can we exclude it? We can sometimes extend (and calibrate) our analysis of the clinical features by use of a decision rule. A clinical decision rule gives an assessment of the probability of a disease, based on findings from the history, examination, and readily available investigations. Clinical decision rules are useful in situations where diagnosis is difficult, the consequences of misdiagnosis are serious, or there are opportunities to achieve savings (e.g. by reducing the use of costly investigations) without loss of quality. Clinical decision rules (like likelihood ratios) enable us to benefit from the collective medical experience of thousands of patients, far more than we will personally meet.

Perhaps surprisingly, there are no well-validated clinical decision rules for acute coronary syndrome or aortic dissection. However, for pulmonary embolism, the Wells score (see NICE Clinical Guideline 144 (2012)) is validated and easy to use. The Wells score includes uses readily available clinical information to yield a score between 0 and 12.5; the clinical probability of pulmonary embolism is dichotomized as 'unlikely' (probability <5%) if the score is ≤4, and 'likely' if >4. It may seem counter-intuitive that data on oxygen saturation, blood gases, or chest X-ray findings are not included in the score: the explanation is that while these data are relevant to the diagnosis, they lack discriminatory power. Our patient has a Wells score of 0, indicating that pulmonary embolism is very unlikely: pretty much what we thought.

Probability and consequences

Risk can be defined as a state of uncertainty in which some of the potential outcomes (present or future) are associated with harm or death. Risk has two dimensions: probability and consequences. As we reason about the case, we weigh up both of these dimensions of potential diagnoses (Table 2.3). Phrases like 'always consider diagnosis X' and 'have a high index of suspicion for diagnosis Y' are often used to remind us of diagnoses which may be unlikely in a given setting (low probability) but carry a high penalty if missed (serious consequences). The strategy of 'rule out worst-case scenario' shares the same philosophy. Given that the mortality rate of untreated aortic dissection is up to 1% per hour, definitive imaging by contrast CT is warranted to rule out the diagnosis. As the probability of pulmonary embolism is low, based on our clinical impression and supported by

the decision rule, a normal level of plasma D-dimer will be sufficient to exclude it.

Probability in the context of diagnostic reasoning is largely an expression of the strength of our belief in a diagnosis. There is an interplay between the strength of this belief—a 'subjective' probability—and the 'objective' probability, as found in descriptive studies of the epidemiology of acute chest pain. We may use the 'objective' probability (e.g. that 10% of adult patients presenting to the emergency department with acute severe chest pain have aortic dissection) as the starting point in our diagnostic assessment, adjusting the probability up or down as we incorporate additional findings about the patient in front of us. The logic underpinning our reasoning is that the presence of a recognized feature of the disease makes it more likely, and its absence, less likely. By how much more or less likely depends on the strength of the association between feature and disease (which can be summarized in its likelihood ratio). The absence of a feature characteristic of the disease (i.e. seen in >95% of patients), or the absence of two or three features each found in >80% of patients, is strong evidence against that disease being present. Making a positive diagnosis of one disease (by demonstrating its defining characteristics) also reduces the likelihood of other competing diagnoses, unless they can be linked pathophysiologically (e.g. proximal aortic dissection with involvement of a coronary ostium causing simultaneous acute coronary syndrome) or are comorbidities. So, for example, while oesophageal rupture should cross our mind in all patients with acute severe chest pain, we don't need to take the diagnosis further if none of the typical clinical features is present, and we can make a confident alternative diagnosis.

Diagnostic testing

Testing often helps us reduce diagnostic uncertainty. Likelihood ratios (see Chapter 1) are a useful summary measure of test performance, and can be applied to individual patients, across the full range of pretest probabilities of disease. A positive finding on a test with a positive likelihood ratio >10 effectively rules in the disease in question, while a negative finding on a test with a negative likelihood ratio <0.1 effectively rules it out. However, not many tests are this accurate.

Diagnostic testing is not without its problems. It may increase rather than reduce our uncertainty, if the test poorly discriminates between patients with and without the disease in question. We need

Table 2.3 Causes of acute chest pain under consideration in this case

	Comment	Probability of diagnosis	Consequences if untreated
Benign musculoskeletal disease	Onset and severity argue against benign musculoskeletal disease	<1% Very unlikely	Nil
Benign oesophageal disease (reflux/dysmotility)	No antecedent oesophageal symptoms	~10% Unlikely	Nil
Biliary colic	Location of pain (exclusively in the chest) and absence of associated nausea atypical for biliary colic	~10% Unlikely	Low
Acute coronary syndrome (ACS)	Several risk factors for coronary artery disease present; the normal ECG at presentation does not exclude ACS	~35% Possible	Moderate
Pulmonary embolism	Both intuitively and by the use of the clinical decision rule, pulmonary embolism is unlikely	~10% Unlikely	Moderate
Aortic dissection	Abrupt-onset pain, but this is not exclusive to aortic dissection, and its complete resolution within 2 hours would be unusual	~35% Possible	High
Oesophageal rupture	No clinical or radiological features in favour of this diagnosis; however, it is a diagnosis notoriously easy to miss	<1% Very unlikely	High

to integrate the test result with our assessment of the pretest probability of disease: when the pretest probability of disease is very high, a negative test result is more likely to be a false negative. Imaging tests are open to errors of technique and interpretation: a 'normal' chest X-ray or CT scan may not be normal when viewed by a more experienced eye. Testing also has costs and may have hazards (if the test is invasive or involves radiation or contrast media). Tests may reveal incidental findings which trigger further investigation, increasing costs without necessarily improving outcomes (e.g. the detection of pulmonary nodules on CT coronary angiography). And testing may delay appropriate management: for example, waiting for the result of contrast CT in a patient with a high clinical probability of aortic dissection rather than focusing on medical stabilization and transfer to a cardiothoracic surgical unit.

Combining diagnostic assessment with safe care

Patients understand that we can't always get the diagnosis right the first time, but they do expect us to minimize their exposure to harm. The evolution of diseases over time means that many diagnoses become apparent after the initial encounter, and we often need to observe and reassess the patient to come to the correct diagnosis. As a general rule, the sicker the patient, the more often should the assessment (particularly the examination) be repeated.

In many patients presenting after an episode of chest pain, we may not be able to make a confident diagnosis, despite observation (the evidence is that this should be for at least 6 hours), reassessment, and testing. Such patients usually have benign disease; we may accept the diagnostic uncertainty implicit in a label of non-specific chest pain, provided we have confirmed their low-risk status, as reflected in normal findings on examination, serial ECGs, chest X-ray, and measurement of biomarkers, as a minimum. How far to take testing for coronary artery disease (or other serious disease) beyond this is a common judgement call.

Safe care also involves giving information to discharged patients as to what symptoms should prompt them to seek further help, making appropriate provision for their follow-up, and ensuring that clinical information is promptly sent from secondary to primary care. These actions can reduce the risk to which the patient is exposed should we have got the diagnosis wrong.

Outcome of the case

Contrast CT was normal, with no evidence of aortic dissection. Serial ECGs showed minor anterolateral T-wave changes only. However, serum troponin I was raised at 8 ng/ml. Treatment was therefore started for non-ST elevation acute coronary syndrome. Coronary angiography the following day showed a severe stenosis in a large left circumflex artery marginal branch, which was treated by percutaneous intervention. The case illustrates the point that diagnostic ECG changes are not always seen in acute coronary syndrome: acute coronary syndromes in the left circumflex artery territory are less likely to result in diagnostic ECG changes than those involving other territories.

Prognostic and management uncertainty

Getting the diagnosis right is important, but we often have patients whose prognosis or management is uncertain, even though their

diagnosis is clear. For example, should a 75-year-old woman admitted with hypercapnic respiratory failure due to an acute exacerbation of severe chronic obstructive pulmonary disease have mechanical ventilation if non-invasive ventilation fails? Is anticoagulation necessary for a 68-year-old woman found to be in atrial fibrillation and who has hypertension but no other medical problems? Can we safely manage as an outpatient a 59-year-old man with pulmonary embolism confirmed on CT pulmonary angiography?

In each case, what we do will be strongly influenced by what we think the outcome (or range of possible outcomes) will be for the patient in question. In pulmonary embolism, for example, the risk of death extends from >50% to <1%, depending on the clinical features. How can we accurately predict the outcome for the patient before us, and so make the right decision?

Clinical acumen and experience are useful guides, but don't always get us to the right answer: we naturally give undue weight to the cases we remember which went particularly well or badly. And, if our experience is limited, what else can we rely on? Which features are the ones to which we should pay most attention when considering prognosis?

There is good evidence that our intuitive risk assessments are often wrong. As regards estimates of survival, doctors veer between the overly optimistic (e.g. overestimating survival in patients under their care with cancer) and overly pessimistic (e.g. underestimating the benefits of intensive care for patients admitted on-take with acute exacerbations of COPD). Prognostic and risk-assessment models are therefore useful to check and calibrate our clinical assessments. A valid model shows good discrimination (its ability to correctly separate patients into different groups (e.g. survivors/non-survivors) and calibration (the degree of correspondence between the estimated probability derived from the model and the actual observed probability in different patient groups). To gain acceptance, the model also needs to be based on readily available clinical or laboratory data, be easily remembered, and to have been validated in more than one patient population. Examples of risk-assessment models that have become part of standard clinical practice are given in Table 2.4.

Even though the use of validated risk-assessment models can improve our assessment of prognosis, we need to bear in mind that these models cannot specify the outcome of individuals: some 'high-risk' patients will inevitably fare better than some 'low-risk' ones. The longer the interval between the prediction and the event (e.g. predicting 1-year as compared to 30-day survival), the less accurate the prediction.

Decision-making in the face of uncertainty

In medicine, we often have to act (or choose not to act) despite uncertainty, and our style of decision-making is largely determined by the demands of the situation (Table 2.5). The approach adopted in relation to the case in the previous section can be characterized as analytical: we had the time to collect the information we wanted, consider it carefully, and, if necessary, ask a colleague for advice. When dealing with emergencies, however, we have to act under time pressure and with high stakes. Studies of doctors and of those in other professions with similar responsibilities (e.g. those in the armed forces, firefighters) reveal that, in emergencies, intuitive decision-making—triggered by situation recognition—usually

Table 2.4 Use of risk-assessment models in clinical practice

Reasons for using the model	Examples	Model
The treatment is of low overall benefit: to identify patients most likely to benefit	Primary prevention with statin therapy	Joint British Societies model
The treatment is of moderate or large benefit but carries significant risk of harm: to identify patients for whom benefit exceeds risk	Anticoagulation in non-valvular atrial fibrillation	CHADS ₂ and CHADS-Vasc score for risk of stroke HAS-BLED score for risk of bleeding with anticoagulation
The treatment is of limited availability	Liver transplantation for liver failure	Model for End-Stage Liver Disease (MELD) score
To identify patients who can safely be managed with only a brief or no inpatient stay	Community-acquired pneumonia Upper gastrointestinal haemorrhage Transient ischaemic attack	CURB65 score Rockall score, Blatchford score ABCD ² score

Table 2.5 Approaches to medical decision-making		
	Analytical	Intuitive
Setting	Used when time pressure is low and the situation is well defined	Used when urgency is high and immediate action needed
Example	Clinic: how should I manage this 78-year-old man with symptomatic severe aortic stenosis who has multiple comorbidities?	Emergency Dept: how should I manage this 78-year-old man admitted following a syncopal episode whose blood pressure is falling?
Concept of decision-making	A choice between alternative strategies, guided by calculation of utility: do A rather than B because A is predicted to have a superior outcome	A choice between actions, guided by the match between situation and appropriate action: do A rather than B because A is a better match to the situation
Drivers of decision-making	Information and analysis	Situation recognition and experience
Principal feature of uncertainty	Limited or ambiguous information	Doubt that hinders action
Response to uncertainty	Focused gathering of information Use of clinical decision rules, prognostic models, and risk-assessment models Use of formal decision analysis Second opinion Multidisciplinary team discussion	Not sure what's going on: rapidly gather the information needed to allow situation recognition Missing information: make assumptions based on the working diagnosis to fill gaps Not sure which course of action to take: weigh the pros and cons before acting; have a back-up plan to use if the first plan is unsuccessful

takes precedence over the analytical approach used when time is less critical. Because experience is of such importance in intuitive decision-making, experts usually perform better than novices in managing emergencies. Experts are generally more astute at recognizing what type of emergency they're dealing with (and when it differs from a typical pattern), more confident in matching their action to the situation, and better able to judge the time available for assessment before action. They are also more willing to change tack when unfolding events show that their initial approach was wrong, and can switch between intuitive and analytical decision-making as the circumstances require.

So, how can we accelerate our progress from novice to expert? Simulation exercises can supplement our clinical experience. Formal debriefing may help us learn more from the cases we have dealt with. And checklists can support our responses to common emergencies, providing us with an expert guide to action (and ensuring that we don't forget crucial information in the heat of the moment). At its simplest, a checklist can be a list of all the diagnoses to be

considered in a given situation (e.g. the causes of cardiac arrest with pulseless electrical activity), but will typically specify a sequence of actions to be taken. The use of checklists to structure the management of medical emergencies is in its infancy but, given its success in improving the outcome of aviation emergencies, holds great promise.

3 Taking the history

David Sprigings

Introduction

Our aim as doctors is to understand the patient and the disease. Taking the history is key to both of these objectives. Only through talking to patients can we get to know them as people, their personal experience of illness, and their concerns. And the history remains the richest source of information about their diseases. Most diagnoses are suggested by the history, with examination and investigation providing supporting and confirmatory evidence. By the same token, if we reach the end of the history without some idea as to the cause of the patient's problem, we need to go back and retake it, because our chances of arriving at the correct diagnosis without this map to guide us are slim.

History taking is a conversation with a purpose, not a cross-examination. In this chapter, we look at some aspects of history taking that are of particular relevance to diagnosis in internal medicine. Let's begin with what the patient tells us.

The patient's account

We need to give patients enough time to tell their story in their own words, without interruption, before we start asking questions. Sometimes the patient's account is so comprehensive that further questioning is superfluous (Box 3.1), but we will usually want to explore the detail of the symptoms, as this detail enables us to distinguish between diagnostic possibilities. For example, chest pain may arise from a broad range of thoracic and upper abdominal diseases, as well as being a sensation transiently experienced by healthy people. However, recurrent retrosternal chest pain, provoked by exertion and relieved promptly by rest, as described by this patient, has a much narrower differential diagnosis.

With experience, we become familiar with the range of diseases that can give rise to a given symptom. We also learn the varied ways patients express the symptoms of a given disease. The patient whose account is given in the box (who proved to have three-vessel coronary disease) was unusual in saying he experienced 'pain': most patients use words such as discomfort, heaviness, pressure, tightness, or 'like indigestion' to describe what myocardial ischaemia feels like. And some symptoms prove on closer questioning to be composites

Box 3.1 The typed account of his symptoms brought by a 63-year-old man to his first cardiology clinic appointment

'Sometimes (but rarely) the pain does not appear at all, especially if I walk slowly. But in the majority of cases it starts after about ¼ of a mile, or even sooner, especially if I walk fast. The pain stops completely and almost immediately (about 10 seconds) if I stop. If I start again the pain comes back after 50 yards or so. As I keep stopping and starting, the pain becomes milder, and frequently may disappear completely and not come back—provided I do not accelerate the pace. The pain seems to rise from the stomach and usually concentrates in the central-upper part of my chest. It takes the form of a hard lump, very much like food sticking in the oesophagus. When it disappears, it often seems to be sinking back. I often feel if I could expel air, I would be all right. Very often this happens and I do feel better afterwards. The pain seems to be worse on wet or humid days. By worse I mean that it starts sooner and does not get better as I keep stopping. Agitation or emotion seems to make matters worse.'

Table 3.1 Diagnostic questions to determine whether transient loss of consciousness is due to seizure or syncope

Question	Points (if yes)
At times do you wake with a cut tongue after your spells?	2
At times do you have a sense of déjà vu or jamais vu before your spells?	1
At times is emotional stress associated with losing consciousness?	1
Has anyone ever noted your head turning during a spell?	1
Has anyone ever noted that you are unresponsive, have unusual posturing, or have jerking limbs during your spells, or have no memory of your spells afterwards? (Score as 'yes' for any positive response)	1
Has anyone ever noted that you are confused after a spell?	1
Have you ever had lightheaded spells?	-2
At times do you sweat before your spells?	-2
Is prolonged sitting or standing associated with your spells?	-2
<i>The patient has seizures if the point score is ≥1, and syncope if the point score is <1.</i>

of several abnormal sensations. Exertional breathlessness in patients with chronic obstructive pulmonary disease, for example, often spans 'shallow breathing', 'can't get enough air in', and 'chest tightness', likely to reflect different pathophysiological mechanisms.

Interpreting the patient's symptoms—in this case, moving from the patient's account of around 200 words to a two-word summary, exertional angina—is a necessary step towards formulating a differential diagnosis, but one that introduces the possibility of error. And error at this point can have a profound influence on clinical outcome, as our formulation of the problem based on the history often determines the diagnostic pathway we take. To avoid misinterpretation, we need time to make sure we have grasped correctly the detail of the symptoms. Careful questioning can also help us distinguish between diagnoses. For example, the answers to nine questions can, in aggregate, determine (with >90% accuracy) whether transient loss of consciousness is due to seizure or syncope (Table 3.1).

The focused history

We must adapt our history taking to the clinical circumstances. When dealing with a patient who may have critical illness, initial history taking has to be abbreviated, and usually combined with an assessment of the physiological status. The focused history—the focus being diagnosis—is based on defining the problem, establishing its context, and then asking those questions which best discriminate between the diagnostic possibilities (Table 3.2).

We usually come to a view as to the nature of the clinical problem within a minute or two of meeting the patient. It's rarely the case that the patient's major symptom (the 'presenting complaint' in UK terminology, and 'chief complaint' in US terminology) is not central to the diagnosis, and overlooking or sidelining this carries a serious risk of diagnostic error. A 66-year-old woman with rheumatoid arthritis presented with erythema and swelling of her right arm following a fall. However, her main complaint was of diffuse severe

Table 3.2 The focused and the complete history

Focused history	Complete history*
Presenting problem and its context (age/sex of the patient; clinical setting; chronology of events)	History of each presenting complaint
Active medical problems (including comorbidities or long-term conditions) and major events in the past history	Past medical, surgical, and mental health history
Current medication	Medication record
Allergies	Relevant legal information
Concise social history: to include as a minimum usual functional status, home circumstances, tobacco and alcohol use	Allergies and adverse reactions
	Risk and warnings
	Social history
	Family history
	Systematic enquiry
	Patient's concerns, expectations, and wishes

Data from Health and Social Care Information Centre, Academy of Medical Royal Colleges (2013): Standards for the clinical structure and content of patient records.

pain in the arm. The importance of this was not recognized, and the correct diagnosis of necrotizing fasciitis was delayed.

The context of a problem has a powerful effect on the differential diagnosis. Context includes the age and sex of the patient, the clinical setting (e.g. primary/secondary care; inpatient/outpatient), and the patient's comorbidities. Grouping causes by context is an effective way of keeping the differential diagnosis manageable. For example, if we are seeing a young adult with delirium in the emergency department, our differential diagnosis will focus on meningoencephalitis, or alcohol or substance use; if called to the oncology ward because of delirium in an older patient receiving chemotherapy for lung cancer, we will be considering electrolyte disorders, metastatic disease, and opioid toxicity. When taking a focused history, we select those questions relevant to the problem and its context, aiming to narrow the differential diagnosis to a few possibilities at which examination and investigation can be directed.

The focused history must establish a clear chronology of events, because this is key to understanding causal relationships. In addition, the mode of onset, the time course, and the duration of symptoms are major clues to the underlying disease or pathophysiology. In neurological disorders, for example, the onset of symptoms over seconds or minutes suggests vascular disorders or epilepsy; over hours or days, infection or demyelination; and over weeks or months, neoplastic or degenerative diseases.

Comorbidities or 'long-term conditions' affect one in three of the UK adult population (one in two of those over 60) and are therefore frequently part of the clinical picture. Defining the patient's comorbidities is important, as these shape the differential diagnosis and often influence the choice of treatment. In suspected sepsis, for example, the range of infections to be considered is very different if there is a background of HIV–AIDS or of chronic liver disease. Establishing the patient's current (and recent) medication is also a central element of the focused history. A list of the patient's medication alerts you to comorbidities the patient may not have mentioned; and the presenting problem may be related to medication. You also need to ask specifically about allergies (and check for these in the patient's records). An abbreviated social history should be taken. As a minimum, you need to know the patient's usual functional status, home circumstances, and tobacco and alcohol use. The occupational, travel, and sexual history may all be relevant to a given problem.

A complete history (Table 3.2) remains central to the holistic care of the patient. In patients admitted to hospital, a complete history should be taken once their condition has been stabilized: this ensures that key diagnostic information has not been overlooked or misinterpreted, addresses psychosocial issues not covered in the focused history, and provides data relevant to longer-term care.

Getting the story straight

'Getting the story straight' is a crucial part of history taking: it is the process of summarizing the information we have gathered and

Box 3.2 A 36-year-old man with acute chest pain and breathlessness

Patient's story: 'I've not felt well for a few days. I thought I was going down with the flu. For the past day or so I've had this pain in the middle of my chest. If I lean right forward, it's a bit easier. The pain makes my breathing difficult.'

Novice trainee: 'The patient is a 36-year-old man with short history of pleuritic chest pain and breathlessness. He was previously well. He has a temperature of 38.0°C. There is a loud systolic murmur. His lungs are clear. His calves are soft and non-tender.'

Expert trainee: 'The patient is a 36-year-old man with central pleuritic chest pain which has developed in the context of a flu-like illness. He has had no previous episodes. There is no past history of connective tissue disease or other major illness. Examination shows him to be mildly unwell with a temperature of 38.0°C. A pericardial friction rub can be heard, with systolic and diastolic components. His jugular venous pressure is not raised and the lungs are clear. The rest of the examination is normal.'

Consultant: 'What do you think is the diagnosis?'

Novice trainee: 'He could have had a pulmonary embolism, which can happen even if you don't have risk factors for DVT. It could be pneumonia, although he hasn't had a productive cough and his lungs are clear. I can't explain the murmur. Infective endocarditis seems unlikely.'

Expert trainee: 'The patient has the features of acute pericarditis, with a diagnostic friction rub. This is likely to be viral in origin. There are no signs of myocarditis or cardiac tamponade. Pneumonia with pericarditis needs to be considered, but there are no clinical signs of pneumonia and he looks too well for purulent pericarditis.'

shaping it into a narrative or story that provides a coherent account of what has happened to the patient. This act of organization may lead us to the diagnosis. When it doesn't, it will usually narrow the differential diagnosis to a manageable number of possibilities, and direct our next steps. Box 3.2 illustrates how our ability to get the story straight is improved by experience, and also demonstrates the interplay between history taking and examination. The novice trainee has taken an adequate history but has failed to see the relevance of some of the answers, has misinterpreted a key physical sign, and cannot pull the information together into a working diagnosis. By contrast, the expert trainee has recognized the pericardial friction rub and deftly summarizes the features which make acute viral pericarditis the likely diagnosis.

So, how can we transform ourselves from novices into experts? Central to this transformation is the acquisition of a broad and deep knowledge of diseases and their clinical presentations. If it takes 10 000 hours practice to become an expert in other fields, it may well take experience of 10 000 patients to achieve this as a doctor. But as well as these clinical encounters, to become experts we have to practice presenting cases to colleagues, articulating the differential diagnosis, and defending our choice of working diagnosis.

Getting the story straight refers to the entirety of information in the history: as well as what we learn from the patient, this will often include the accounts of doctors, nurses, paramedics, and others and, depending on the problem, those of family members or carers. Memory is, of course, fallible, and we need to confirm and supplement these accounts with evidence from relevant documents. In a patient with a complex problem on a background of several major comorbidities, we can be dealing with a mass of information, often contained in multiple volumes of hospital notes. To manage this information effectively, we have to give it structure: we need a problem list.

Handling complexity: The use of problem lists

A problem list is a summary of all of the patient's medical problems, including psychiatric, social, and other factors that may be relevant to care. The problem list of a 66-year-old woman admitted on-take with acute kidney injury is shown in Table 3.3. Problems are stated at the

Table 3.3 The problem list of a 66-year-old woman admitted with acute kidney injury

Active problems	Inactive problems
Acute kidney injury? cause Dec 2014, normal renal function Nov 2014	Ulcerative colitis 2004
Acute coronary syndrome Nov 2014, single-vessel coronary disease, PCI of proximal LCX stenosis (bare-metal stent), normal LV systolic function on echocardiography	Right hip replacement 2008
Psoriasis with arthritis 2002	Left hip replacement 2009
Primary hypothyroidism 1990	

level of current understanding; unexplained clinical features or laboratory results should be included (e.g. Thrombocytopenia? cause). In the case of diseases such as diabetes or ischaemic heart diseases, which have a wide clinical spectrum, it is helpful to add relevant information in summary form, with dates. Inactive problems are those medical problems the patient has had in the past but do not currently need treatment.

A concise, up-to-date summary of all clinical problems benefits the patient in several ways. It helps offset the detrimental effects of care fragmented between medical shifts and between specialists. Discerning the potential interrelationships between problems is made easier by listing them. For example, in the case shown in the box, the onset of acute kidney injury shortly after percutaneous coronary intervention suggested cholesterol embolism, contrast nephropathy, or statin-induced rhabdomyolysis as possible mechanisms (it proved to be the last). The problem list also reminds us of those pieces of information (e.g. anaphylaxis from meropenem, renovascular disease), which might be buried in Volume 3 of the notes but are of great importance to safe prescribing.

The future

In most hospitals, we still write the history in the notes. But, as UK secondary care moves from paper to electronic records, history taking faces challenges and opportunities. A major challenge is to get hardware and software suited to the way we work. We don't want to be using desktop computers with keyboard entry of data into systems built around tick boxes: this will slow down the

assessment of patients and degrade the quality of the information recorded. Rather, we need portable wireless devices with hand-writing, sketch, and voice-recognition software, so that we can easily gather complete information whether we are seeing the patient in the emergency department, on the ward, or in clinic. And the way in which the data are stored must preserve the richness of language.

With electronic recording comes the opportunity to use real-time diagnostic software, which could suggest a differential diagnosis as the history evolves, remind us of the relevant questions we haven't yet asked, and prompt us as to what information should be sought from the examination and investigation. Problem lists could be automatically generated from both primary and secondary care records, with links to source documents, imaging, and laboratory results. The diagnostic usefulness of the history, as well as its other functions, would be enhanced by these changes.

Whether written on paper or recorded electronically, the history—the narrative of the patient's illness—will remain the foundation of care. In the craft of bedside clinical assessment, history taking is closely linked to examination: examining the patient enables us to test immediately diagnoses suggested by the history, and the physical signs often evoke new diagnostic possibilities which can be explored by further questioning. In Chapter 4, we look critically at the place of physical examination in twenty-first-century medicine.

4 The physical examination

David Sprigings

Introduction

A 37-year-old man is admitted on the medical take with right hemiparesis. Examination shows Horner's syndrome contralateral to the weakness. Within a few moments, we have a working diagnosis of ischaemic stroke due to left carotid artery dissection. Although often focused on diagnosis, as powerfully demonstrated in this patient, the physical examination has broader purposes (Box 4.1). It has been traditionally defined as the evaluation of the body and its functions by the methods of inspection, palpation, percussion, and auscultation, but is more than this. Instruments such as the thermometer, stethoscope, tendon hammer, and ophthalmoscope increase the range and precision of our findings. And some tests which can be readily done at the bedside (such as measurement of oxygen saturation or blood glucose) have become incorporated into the examination, as they too provide immediately available data for integration into diagnostic thinking and patient management.

Notwithstanding the advances of the past 40 years in imaging—which is in effect an extension of the examination—the physical signs remain central to our assessment of patients, especially those with acute illness. And failure to detect these signs contributes to misdiagnosis. A study from a US hospital found that one-quarter of acute medical patients when re-examined had signs which had been overlooked on admission and which changed the diagnosis and management. To be effective clinicians, we must have a competent examination technique, but also need a clear understanding of what the signs can and can't tell us in a given clinical situation (Box 4.2).

Box 4.1 Purposes of the physical examination

- In acute illness, to define the physiological status of the patient and need for immediate organ support
- To test diagnostic hypotheses suggested by the history by the presence or absence of signs of disease
- To evoke diagnostic hypotheses
- To assess the severity of a known disease
- To contribute information (e.g. height and weight) to the database of the patient
- To check for asymptomatic abnormalities of diagnostic or prognostic importance (e.g. breast lump, enlarged prostate, hypertension)
- To meet the expectations of the patient, and strengthen the doctor–patient relationship
- To maintain clinical skills at examination

Box 4.2 Facts we need to know about physical signs

Significance

How likely is a patient with this sign to have disease?
Which diseases may give rise to this sign?
How often is this sign seen in a given disease?
How is this sign influenced by age and comorbidities?
How much does the presence or absence of this sign change the probability of a given disease?

Accuracy

How closely does this sign agree with an objective standard?

Reliability

How well do doctors agree with each other or with themselves on the presence or absence of this sign?

Let's begin by considering how we use examination findings in diagnostic reasoning.

Physical signs and diagnostic reasoning

There is two-way traffic between our thoughts about diagnosis and the physical signs. Diagnostic hypotheses suggested by the history can be tested by examination: if the signs of the disease in question are present, that disease becomes more likely, and if absent, less likely. And the examination may yield signs which suggest diagnoses we hadn't previously considered. As diagnosticians, we therefore need ready access to two categories of information: the diseases associated with a given sign, and the signs associated with a given disease.

Consider a 68-year-old man, an inpatient receiving chemotherapy for lung cancer, who has become breathless. As the medical registrar leading the night team, you are called to see him on the oncology ward. The differential diagnosis is wide and includes cardiac tamponade, superior vena caval (SVC) obstruction, and pleural effusion. You were told over the phone that he has an oxygen saturation of 90% breathing air, a pulse rate of 110, a blood pressure of 135/80, and a temperature of 38°C. Your first thought is that he has pneumonia. However, the chest examination is unremarkable, and the sign that strikes you is an elevated jugular venous pressure.

Cardiac tamponade now seems more likely than pneumonia. Pulmonary embolism and SVC obstruction also cross your mind. You also wonder about whether his chemotherapy could have resulted in heart failure. Indeed, a number of diagnoses are possible (Table 4.1). As you continue the examination, you weigh up the significance of the other findings and how they affect the likelihood of the diseases under consideration.

The logic driving your assessment is that the absence of a sign which is characteristic of a disease (seen in >95% of patients), or the absence of two or three signs each found in >80% of patients, is strong evidence against that disease being present. If this were cardiac tamponade causing breathlessness, you would expect a low blood pressure with pulsus paradoxus (Table 4.2), and your patient does not show these signs.

So, tamponade is not the leading diagnosis, but hasn't been definitively ruled out. How likely is pulmonary embolism? Here a clinical decision rule can sometimes help. The Wells score (see Chapter 101), which provides a guide to the likelihood of

Table 4.1 Possible causes of an elevated jugular venous pressure in a breathless 68-year-old man receiving chemotherapy for lung cancer

Pathophysiology	Mechanisms
Fluid overload	Acute kidney injury due to chemotherapy Excessive intravenous fluid administration
Superior vena caval obstruction	Extrinsic compression by the primary tumour or mediastinal lymphadenopathy Thrombosis around a central venous catheter
Mediastinal shift	Massive pleural effusion causing mediastinal compression
Raised intra-pericardial pressure	Metastatic pericardial disease with effusion
Raised right atrial pressure	Pulmonary embolism with right ventricular dysfunction Cardiomyopathy due to chemotherapy Acute inferior myocardial infarction with right ventricular infarction

Table 4.2 Frequency of physical signs in cardiac tamponade

Sign	Pooled frequency (95% confidence interval)
Pulsus paradoxus >10 mm Hg	82 (72–92)
Elevated jugular venous pressure	76 (62–90)
Tachycardia	77 (69–85)
Hypotension	26 (16–36)

Data from Roy CL, et al. Does this patient with a pericardial effusion have cardiac tamponade? *JAMA* volume 297: 1810–8, 2007.

pulmonary embolism, is 4 (heart rate >100/min, immobilization, malignancy), indicating that the probability of pulmonary embolism is unlikely. As his breathlessness came on abruptly, you feel the likelihood of pulmonary embolism is higher than predicted by the score; however, he has been receiving prophylaxis against venous thromboembolism.

By examining the patient, and applying a knowledge of the significance of signs, within a few minutes you have been able to assemble a differential diagnosis in a complex clinical situation, and come to a rational decision about immediate management. No technology can rival this. Imaging will, of course, be part of your management, and we next consider the relation between examination and imaging.

Examination and imaging

The fact that examination may be an unreliable guide to the presence of disease leads some doctors to maintain it is better to get the relevant scan than to spend time examining the patient. This extreme view is clearly wrong (although has some attraction when one is faced with a complex neurological problem on a particularly heavy take), not least because the scan you want may not be immediately available and, in the setting of acute illness, can't do what the examination can, that is, define the physiological status of the patient and the need for immediate organ support. The information provided by the history and examination is crucial to our choice of imaging, our judgement as to how urgently it is needed, and the interpretation of the findings. Deciding if a patient has had an ischaemic stroke and should receive thrombolysis requires integration of clinical and CT data. Identical right upper lobe shadowing on the chest X-rays of two patients with cough and weight loss has a different significance for the 22-year-old student back from India and the 58-year-old smoker who has never travelled abroad. And if the scan result is discordant with the clinical findings, we will need to reassess the patient (and the scan).

Of course, doctors (and patients) may not be satisfied by a normal examination. There are many clinical situations in which the examination findings are of limited use in ruling in or ruling out serious disease. This is notoriously the case in relation to coronary artery disease. In the diagnosis of stable coronary disease, the examination is of little help (although may point to an alternative cause for angina, such as aortic stenosis or hypertrophic cardiomyopathy). Nor can the signs accurately identify patients with acute coronary syndrome. And the examination is a very poor guide to left ventricular systolic function, a key prognostic variable in coronary disease.

So we need to know the limitations of the examination in specific situations, and when imaging or laboratory testing is required in addition to clinical assessment. Imaging is often costly, may not improve outcomes, and if radiation based contributes to the risk of cancer: the challenge for healthcare systems is to define the appropriateness of imaging in a given clinical setting, and in which order tests should be done. The definition of appropriateness will necessarily be based on clinical assessment, and this brings us back to the value of physical signs.

How good is that sign?

As well as knowing its associations with diseases, to fully understand the significance of a sign, we need to have a feeling for its accuracy and reliability.

Table 4.3 A 2 × 2 table showing the frequency of dullness to percussion in patients with and without pleural effusion

		Pleural effusion (by radiography)	
		Present	Absent
Dullness to conventional percussion	Present	89%	19%
	Absent	11%	81%

Reprinted from *Evidence Based Physical Diagnosis*, Steven McGee, p 288–290, Copyright 2012, with permission from Elsevier.

Accuracy

Accuracy is a measure of the extent to which the sign agrees with an objective standard. For example, consider dullness to percussion as a sign of pleural effusion. Table 4.3 shows the frequency of this sign in patients with pleural effusion defined by radiography. Dullness to percussion is not invariably present in patients with pleural effusion (as small effusions are not detected), nor invariably absent in patients without pleural effusion (as it may be found in other pleural, pulmonary, and diaphragmatic disorders). Nevertheless, we can see from the data in Table 4.3 that its presence makes the diagnosis of pleural effusion more likely, and its absence less likely. But by how much? Likelihood ratios (LRs) can help answer this question.

We met LR in Chapter 1. Applied to the sign of dullness to percussion, the positive LR is the percentage of patients with pleural effusion who show the sign, divided by the percentage of patients without pleural effusion who also have the sign, that is, 89% divided by 81%, which gives an LR of 4.7. We can also calculate the negative LR, that is, the percentage of patients with pleural effusion who don't show dullness to percussion, divided by the percentage of patients without pleural effusion and who also lack the sign. The negative LR is 11% divided by 81%, which is 0.1. These LR can be translated into approximate changes in the probability of disease (see Chapter 1). So, the presence of dullness to percussion means that the probability of pleural effusion is increased by around 30%; the absence of the sign equates to a decrease in probability of around 45%.

Accurate signs are therefore signs with high positive or low negative LR. Signs with high positive LR help rule in specific diseases, while signs with low negative LR help rule these out. As can be seen from Table 4.4, few signs in isolation have the power definitively to rule in or rule out diseases (i.e. positive LR >10 or negative LR <0.1). Combinations of signs are more powerful in diagnosis. For example, the presence or absence of lung crackles, on its own, makes little difference to the likelihood of pneumonia. But the combination of fever >37.8°C, tachycardia, lung crackles, and reduced breath sounds has a positive LR of 8, increasing the likelihood of pneumonia (from whatever value is indicated by the clinical setting and the patient's symptoms) by around 40%.

Table 4.4 Accuracy of some physical signs

Sign	Positive LR	Negative LR
Conjunctival pallor as a sign of anaemia	4.7	0.6
Neck stiffness as a sign of subarachnoid haemorrhage	5.4	0.7
Lung crackles as a sign of pneumonia	1.8	0.8
Splenomegaly as a sign of cirrhosis in a patient with chronic liver disease	2.5	0.8
Presence of ascites as a sign of hepatocellular disease in the patient with jaundice	4.4	0.6
Palpable bladder, for detecting >400 ml urine in bladder	1.9	0.3
Extensor plantar response as a sign of unilateral cerebral hemispheric disease	8.5	Not significant

Abbreviations: LR, likelihood ratio.

Data from McGee S. *Evidence-Based Physical Diagnosis*. 3rd edition, 2012. Elsevier Saunders.

Reliability

Reliability usually refers to the extent to which two or more doctors agree on the presence or absence of the sign (inter-observer reliability). Doctors may disagree about examination findings for several reasons. The definition of the sign (e.g. an increased or decreased carotid pulse volume) may be imprecise. The sign may change with time or treatment (e.g. pericardial rub in acute pericarditis, or the jugular venous pressure in heart failure). The examination technique of one doctor may be flawed (e.g. failing to position the patient appropriately to hear the murmur of mitral stenosis or aortic regurgitation). The environment (e.g. a noisy emergency department) or factors such as fatigue and distraction may interfere with the examination. And, finally, a doctor's view as to the likely diagnosis may bias his or her interpretation of borderline abnormalities.

Reliability can be measured in several ways. The kappa statistic, which takes account of agreement by chance, is often used: this ranges from -1.0 (complete disagreement) through 0 (chance agreement) to $+1.0$ (perfect agreement). A kappa statistic of <0.4 indicates poor agreement, and one of >0.8 , excellent agreement between doctors. When put to the test, the reliability of many signs is surprisingly limited. For example, one study of patients with respiratory diseases found that almost all signs (reduced chest movements, cyanosis, prolonged expiration, impalpable apex beat, cricosternal distance, tachypnoea, increased or decreased tactile fremitus, and displaced trachea) had kappa values of <0.4 . Only finger clubbing had a kappa value over 0.4 (just—at 0.45). Other studies have shown similar results, although with better agreement as regards pleural rub and wheeze.

A low kappa value doesn't mean the sign has no value: provided the accuracy of the sign is high, and its intra-observer reliability is good (i.e. a doctor agrees with him- or herself about the presence or absence of the sign on repeated examinations), it may still be a very useful sign. The sign of spontaneous retinal vein pulsation exemplifies this. It's a difficult sign, but once you have learnt to see it, you will be confident as to its presence or absence. And its presence effectively establishes that intracranial pressure is normal (although the converse is not the case, as 10% of normal subjects don't show the sign).

Of course, issues of accuracy and reliability also apply to imaging tests: interpreting a scan requires the examination of the images. And we soon learn that a normal scan doesn't necessarily mean the absence of disease: as with physical examination, subtle findings can be missed, or the disease in question cannot be detected by that particular scan.

Other factors

The accuracy and reliability of the examination are strongly influenced by experience and training. Some signs, such as jaundice or

hemiplegia, are readily apparent, whereas others (e.g. fixed splitting of the second sound) are harder to detect, and will often be missed by non-specialists. Specialists become better at the examination of their system as they do the examination more often, see more patients with abnormal signs, are highly motivated to interpret the signs correctly, and have their findings repeatedly compared with imaging and laboratory results. Of course, whether you are a novice or a specialist, physical signs will be missed if the patient is not examined systematically and thoroughly.

Aging and comorbidities also affect the accuracy and reliability of physical signs. A patient with end-stage kidney disease due to diabetes, treated by haemodialysis via an arteriovenous fistula, has many abnormal signs that may make distinguishing new from established disease difficult. The standard 70 kg man has been left behind in the twentieth century, and we must take account of the effects of obesity on the physical signs, particularly in relation to cardiovascular, respiratory, or intra-abdominal disease.

The future

The physical examination has changed over time and will continue to change. We no longer estimate cardiac size by percussion. Pulse oximetry is a much better guide to oxygen saturation than the presence or absence of cyanosis. Imaging with a portable ultrasound machine and immediate point-of-care measurement of biomarkers will be of increasing importance to our assessment of patients in the emergency department, on the ward, or in clinic. The information provided by these tests will require us to question which elements of the examination add value, and which are now redundant. But given the diagnostic and prognostic information yielded by physical examination, and the fact it can be done anywhere, repeated at any time, and needs no power source, it is safe to say the ability to examine a patient and make sense of the findings will remain a defining characteristic of a doctor.

5 The psychological examination

Jonathan Price

Approach to psychological diagnosis

Have broad aims

The aims of psychological assessment are broad:

1. to rule in/rule out common and important psychiatric diagnoses, including dementia, delirium, alcohol and substance use (harmful use, intoxication, dependence, withdrawal), depression, and health anxiety
2. to rule in/rule out possible risks of psychiatric illness, including their nature, degree, and timeline
3. to consider the influence on prognosis of the patient's beliefs about their illness
4. to rule in/rule out possible treatments, through patient's attitudes to treatments

Use an integrated, biopsychosocial approach

In medicine, psychological factors are often regarded as separate to physical factors, and psychological illness as distinct from physical illness. Yet health and illness states reflect multiple, interrelated physical, psychological, and social factors. In the weeks after myocardial infarction, the beliefs that a person has about their heart and damage to it will influence their willingness to take medicines and to engage in physical rehabilitation. Their mood will also be influential, as will social factors such as availability of a supportive partner, and opportunity for gainful employment.

Diagnose positively

Many doctors diagnose psychological illness through a process of exclusion of multiple physical causes. This is potentially harmful for two reasons: first, it means that psychological illness is diagnosed and treated late; and, second, it means that psychological factors, which contribute to the outcome of almost all patients, may not be considered at all.

Consider the risks

Assessing the nature, severity, and timeline of risks of psychiatric illness is a core component of the psychiatric assessment. When doctors think of the risks of psychiatric illness, they often think only of risk of harm to self (such as overdosing, jumping, or hanging) and risk of harm to others (such as assault or killing). However, there are several other important risks to consider (Table 5.1).

Stray outwith your comfort zone

Many doctors consider psychological assessment and management to be outwith their expertise or remit. They may refer on for formal psychiatric assessment, refer back to primary care, or simply ignore the issue. Doctors in any setting must be able to identify patients with core psychiatric problems and conduct a basic assessment.

Stay safe

The safety of the assessing doctor is paramount, and is often taken for granted in general hospital settings, whereas psychiatrists and doctors working in the community are acutely aware of their vulnerability.

Integrate information through time

Integrate information across background history, history of presenting complaints, and mental state examination (MSE). In the background,

has the person harmed themselves before and, if so, how often, and how? In the recent history, has the person suffered from low mood, hopelessness about the future, or suicidal thoughts or impulses and, if so, have they acted on them? In the MSE, are they currently depressed, with hopeless thoughts, suicidal thoughts, or suicidal plans? If so, how detailed are their plans and how likely are they to act?

Key points in the history

Interview a corroborator

A corroborator is a person who knows the person's recent situation. Usually, this will simply confirm the patient's account, but sometimes it will refute the patient's account or give important new information. For example, an elderly woman asks her GP for help with rehousing, as her neighbours are threatening her through the walls. Is this real, or is she suffering from auditory hallucinations and persecutory delusions? Various corroborators can be helpful—most usual is a husband, wife, partner, or carer. Take care to obtain the patient's permission, or to be sure that this is not required (such as through focused history taking with a close relative of a patient with a confusional state).

Background history

Is there a family history of mental illness?

If so, which illness, and in which relative(s)? Draw a genogram. Is there a family history of suicide?

What is the nature of the person's social situation?

With whom do they live, and are those people supportive and reliable or unsupportive and chaotic? Is the person currently employed and, if so, does their job provide a clear structure for their day/week? Do they have dependents, such as children or ageing relatives?

Take a careful alcohol and illicit drug history

Be systematic: alcohol and illicit drugs are common contributors to mental illness. Harmful use may not be mentioned by the person because they are using alcohol or illicit substances such as cannabis as 'self-medication'.

Take a careful medicines history

Ask about prescribed medicines and non-prescribed medicines such as those available from chemists. Don't forget herbal remedies, vitamins, and minerals—these help our understanding of attitudes to health, illness, and treatment.

Don't forget the person's medical history

People with psychiatric disorder such as schizophrenia are at high risk of physical disorder, due to poor self-care, poor access to physical health care, and the metabolic side effects of some antipsychotics. People with physical disorder such as stroke are at high risk of psychiatric disorders such as depression, due to resulting disability, direct effects on brain function, and indirect effects on brain function via stroke-related medicines such as antihypertensives.

What is the person's past psychiatric history?

The past is a key predictor of the future. Have they had a mental illness before, and, if so, which? How were they treated? Have they been hospitalized? What risks were evident during these episodes? (See Table 5.1.)

Risk	Example(s)
Suicide/risk of harm to self	Depression
Homicide/risk of harm to others	Schizophrenia
Deterioration in mental state	Any major mental illness
Wandering	Dementia
Abuse/exploitation (sexual, physical, financial)	Dementia
Driving/operating machinery	Drowsiness due to medication; poor concentration due to depression
Care of dependents, such as children and elderly	Moderate-severe depression;
Fire (due to fire-setting or inattention)	Mania, schizophrenia, cognitive impairment
Sexual disinhibition, leading to STIs/pregnancy/relationship breakdown	Mania
Overspending	Mania

History of presenting complaints

First, ascertain the main symptom(s), their duration, precipitants, and impacts.

Second, enquire specifically about symptoms and behaviours associated with the main symptoms. Table 5.2 outlines, within a biopsychosocial framework, the symptoms commonly associated with depression. Don't forget to enquire about risks, such as suicidal thoughts, suicidal impulses, and suicidal acts. Distinguish between **subjective** and **objective lethality**. As doctors, we may dismiss an overdose of ten amoxicillin tablets as trivial (objective lethality), and yet it might have high subjective lethality—the patient may report that they thought they would die because it is many times the standard dose.

Finally, what treatments have been tried, and how acceptable and effective have they been?

The psychological examination

The psychological examination is usually called the MSE. It aims to determine both current **symptoms** (what the patient reports about current psychological symptoms, such as mood, thoughts, beliefs, abnormal perceptions) and current **signs** (what you observe about the patient's current mood, thoughts, beliefs, abnormal perceptions). A symptom which has resolved, such as a belief held last week but not reported or evident today, is part of the history but not of the MSE. The MSE should not be used in isolation; rather, the background history, history of presenting complaint, corroborative history, MSE, and physical examination will all contribute to diagnostic decision-making.

Several aspects of the MSE involve complicated symptoms and signs of mental illness, some of which are rare. Therefore, any

Risk	Example(s)
Biological	Low energy; poor sleep (including early morning waking); poor appetite; weight loss; constipation; amenorrhoea; low libido
Psychological	Poor motivation; self-neglect (e.g. eating, washing, medicating); poor enjoyment of usually pleasurable activities; diurnal mood variation (usually feeling worse in the morning); hopelessness (negative about the future); guilt (negative about the past); low self-esteem (negative about the present self); suicidal thoughts, impulses, and acts; homicidal thoughts, impulses, and acts; helplessness (negative about prospect of being helped by others or by treatment)
Social	Social withdrawal; absence from work; poor performance at work; relationship difficulties

observations made during an individual MSE should be used with caution, and only in their clinical context. It is also important to consider the diagnostic implications of any MSE abnormalities recorded, taking care not to document findings which have a high diagnostic specificity unless their presence is certain. For example, if someone laughs while describing a death, is this because they are uncomfortable (common, and normal) or is it 'incongruity of affect' (uncommon, abnormal, and seen specifically in schizophrenia alongside other symptoms and signs of the disease)?

A Bayesian approach to psychiatric diagnosis is desirable. Pretest probability (from the presenting complaints) informs an initial differential diagnosis, allowing the appropriate use of further specific questions during the history and MSE to rule in or rule out those diagnoses. For example, if a patient has a history of bipolar disorder and now presents with recent elevated mood, his pretest probability of a manic episode is high. In this case, it would be very appropriate to ask questions to further 'rule in' the diagnosis such as 'Have you been buying any interesting things recently?'—a question which would be much less useful if the pretest probability of bipolar disorder were low. In the same way, it is important to use general screening questions during the MSE to identify patients who may require further, more detailed questioning.

Preparation for the MSE

Preparation involves consideration of the needs of the patient (comfort, privacy) and the needs of the interviewer (safety). It is helpful to consider the questions 'Who?', 'Where?', 'With whom?', and 'With alarm?'.

Who is the patient?

How much risk does the patient pose to the interviewer? If this is unknown, assume a high risk. What risks are there for the patient? These include the risk of absconding with intent to self-harm, and the risk of being unforthcoming about their problems unless they are relaxed in a private, quiet setting.

Where is the patient to be seen?

The setting should be conducive to confidential discussion, but should never compromise the interviewer's safety. If there is a designated interview room, is this close to other staff, and is there an alarm button? Is the risk too high for such a room to be used? Seating should be arranged to ensure that the exit is easily accessible for the interviewer, and that any alarm button is within reach.

With whom is the patient to be seen?

It may be necessary to interview a patient with another member of staff. This is especially important if the patient is unknown to you or your team, may behave threateningly, or is sexually disinhibited, manipulative, or litigious. Should hospital security staff be called to supervise?

With alarm?

If an alarm system is in use, make sure you are familiar with its operation, and that you can activate it if needed. Know how to summon help, such as via the emergency number for your hospital's security service.

The components of the MSE

The MSE typically comprises seven areas of assessment: (1) appearance and behaviour, (2) speech, (3) mood, (4) thoughts, (5) perceptions, (6) cognition, and (7) insight. The interview begins with a brief explanation of the duration and purpose of the interview, followed by data gathering to illuminate the history. This allows the examiner to gain a general impression of the patient, while assessing (1) appearance and behaviour, and (2) speech, which require no direct questioning. These observations need to be recorded descriptively, rather than interpretatively, to allow other health professionals to reach their own conclusions from the 'raw' observations. Subsequent sections of the MSE are assessed both subjectively (by asking the patient) and objectively (by recording the observations of the interviewer).

Appearance and behaviour

Relevant aspects of the patient's appearance include apparent body mass index, posture, clothing (e.g. appropriateness and cleanliness),

hygiene and grooming (e.g. hair, make-up), and evidence of self-harm or IV drug use. Relevant behavioural features include eye contact, facial expression, the level and nature of the patient's activity, and the quality of rapport developed. A depressed patient, for example, may be downcast, with poor eye contact, a furrowed brow, slow motor activity, and poor rapport.

Speech

Recording the **content** of the patient's speech is deferred until the 'Thoughts' section of the MSE. The patient's speech is assessed by considering:

Rate and quantity: Copious speech that is hard to interrupt is 'pressure of speech', which occurs in mania. Slow, sparse, or monotonous speech is described as 'retardation' and may occur in depression or dementia. The combination of slow speech and slow movements is termed 'psychomotor retardation'.

Volume: The patient may speak quietly (depression or paranoia) or loudly (mania or deafness).

Spontaneity: Most people talk spontaneously once they relax, but people with depression, schizophrenia, or anxiety may find it difficult.

Mood

First, assess subjective mood, by asking the patient, 'How are you feeling in your spirits/mood?'

Then, assess objective mood, which includes:

The predominant mood(s) during the examination: e.g. depressed, elated, angry, anxious, or suspicious; alternatively, record that the mood was 'unremarkable'

The variability of the mood(s) during the examination: i.e. whether the patient seems emotionally labile (dementia, mania), emotionally flat (depression), or shows normal situational reactivity

Congruity: does the patient's mood 'fit' with his perceptions and thoughts (congruent mood, normal) or does it clash (incongruity of mood, sometimes seen in schizophrenia)

Thoughts

Information about a person's thoughts is mainly derived from their speech, but may also be derived from writing or drawings, or their behaviour. Thoughts are assessed in two stages: form and content.

Form of thought: This is normal if 'words' and 'sentences' are linked together unremarkably, in the logical way that we usually take for granted. It is abnormal if these links are unusual (such as words or phrases being linked by puns or rhymes, as in the 'flight of ideas' seen in mania) or absent (such as shifts to another, unrelated phrase, which the patient struggles to explain, as in 'loosening of associations', seen in schizophrenia).

Content of thought: The interviewer should ask specifically about (a) depressive thinking including suicidality, (b) obsessions, and (c) delusions.

Depressive thinking: Questions address current helplessness, hopelessness, and guilt. Screen for current suicidal ideation with 'Do you feel as though you would rather not wake up in the morning?' and 'Are you having any thoughts about harming yourself at the moment?' If so, further questions are required, such as 'Have you considered how you might end your life?' and 'Have you got any plans to carry out your ideas?' Asking about suicidal thoughts can be difficult, but is essential.

Obsessions: These are recurrent, intrusive thoughts, images, impulses, or actions that occur despite attempts to suppress them. The interviewer can ask whether the patient is experiencing any thoughts which are repetitive and intrusive, but do not make logical sense. Obsessional phenomena appear to originate from the patient's own mind, rather than from outside his/her head. Obsessional actions such as rechecking are detected by 'Do you have to do any things over and over again?'

Delusions: A delusion is a belief that is firmly held on inadequate grounds, and which is not a conventional belief held by others from a similar cultural background. To a patient, a delusion is

identical to any strongly held belief, and it is therefore pointless to ask whether they have any delusions. Rather, delusions become evident on speaking to other people, or by following up elements of the history—once revealed, the patient is asked sympathetically to expand on these beliefs. Fixity of belief must be tested, by tactfully but firmly suggesting an alternative interpretation of the evidence.

Perceptions

Abnormalities of perception include distortions, illusions, and hallucinations.

Distortions

Manic patients may report that perceptions such as colours are more intense during manic phases; and depressed patients may report that the world appears more grey. Changes in hearing sensitivity (hyperacusis/hypoacusis) may be an indication of either physical disorder or psychiatric disorder, such as mood disorder.

Illusions

These occur when the patient misinterprets normal stimuli. When walking alone (and therefore anxious) through a park at night (and therefore sensorily impaired), it is normal to occasionally 'see' something alarming rather than the bush that is actually there.

Hallucinations

A hallucination is a sensory experience perceived in the absence of an external stimulus. Hallucinations are usually auditory or visual in form, although olfactory, gustatory, or somatic hallucinations are sometimes described. Auditory hallucinations usually indicate psychotic illness, whereas visual hallucinations are more common in physical disorders, including dementia, and drug/alcohol intoxication or withdrawal. Ask sensitively about hallucinations by starting with a screening question such as 'Some people experience things that might not actually be there—have you had anything like that?' Then ask whether the patient is experiencing 'voices' from outside their head, or people, objects, sounds, or lights that others cannot see. Are auditory hallucinations second person (voices speaking to you) or third person (voices speaking about you, a first-rank symptom of schizophrenia)? Some people misinterpret their own mind's 'voice' as an auditory hallucination, and so attempt to distinguish whether the perceptions are coming from within ('pseudohallucinations') or from without the patient's head (true hallucinations).

Cognition

If there is any suspicion of cognitive impairment (e.g. patient or corroborator mention poor concentration, poor memory, or a history of head injury or alcohol abuse), or if the patient is over 50 years old, an appropriate cognitive screen should be conducted to assess the following domains: orientation, attention, language, memory ('short-term' and 'long-term'), executive function, praxis, and visuospatial skills. The **Mini-Mental State Examination (MMSE)** is the most widely used screening test of cognitive function. A **clock-drawing test** may also be helpful to detect problems with praxis or executive functioning. Depending on the findings, detailed assessment by a specialist may be required.

Insight

The 'psychiatric' concept of 'insight' is similar to that of concordance. How does the patient explain or understand his difficulties, and how does he view treatments, including self-management? How similar is the patient's understanding to that of those treating him?

How to present the psychological history and examination

The method of presentation will clearly depend upon the setting and the time available. Although a psychiatric assessment may be long and complex, the effective clinician will distil this into

something much briefer and more easily comprehensible. A simple approach is to:

1. summarize the **key** points in the history and examination
2. present the preferred diagnosis and differential diagnosis, with a brief justification for each
3. comment on the nature and degree of the main risks

6 Confidentiality

Anna Rathmell

Introduction

There is a strong public perception that healthcare professionals can be trusted to keep medical information confidential. This trust is the key to patients' feeling comfortable with their doctors and being honest about the nature of their medical complaints and is therefore essential for the provision of a good healthcare system. However, this obligation to respect medical confidentiality is not, as is sometimes believed, absolute and there are circumstances where breaching confidentiality may be morally the best course of action and legally required.

Basic concepts

Ethical principles

The importance of medical confidentiality is underpinned primarily by two ethical principles. The first is respect for patient autonomy, or the right of a patient to have control over his own life and in this context to decide who should have access to his personal medical information. The second is a consequentialist idea that there is a duty to bring about the best possible consequences. A great deal of public trust is invested in the medical profession, and breaching medical confidentiality could result in a loss of this trust. Patients who do not trust their doctors may feel less inclined to divulge information about their condition, making it more difficult for them to be treated, the ultimate consequence being a lower standard of health care.

When has confidentiality been breached?

Confidentiality has been breached once a patient has been identified. A patient may be identified either by name or as a result of the nature of the information that has been divulged, for example, if the description of a patient's skin complaint means that he can then be identified by those who see him. If a patient has given valid consent for release of the information, however, this is not considered to be a breach of confidentiality. It is worth mentioning that something as simple as a note above a patient's bed saying 'Diabetic Diet', or a whiteboard displaying the names of patients on a ward could potentially be a breach of confidentiality.

Consent for disclosure of confidential information

In most circumstances, express consent should be obtained from the patient before disclosing his personal medical information (see Chapter 7). There are situations in which consent to sharing information about a patient can be implied. For example, patient information is routinely shared amongst members of a healthcare team without the need for express consent. However, information discussed within the team should be on a need to know basis, and each member of the team has a duty to keep the information confidential outside of this setting.

If an adult patient lacks competence to give consent to release of confidential information, then doctors should act in the patient's 'Best Interests' under the Mental Capacity Act 2005. It would normally be considered to be in a patient's best interests for information about his medical condition to be discussed with carers or close relatives. However, patients who are incompetent have the same legal rights for information about them to be kept confidential, and the same legal protection from unjustified breaches of confidentiality.

Minors over the age of 16 are assumed to be competent to give or refuse consent for disclosure of medical information. Minors below the age of 16 are assumed to be incompetent to give or

refuse consent for disclosure of medical information, unless they are assessed as being 'Gillick competent' (See Chapter 7 for further information on Gillick competence). However, in contrast to the situation with competent adults, doctors have a legal obligation to act in the best interests of a competent minor. This means that, if a doctor believes that it is in the competent minor's best interests for confidential information to be shared but the minor refuses consent, then it would generally be considered lawful for the doctor to disclose the information.

Doctors should normally discuss medical information about minors below the age of 16 with their parents. However, if a Gillick competent minor refuses consent for disclosure of information to their parents and it is in the minor's best interests for the parents not to be informed, then information may be withheld from the parents.

Balancing public interests

The law looks mainly at patient confidentiality from the perspective of 'public interests' rather than from the perspective of the individual patient. Article 8 of the Human Rights Act 1998 (HRA) establishes that individuals do have a 'private' right to confidentiality. However this right is not absolute and the public interest in maintaining confidentiality is so strong that, in the context of medical confidentiality, the HRA is of little significance. Therefore, when deciding whether or not a breach in confidentiality is justified, it is necessary to weigh up the public interest in breaching confidentiality versus the public interest in not breaching confidentiality.

The General Medical Council (GMC) offers guidance on when and how a breach of patient confidentiality may be justified. The three main points are as follows:

1. Disclosure of confidential information without consent would normally be justified only in order to prevent risk of death or serious harm to the patient or others. Preventing damage or theft of property would not normally be sufficient reason to breach confidentiality.
2. Disclosure of confidential information should only be made to an appropriate authority.
3. The patient should be informed before disclosure of his confidential information.

While there is a wide range of situations when a doctor must use his own judgement as to whether or not a breach of confidentiality is justified, there are some situations when there is a legal obligation for doctors to breach confidentiality, and some situations when a doctor should not breach confidentiality.

Some situations when doctors are legally obliged to breach confidentiality are as follows:

- notifiable diseases: Public Health (Control of Diseases) Act 1984 (Notifiable Diseases)
- termination of pregnancy: Abortion Act 1967
- births and deaths: Births and Deaths Registration Act 1953
- to the police, on request, name and address (but not clinical details) of someone alleged to be guilty of certain road traffic offences: Road Traffic Act 1988
- certain treatments for infertility: Human Fertilisation and Embryology Act 1990, modified by the Human Fertilisation and Embryology (Disclosure of Information) Act 1992
- suspected terrorist activities: Terrorism Act 2000
- search warrant signed by circuit judge
- under court orders

Disclosure of confidential information in these circumstances should only be made to specific authorities.

Doctors should not normally breach confidentiality in the following circumstances:

- prevention of minor harms to others
- prevention of minor crime (e.g. to property) or to help conviction in the case of minor crimes
- providing information leading to the identity of a patient being treated in a genitourinary clinic for any sexually transmitted disease
- providing reports or fill in forms (e.g. to insurance companies) disclosing confidential information without the patient's consent
- to satisfy someone's curiosity
- 'casual breaches' (e.g. gossip, or carelessly leaving patient notes on the train, etc.)

It would however be unwise for a doctor to lie, for example, to police or insurance companies. Instead, it might be sensible simply to refuse to discuss a patient's confidential medical information.

An important case

W v Egdel [1990]

W was a patient detained in a secure hospital as a potential threat to public safety after he killed five people and wounded two others. He was diagnosed with schizophrenia and treated with medication. After ten years in the secure hospital, he applied to a mental health review tribunal to be discharged or transferred to a regional secure unit, with a view to eventually being discharged. W's solicitors instructed a psychiatrist, Egdel, to examine W and write a report which they hoped would support W's application. However, Egdel's report strongly opposed W's discharge or transfer, instead suggesting he have further treatment. When W's solicitors received the report, they withdrew their application. They did not send a copy of the report either to the tribunal or to the hospital caring for W. When Egdel realized this, he contacted the medical director of the hospital and sent a copy of his report to the hospital and to the Secretary of State, who then passed it on to the tribunal.

When W discovered that confidential information about his condition had been disclosed, he made a claim for breach of confidentiality. However, it was held that the public interest in disclosure of the report outweighed the public interest in keeping the findings in Egdel's report confidential. Egdel had relevant information about W's condition which, had he kept it to himself, would have deprived the hospital and the Secretary of State of information which was relevant to public safety.

W v Egdel established four important principles with respect to breaches of confidentiality, which should be considered along with the GMC guidance (see 'Balancing public interests'):

1. There must be a serious risk of danger to the public or an individual to justify disclosure of confidential information.
2. The courts take GMC guidance on confidentiality very seriously.
3. Disclosure should only be to appropriate people with a legitimate interest in the information.
4. Only the minimum amount of information necessary to prevent the risk of danger should be disclosed.

Common issues

The consequences of breaching patient confidentiality

A patient who feels that a doctor has breached confidentiality may pursue his complaint in one or more of the following ways:

- by making a complaint to the doctor himself or, in the case of a trainee doctor, to the doctor's supervising consultant
- by complaining to the doctor's employer, for example, to the hospital in which the doctor works
- by taking his grievance to the GMC; this is a more likely course of action than the patient taking the case to court
- by taking the case to court; note that the courts pay particular attention to the GMC guidance on confidentiality

Casual breaches of confidentiality

Most breaches of confidentiality are accidental or careless, for example, leaving patient notes on a train or being overheard in a lift. These casual breaches of confidentiality are taken extremely seriously by both the courts and the GMC and could well be considered to constitute serious professional misconduct.

Use of patient records

Either disclosure of patient information for audit or research purposes should be anonymized or express consent should be obtained from the patient. When using patients or pictures of patients as case studies in textbooks and clinical papers, express consent should again be sought. Even if the patient cannot be identified, it would be wise to obtain consent wherever possible.

Disclosure after death

Doctors have an obligation to maintain patient confidentiality after a patient has died. However, information may be disclosed in order to assist a coroner with his duties.

Some legal/ethical dilemmas

A 35-year-old patient has been recently diagnosed with epilepsy and regularly suffers from seizures. Although advised that he should inform the DVLA and not continue to drive, it is apparent that he is ignoring that advice, despite the risks to himself and to other road users. What should I do?

Under these circumstances, the GMC advises that every effort should be made to persuade the patient to inform the DVLA and to give up driving voluntarily. If the patient continues to drive, you would be justified in breaching patient confidentiality in the public interest in order to prevent risk of death or serious harm. In this case, you would need to speak in confidence to the medical adviser at the DVLA, disclosing only the minimum amount of patient information necessary. You should also inform the patient of your decision to speak to the DVLA and document your actions in the patient's notes.

A patient has been admitted to A & E with a gunshot wound to the leg. However, he denies being shot and refuses to speak to the police. Should we inform the police and, if so, what information should we give them?

GMC advice states that the police should be informed if anyone arrives at a hospital with a gunshot wound; however, initially, you should not usually identify the patient. Once the patient is well enough to speak to the police, he should be asked whether he is willing to do so. If he refuses to speak to the police and refuses consent to disclosure of confidential information, you may be justified in disclosing information, but only if there are grounds for believing that it would be in the public interest in order to prevent risk of death or serious harm either to the patient or others to do so.

I am a GP and one of my patients, a 40-year-old man, has been recently diagnosed with HIV. Although he claims to be taking his medication, which will reduce the risk of transmission, and says that he is using appropriate contraception, he is refusing to tell his wife that he has HIV. His wife is also one of my patients. Should I inform her?

In cases of this nature, the GMC advises that there are grounds for disclosure of information if there is a serious and identifiable risk to a specific individual who, if not so informed, would be exposed to infection. You should make every effort to persuade your patient either to inform his wife or to consent to you informing her. However, if he still refuses, you may consider it necessary to inform her in order to protect her from a risk of death or serious harm. In this situation, you should advise your patient of your intentions and document this in his medical notes.

7 Consent

Anna Rathmell

Introduction

In contemporary medicine, the traditional paternalistic model of healthcare has largely been replaced with a model which focuses on patient autonomy and the right of patients to have as much control as possible over decisions relating to their medical care. In English law, this has led to the concept of informed consent and the right of patients to withdraw their consent at any time, even if they have previously given consent or signed a consent form.

Basic concepts

Informed consent

For consent to be valid under English law, three criteria must be met.

- The patient must be **informed**. They should be given general information about the purpose and nature of the procedure, the risks and benefits, and any reasonable alternatives.
- The patient must also be **competent** (have legal **capacity**) to understand the information given to him.
- The consent must be **voluntary**, that is, the patient must not have been coerced.

Consent would normally be express. However, in certain circumstances, it can be implied, for example, when a patient holds out his arm to have blood taken.

Battery and negligence

Legal cases relating to consent for medical procedures normally focus on battery (touching without consent) or, more frequently, negligence.

A doctor can be sued for battery if he has not given the patient information about the specific procedure that he undertakes. For example, if consent has been given for removal of an ovarian cyst, and the doctor performs a hysterectomy, then this could constitute a battery, for which damages would be awarded. The patient would not need to prove that any harm was caused as a result of the battery.

For a doctor to be found liable in negligence, a claimant would need to show that the doctor was in breach of his duty of care. In the context of consent, this would mean showing that the doctor had not provided some relevant information about the procedure. However, in contrast to battery, the claimant would also need to show that harm was caused as a result of the lack of information. In other words, the patient would need to convince the court that had he been properly informed (e.g. of the risk of paralysis following a spinal operation), he would not have consented to the procedure, and so the procedure would not have taken place and no harm would have resulted (in this example, the patient would not have suffered paralysis).

In general, in the context of medical negligence, if a doctor has 'acted in accordance with the practice accepted as proper by a responsible body of medical men skilled in that particular art', he will not be found negligent. This is known as the 'Bolam test'. However, in determining the level of information required for consent to be valid, the courts are increasingly moving away from the Bolam test and are expecting doctors to provide patients with more information, at a level that a 'prudent' patient would require.

Patients who lack capacity, and the Mental Capacity Act 2005

In English law, a person over 16 years of age is assumed to have capacity unless it can be shown to the contrary. Under the Mental

Capacity Act (Section 3(1)), a person lacks capacity if he is unable to do at least one of the following:

- **understand** the information relevant to the decision
- **retain** that information
- **use or weigh** that information as part of the process of making the decision
- **communicate** his decision (whether by talking, using sign language, or any other means)

Capacity relates to the ability of the patient to make a particular decision, not to the patient as a whole (see 'Re C [1994]'). Furthermore, a patient does not lack capacity simply because he makes a decision that could be considered by others to be unwise (Mental Capacity Act, Section 1). If a patient is assessed as lacking capacity to make a decision, then, under the Mental Capacity Act, there is a duty to take all practicable steps to enhance his capacity in order to enable him to make that decision.

Under the Mental Capacity Act (Section 9), it is now possible for a person (the 'donor') with capacity to appoint another person (the 'donee') as a **Lasting Power of Attorney (LPA)**. This enables the donee to make decisions for the donor about specified matters of personal welfare, including medical treatment, should the donor lose capacity in the future. Under the Mental Capacity Act, it is also possible for people with capacity to make **Advance Decisions** to refuse treatment at a future point when they may lack capacity (Mental Capacity Act, Sections 24–26). An Advance Decision can also relate to life-sustaining treatment if it is stated to that effect in writing specifying 'even if life is at risk', signed, and witnessed.

Patients who lack capacity and who do not have an LPA or an Advanced Decision should be treated in their 'Best Interests' (Mental Capacity Act, Section 4). The Mental Capacity Act gives guidance as to how a patient's best interests should be assessed, including encouraging the patient's participation in the decision as far as is practicable, considering the patient's past and present wishes, feelings, beliefs, and values, and consulting those with an interest in his welfare. The General Medical Council (GMC) also offers guidance in this area.

Minors (<18 years old)

Minors aged 16 or 17 are presumed to have capacity to consent to treatment unless it can be shown otherwise. If, however, a minor refuses to consent to treatment that a doctor believes is in the patient's best interests, then someone with parental responsibility can consent on his behalf. If no one with parental responsibility is willing to give consent, then the doctor should approach the court for assistance. In an urgent situation where consent is not forthcoming from the minor or from those with parental responsibility, treatment that is immediately necessary to prevent the minor from coming to serious harm should be given without consent. In reality, most doctors would be reluctant to enforce treatment on a competent 16- or 17-year-old unless it were an emergency situation. If a minor aged 16 or 17 lacks capacity, he should be treated in his best interests, preferably with consent from someone with parental responsibility.

Minors under 16 years of age are presumed not to have capacity to consent to medical treatment. However, if the doctor assesses them as being 'Gillick competent' (see 'Gillick v West Norfolk and Wisbech Area Health Authority [1985]'), then they should be treated as for minors aged 16 or 17. Consent for treatment of minors under 16 years of age who are not Gillick competent should be obtained from someone with parental responsibility (usually the

parents). Consent is only required from one person with parental responsibility. Even if one parent refuses to consent to a procedure, it would be lawful to proceed with treatment, provided that consent has been obtained from the other parent and provided that the procedure is in the patient's best interests. If all those with parental responsibility refuse consent, then the doctor has three options:

- It is lawful to not give treatment to a minor, providing that failure to treat is not significantly against the minor's interests, for example, if those with parental responsibility do not want to consent to a vaccination for their child. However, it is worth being aware that should the doctor be subsequently sued for negligence in not treating the minor, it would not be a defence that those with parental responsibility had refused consent.
- If to not give treatment would be significantly against the minor's interests, then the doctor should apply to the court for a 'specific issue order'. This can be obtained within a matter of hours.
- As for minors aged 16 or 17, if treatment is immediately necessary to prevent serious harm to the minor, then this should be administered, even if consent cannot be obtained.

Cases

Re C [1994]

C was a paranoid schizophrenic patient who had developed gangrene in his foot. The consultant recommended that C should have his leg amputated below the knee, as it was considered that his chances of survival without the amputation would only be 15%. C refused the operation, saying that he would rather die with two feet than live with one. The hospital questioned C's capacity to make this decision and so an application for an injunction was made to the court on C's behalf, preventing the hospital from carrying out the amputation without C's express written consent.

It was held that, although C was a diagnosed schizophrenic, he was able to understand, believe, and use the relevant information in order to come to a decision as to whether or not he wanted to have his leg amputated. In other words, he did have capacity to refuse consent in relation to this matter.

Re C effectively incorporated into English common law the criteria for capacity, which were then amended to form the four legal criteria as specified in the Mental Capacity Act (see 'Patients who lack capacity, and the Mental Capacity Act 2005').

Re C also established that a general reduction in capacity does not necessarily mean that the patient lacks capacity in all areas of his life. Whether a patient lacks capacity relates to the specific decision to be made and not to the patient as a whole.

Gillick v West Norfolk and Wisbech Area Health Authority [1985]

The Department of Health and Social Security had issued a circular to area health authorities containing advice that, under certain circumstances, doctors could give contraception advice and treatment to children under the age of 16 without parental knowledge or consent.

Mrs Gillick sought assurance from her local health authority that her daughters would not be given such advice and treatment before the age of 16. The health authority refused to give such assurance and so Mrs Gillick brought an action against the health authority and the Department of Health and Social Security, arguing that the advice contained in their circular was unlawful.

The case went to the House of Lords where it was decided against Mrs Gillick. Lord Scarman said, 'the parental right to determine whether or not their minor child below the age of 16 will have medical treatment terminates if and when the child achieves a sufficient understanding and intelligence to enable him or her to understand fully what is proposed'.

This case has led to the concept of 'Gillick competence', that is, children under the age of 16 to whom Lord Scarman's judgement applies may give consent to medical treatment. It is unlikely that a child under the age of 12 would be assessed as 'Gillick competent'.

Common issues

Documenting consent

Most hospitals have procedures and guidance in place regarding the taking and documenting of consent. Legally, however, the most important thing is that consent is valid and informed, not whether the patient has signed a consent form or who has obtained consent from the patient. The consent form is useful legally in that it provides evidence that consent has been given. It is also useful as part of an official process to ensure that consent is taken prior to a medical intervention.

The GMC guidance is that responsibility for taking consent can be delegated by the doctor providing the medical treatment to another team member, provided that this team member is suitably trained and qualified and has sufficient knowledge of the proposed investigation or treatment and understands the risks involved. However, overall responsibility for ensuring that consent has been given lies with the doctor undertaking the procedure.

What should the patient be told about risks, benefits, and alternative treatments?

The GMC offers guidance on this. In summary, patients should be given information about common adverse effects and serious adverse effects, even if the likelihood of the serious adverse effect is very small. Even if the patient prefers not to discuss these aspects of their treatment, it would be very unwise to proceed without informing him of the key risks and benefits. If a patient specifically asks for detailed information on risks, benefits, or alternatives, then this information should be given as honestly and fully as possible.

Unexpected findings

If a surgeon makes an unexpected finding during the course of an operation, for example, if, during an appendectomy for which the patient has consented, he discovers an ovarian tumour, he would be unwise to remove the tumour at this stage, even if this would be in the patient's best interests. Although, ethically, removal of the tumour might be the right thing to do, it would only be justified legally if there were good reasons as to why the operation could not be performed at a later stage with the patient's explicit consent. For example, if a delay in the operation would expose the patient to significantly increased risk of death or serious harm. The surgeon could, of course, take the legal risk of removing the tumour on the grounds that he knows the patient well enough to consider legal action very unlikely.

What is the role of the family of an adult (>18 years of age) who lacks capacity?

Unless they have been appointed as an LPA (see 'Patients who lack capacity, and the Mental Capacity Act 2005'), family members have no legal powers to make medical decisions on behalf of an adult who lacks capacity. However, the Mental Capacity Act obliges doctors to act in the best interests of patients who lack capacity. This involves considering patient's previous wishes and values before they lost capacity, and relatives may be in the best position to provide evidence of this. The Mental Capacity Act also specifies consulting a range of people with an interest in the patient's welfare, and this range would most likely include family members.

Some legal/ethical dilemmas

A healthy 3-year-old man has been admitted into A & E with a gunshot wound to the abdomen. His wife says that they are both Jehovah's Witnesses and that her husband has made an Advanced Decision refusing a blood transfusion under any circumstances. Although this Advanced Decision is not in writing, she is quite insistent that both she and her husband would be most distressed at the idea of him receiving blood. The patient has lost a lot of blood and it is now apparent that he will require a blood transfusion immediately in order to save his life. Should we proceed with the transfusion or comply with the patient's and his wife's wishes?

In order for an Advance Decision refusing treatment to be valid and applicable to life-sustaining treatment, it needs to be in writing, stating 'even if life is at risk', signed, and witnessed. This patient has no such written statement and therefore should be treated under the Mental Capacity Act in his best interests. This would involve consultation with the patient's wife, as she will probably have a good insight into the patient's previous wishes and values; however, her opinion does not carry any legal weight. Under these circumstances, since you cannot be sure of the patient's wishes and given the urgent nature of the situation, it would be wise to proceed with the blood transfusion and save the patient's life.

An 84-year-old woman with Alzheimer's disease has been admitted to hospital with suspected pneumonia. She seems unaware of her surroundings and does not recognize her daughter, who has brought her in to hospital. She is very confused and is refusing blood tests and IV antibiotic treatment. Her daughter says that her mother has a fear of needles. It is clear that the patient lacks capacity to consent to this approach to her

medical care; however, she is refusing to cooperate. How much force can we impose in order to act in her best interests?

For restraint (use of force or threats) of a patient to be lawful under the Mental Capacity Act (Section 6), the doctor must reasonably believe that restraint is necessary in order to prevent harm to the patient. In addition, the use of restraint must be proportionate to the likelihood and seriousness of that harm. In this situation, where the proposed treatment has been assessed as being in the patient's best interests, it would be necessary to evaluate whether or not the blood tests and IV antibiotics being proposed are necessary to prevent harm to the patient and, if so, to use proportionate restraint to get her to comply.

PART 2

Assessment of symptoms
and presenting problems

8 Palpitation

Patrick Davey

Definition of the symptom

Palpitation is a symptom defined as unpleasant awareness of the heartbeat and is typically described by patients as a disagreeable sensation of pulsation or movement in the chest or adjacent areas. Palpitations can be due to cardiac arrhythmias or a broad range of other disorders. This chapter addresses the differential diagnosis of palpitations as well as the main causes, the specific clues indicating the presence and nature of an arrhythmia, diagnostic tests, therapies available, prognosis, and dealing with uncertainty.

Differential diagnosis

The main causes of palpitations are listed in Box 8.1. Most patients with palpitations are managed in primary care (see Table 8.1).

Context

Palpitations are very common, and probably affect most people at some time during their lives. They comprise 10% of new referrals to cardiology clinics. They can be due either to an appreciation of the normal heartbeat (by far the commonest cause), or an arrhythmia (Box 8.1). When patients present to medical care, and these are very much the minority of those with symptoms, it is usually because they have given rise to concern in the patients' mind that they may have a serious cardiac illness. Clearly, occasionally, this is the case. Much more frequently, either there is no cardiac abnormality at all or there is a low-grade arrhythmia, not associated with any underlying heart disease or impact on outlook. The key to management is to establish the diagnosis rapidly and, usually, reassure the patient. Sometimes psychological support is necessary. Occasionally, though usually more to reassure the patient, it is necessary to undertake some investigation to exclude any underlying heart disease. Very rarely, a dangerous arrhythmia, or serious underlying heart condition comes to light, needing appropriate specialist therapy—this, however, is very much the exception, and certainly not the rule.

Box 8.1 Main causes of palpitations

Cardiac arrhythmias

Supraventricular/ventricular extrasystoles
 Supraventricular/ventricular tachycardias
 Bradyarrhythmias: severe sinus bradycardia, sinus pauses, second- and third-degree atrioventricular block
 Anomalies in the functioning and/or programming of pacemakers and ICDs

Structural heart diseases

Mitral valve prolapse
 Severe mitral regurgitation
 Severe aortic regurgitation
 Congenital heart diseases with significant shunt
 Cardiomegaly and/or heart failure of various aetiologies
 Hypertrophic cardiomyopathy
 Mechanical prosthetic valves

Psychosomatic disorders

Anxiety, panic attacks
 Depression, somatization disorders

Systemic causes

Hyperthyroidism, hypoglycaemia, postmenopausal syndrome, fever, anaemia, pregnancy, hypovolaemia, orthostatic hypotension, postural orthostatic tachycardia syndrome, pheochromocytoma, arteriovenous fistula

Effects of medical and recreational drugs

Sympathomimetic agents in pump inhalers, vasodilators, anticholinergics, hydralazine
 Recent withdrawal of β -blockers
 Alcohol, cocaine, heroin, amphetamines, caffeine, nicotine, cannabis, synthetic drugs
 Weight reductions drugs

Reproduced with permission from Raviele A, Giada F, Bergfeldt L, et al., Management of patients with palpitations: a position paper from the European Heart Rhythm Association, Europeace, volume 13, issue 7, pp.920-34, copyright © 2011 Oxford University Press

Table 8.1 Common causes of palpitations in primary and secondary care

In primary care	%	In secondary care	%
Non-arrhythmic palpitations	70%	Ventricular and supraventricular extrasystoles	30%
<ul style="list-style-type: none"> ● anxiety ● hyperventilation syndromes ● caffeine excess ● thyrotoxicosis ● phaeochromocytomas 			
Ventricular and supraventricular extrasystoles	25%	Non-arrhythmic palpitations	30%
Supraventricular tachycardias	3%	Atrial fibrillation	20%
Other arrhythmias, including atrial fibrillation	2%	Supraventricular tachycardias	10%
		Other arrhythmias, including ventricular tachycardia	10%

Approach to diagnosis

Though the key to the diagnosis is to obtain an ECG during an attack, many clues to the underlying diagnosis can be obtained from the demographics, family history (especially if the patient is young), knowledge of whether there is any underlying heart disease, exact description of the symptoms, and simple tests such as a 12-lead ECG.

Demographics: Young patients, especially if female, are much more likely to have non-arrhythmic symptoms than older male patients are. Patients with known anxiety symptoms are also less likely to have arrhythmic palpitations.

Family history: A family history of palpitations is without any diagnostic value whatsoever, despite the value placed on this by patients. However, a high-level danger alert signal is finding sudden cardiac death in a young first-degree family member—young meaning <40 years for men, <50 years for females—and the younger they are, the more worried one is that there is either a genetic disorder of cardiac ion channels (a channelopathy) or myocardium (e.g. hypertrophic cardiomyopathy).

Heart disease: The presence of heart disease substantially increases the chance that palpitations relate to ventricular tachycardia, a potentially dangerous rhythm disturbance. The more substantial the cardiac illness, the greater the worry—so, mild left ventricular hypertrophy due to hypertension only mildly increases the risk of ventricular tachycardia, whereas substantial left ventricular dysfunction due to a remote myocardial infarction substantially increases the chance of finding ventricular tachycardia. If syncope is present, then there is considerable concern, and aggressive investigations to determine whether intermittent ventricular arrhythmias are present should be undertaken urgently.

Exact nature of the symptoms: Use the symptoms listed in Table 8.2 to determine whether or not you think an arrhythmia is present; then, try and determine which arrhythmia this might be. Unless you have clearly demonstrated what is going on, refrain from being categorical with the patient; tell them what you think the diagnosis is, but do explain that there is some uncertainty.

Red-flag features: These are features which increase the likelihood of a dangerous arrhythmia, and mandate further cardiac

assessment. Red flags are: palpitations associated with chest pain, breathlessness or syncope; palpitations provoked by exercise; a family history of cardiomyopathy or sudden death; signs of structural heart disease or heart failure; and an abnormal 12-lead ECG.

Specific clues to the presence of an arrhythmia

There are numerous clues in the history to the diagnosis (Table 8.2).

Specific clues to the nature of the arrhythmia

Extrasystoles (ectopic beats): The patient either feels the beat itself (irregular palpitations, with a normal overall heart rate)—‘like the car hiccupping’—or the beat after the ectopic, which is of increased strength—the heart misses a beat, then restarts with a thud’.

Supraventricular tachycardia: Supraventricular tachycardia (SVT) is instantaneous-onset, rapid, regular palpitation, of defined but usually brief duration (few minutes), sometime stopped by vagotonic manoeuvres, which the patient has discovered for themselves (e.g. coughing, straining, cold drinks, breath holding). Rarely, post-event polyuria occurs.

Atrial fibrillation: Atrial fibrillation is sudden-onset, fast, irregular palpitation (unlike the irregular palpitations with a normal heart rate of ectopy).

Ventricular tachycardia: Ventricular tachycardia is sudden fast regular palpitation (just like an SVT), but sometimes (not always) accompanied by additional symptoms (dizziness, frank syncope). The real clue is finding a family history of sudden death, an abnormal ECG suggesting a channelopathy, or known cardiac disease.

Table 8.2 Clues to the presence of an arrhythmia

	Non-arrhythmic palpitations	Arrhythmic palpitations
Characteristic phrase	Heavy (sometimes slow and regular) thudding	Racing heart rate (sustained arrhythmia); ‘fluttering’ (ectopics)
Situation	Sometimes when overtly anxious, often not	Not usually related to any stress
Diurnal variation	Rare	Usually none, though ectopic beats more common in the evening/ at night
Onset	Slow—over many minutes	Instantaneous
Offset	Often poorly recalled, otherwise, gradual wearing off	Usually instantaneous, sometimes not recalled
Duration	Often poorly recalled, many hours or all day, sometimes several days	Well defined and remembered, often minutes, though can be seconds, or hours
Heart rate during the attack	Usually normal or near normal	Usually very fast
Associated symptoms during the attack	Often many, though rarely any particular disease-related symptoms complex	Usually none, sometimes breathlessness, angina, very rarely syncope
Associated symptoms after the attack	Often many symptoms remote from an attack—especially tiredness, often rather diffuse, free-floating symptoms	Often no symptoms remote from the attack, rarely symptoms from underlying heart disease
Ability to answer a direct question clearly and in a focused manner	Very poor, often answers a question by expressing a new symptom	Usually very good
Inter-attack ECG	Usually normal	Usually normal, but may show a variety of abnormalities indicating arrhythmia propensity (delta wave, long-QT interval, Brugada syndrome) or underlying cardiac illness (Q waves, etc.)
Physical examination	Normal	Usually normal

Key diagnostic tests

The absolute key to diagnosis is to obtain an ECG during an attack—how easy this is depends on the frequency and duration of symptoms (Table 8.3). In addition, all patients should have a 12-lead ECG obtained between attacks, as this can give key clues to the presence of pro-arrhythmic conditions, such as Wolff–Parkinson–White (WPW) syndrome, hereditary long-QT syndrome, Brugada syndrome, or any underlying heart disease. A normal 12-lead ECG between attacks makes a dangerous arrhythmia unlikely.

Other diagnostic tests

These depend on the presumed diagnosis. Most patients should have thyroid function tests, a full blood count, and a biochemical screen performed, to ensure there is no non-cardiac illness

Table 8.3 Frequency and duration of symptoms during an arrhythmia

Frequency	Duration	Test
Few minutes	>1 month	Depends on probability of serious arrhythmia; if very low (normal inter-attack ECG, no cardiac disease), consider doing no further investigations; if probability of serious arrhythmia higher, consider either invasive evaluation or an implantable loop recorder
Few minutes	Every fortnight	Cardiac memo (simple ECG machine loaned to the patient for a few weeks)
Few minutes	Every week	7 day ECG recording
Few minutes	Every day	24 hour ECG
>30 minutes	Any frequency	Attend Emergency Dept at any time of day or night for a 12-lead ECG

presenting as palpitations. If the presumed diagnosis is non-cardiac palpitations, a few patients also need urine tests to exclude pheochromocytoma (catecholamine secreting with paroxysmal secretion: patients usually have intermittent symptoms of palpitations, sweating, or overwhelming anxiety, and many will have lost weight). If there is a possibility of serious heart disease, appropriate tests may include a cardiac ultrasound, exercise stress test, and so on.

If obtaining an ECG at the time of palpitation proves elusive, and a definitive ECG diagnosis is needed, in patients with no red-flag features, a smartphone device (monitor and app) that allows the recording of a single channel ECG can be very helpful. This technology is likely to be increasingly used. In patients with red-flag features (e.g. associated syncope, abnormal resting ECG, left ventricular dysfunction and/or known ischaemic heart disease), then a very small leadless ECG recording device can be implanted subcutaneously in the left chest near the heart. Such devices are typically 1x2x0.5 cm in size, and have battery lives of 2–3 years. They can be remotely interrogated and store all significant brady- or tachy-arrhythmias. Implantation of an ECG loop recorder is very rarely indicated in the assessment of palpitation in the absence of red-flag features.

Introduction to therapy

Unless there is a signal that there is a dangerous arrhythmia present, often the best approach is simply to reassure the patient, on the basis of a presumptive diagnosis from the history, that either that their symptoms are likely to be non-arrhythmic, and so benign, or that they probably represent a non-dangerous arrhythmia. Most patients, either without arrhythmias or with brief arrhythmias (e.g. ectopic beats) responds to such reassurance. Patients with a presumptive diagnosis of an SVT should be taught vagotonic manoeuvres. If these approaches are unsuccessful, then beta blockers can often be effective (often given for only a few months). They are both effective for non-arrhythmic palpitations and very good for most arrhythmias and, unless there are any of the usual contraindications, they are very safe.

Prognosis

Unless a dangerous arrhythmia is present, which is most unlikely, the prognosis is for a normal life expectancy. The vast majority of

patients with a normal inter-attack 12-lead ECG fall into this category. However, be aware of the following:

- In those with ventricular extrasystoles, occasionally there is underlying heart disease, which clearly must be detected and treated.
- In those with atrial fibrillation, life may be shortened (by stroke) unless appropriate anticoagulation is given. If you suspect this diagnosis, go to some lengths to prove or disprove this, as it is crucial to give anticoagulation if the benefits outweigh the risks.
- If you suspect a channelopathy, or know there is underlying heart disease, the prognosis may be seriously decreased. These patients need specialist cardiac workup.

How to handle uncertainty in the diagnosis of this symptom

If you cannot prove the diagnosis, that is, obtain an ECG during an attack, then take steps to exclude:

- WPW syndrome with an obvious delta wave
- channelopathies (in practice, done by ensuring that there is no family history of sudden cardiac death in young relatives, and the inter-attack 12-lead ECG is normal)
- underlying heart disease (from the history, physical examination, and echocardiography; most cases have an abnormal inter-attack ECG)
- atrial fibrillation (irregular fast palpitations)

The patients who remain (who comprise the overwhelming majority) are extremely unlikely to have any arrhythmia that affects prognosis and, even without any diagnostic ECG, can usually be managed by reassurance and, if needed, low-dose beta-blocker therapy.

9 Acute chest pain

Jonathan Timperley and Sandeep Hothi

Definition of the symptom

Acute chest pain constitutes pain (or any unpleasant sensation) in the chest that has been present for less than 2 weeks, and in many cases for less than a few hours. Patients with acute chest pain usually (but not always) present as an emergency to hospital as they are aware that there may be an immediately life-threatening cause. The main issue with acute chest pain is therefore the differentiation of the serious causes from the benign ones, so that patients with life-threatening illness can be treated early and effectively, and those with benign chest pain can be safely discharged early.

Differential diagnosis in primary care and secondary care

Box 9.1 outlines the differential diagnosis in primary care and secondary care, ordered by probability.

Context

Acute chest pain is a common and typically frightening symptom. The main diagnosis to be considered (although certainly not the only one) is an acute coronary syndrome (ACS), with all its attendant dangers, as opposed to the main diagnosis in chronic chest pain, which is stable angina. These diagnostic differences explain the momentum of the illness and so the speed at which diagnosis and treatment should occur—in chronic chest pain, diagnosis and treatment can occur at a relatively leisurely rate, as complications from stable angina usually occur at a relatively low rates whereas, in acute chest pain, time is of the essence, as many conditions are associated with early death; even if initially it appears that the patient with acute chest pain is well,

Box 9.1 Diagnosis in primary care and secondary care, ordered by probability

Common

- non-specific chest pain
- gastro-oesophageal chest pain
- musculoskeletal pain, including chest wall trauma
- acute coronary syndromes
- stable angina:
 - coronary disease +/- anaemia
 - aortic stenosis

Uncommon

- pleurisy, due to:
 - pneumonia
 - pulmonary embolism
 - pneumothorax
 - pericarditis
 - viral pleurisy
- chest manifestations of subdiaphragmatic illness:
 - cholecystitis
 - dyspeptic syndromes

Rare

- aortic syndromes, including aortic dissection
- oesophageal rupture
- viral chest wall infection, herpes zoster and simplex

life-threatening complications can occur quickly and indeed often do so. This means that, in acute chest pain, a rapid diagnosis must occur, preferably within minutes and certainly within a few hours. However, the diagnosis may prove elusive and, given that the time window for effective therapy is often small, sometimes, indeed, quite often, empiric therapy must sometimes be given without complete confidence over the diagnosis. Such 'blind' therapy is certainly appropriate in many situations—however, you should always weigh up the risks versus the benefits—for example, it is 2 am, you may believe the likely diagnosis is a pulmonary embolus (PE), and for many patients it is appropriate to give a heparin-type anticoagulant even if the diagnosis is not as yet proven. However, if the patient also has a profound microcytic anaemia, which could be due to chronic gastrointestinal blood loss, heparin may provoke brisk and therefore dangerous gastrointestinal bleeding. What should one do? This is but one example of uncertainty in diagnosis—for the cause of the chest pain as well as comorbidities increase the risk of therapy. Such uncertainty is difficult both for physicians and patients, but nonetheless is the very real-world situation in which we find ourselves. This does mean that if the diagnosis is not clear, the physician must have a strategy that deals effectively with uncertainty. Individual clinicians will develop this for themselves as they become more experienced; often discussing the problem with other clinicians allows one to frame the situation in such a way that the solution becomes obvious. If initial discussions within your unit have not led to a solution, then discuss the problem outside the unit with specialist physicians—in the aforementioned case, titrate the risk of the possible PE (is there evidence of haemodynamic instability such that immediate therapy is needed?) against the risk of gastrointestinal bleeding (and if you don't know what the risk is, ask a senior gastroenterologist).

Approach to diagnosis

The main aim of management is to quickly diagnosis and treat all conditions—both those that are benign (to ensure early and safe discharge), and those that are dangerous and require immediate treatment, sometimes of a very complex nature.

In terms of thinking about the diagnosis, it may be helpful to answer the questions 'What is the most likely diagnosis?', 'How do I diagnose this?', and 'What is the most likely dangerous diagnosis, and how do I exclude this?' If the most likely diagnosis is disproven by investigation, move on to the next most likely diagnosis. The most dangerous diagnosis is often either an ACS or PE; occasionally, such diagnostic doubt exists that both need to be excluded. Aortic syndromes are rare, they often not top of the diagnostic list, and they are easily forgotten, so it is helpful to always ask oneself in patients with undiagnosed pain whether this could be an aortic syndrome. Sometimes the diagnosis cannot be readily made, but one can risk stratify the patient anyway.

In order to develop a model of how we approach diagnosis generally, it is always helpful to remember the words of the great cardiologist JW Hurst on how to make a diagnosis:

Step 1: Obtain the history, perform the physical examination, obtain a resting ECG, and obtain chest X-ray. These four methods, used properly, will enable us to come to a reasonable conclusion about most patients.

Step 2: The data collected by using the history, physical examination, resting ECG, and chest X-ray must be interrelated so that the whole of the parts give an understanding of the patient's problem that is greater than each of the individual parts considered separately.

Step 3: The data collected by the four methods mentioned in Step 1 should enable the physician to state the diagnosis with certainty or formulate the problem so precisely that it is possible to think clearly about it and develop plans related to it

Step 4: If the diagnosis is not clear, it is then necessary to ask whether the remaining questions should be solved. Will clearer answers really improve the care of the patient?

Step 5: If the answer is no, clearer answers to various questions will not assist in the care of the patient, then doctoring with all its meaning should be implemented. If the answer is yes, clearer answers will assist in the care of the patient, then one must determine if the questions raised are clearly stated. As a rule, the question should be one or more of the following. Is there a structural abnormality? Is cardiac performance or myocardial contractility abnormal? Is there an electrical abnormality? Is myocardial ischaemia present?

Step 6: If further workup can be justified and the questions are clearly stated, it is then possible to choose the technique that is most likely to answer the question. It is not necessary to perform all tests that might answer the question. It is adequate to choose the technique that gives a result with the highest predictive value.

This is as clear an exposition of diagnostic thinking as you will come across—and in this situation, like most others, it tells us that relatively simple data used correctly enable the diagnosis to be made and appropriate therapy instituted—and this is something that should not be forgotten in this age of increasingly sophisticated investigation and treatment.

In terms of Step 1, you need to know what the possible diagnoses are (Box 9.1) and what the key diagnostic clues are (see ‘Specific clues to the diagnosis’).

If the diagnosis cannot be made immediately, follow Hurst’s approach—which single investigation is required to make the most likely diagnosis and exclude the most dangerous diagnosis? For example, you think the diagnosis is benign musculoskeletal chest pain, but the most likely dangerous diagnosis is PE. There is no test for musculoskeletal chest pain—fine; for PE, a D-dimer test with or without CT pulmonary angiography (CTPA) is required.

Sometimes even the best clinicians working within real-world systems cannot make the diagnosis—in this situation, it is helpful to risk stratify the patient (see Table 9.1).

Specific clues to the diagnosis

The history, physical examination (including pulse oximetry), and simple investigations via a chest X-ray and a 12-lead ECG should lead to the correct diagnosis or diagnostic and therapeutic strategy. Establish key points from the demographics and history to determine the initial chance of coronary disease versus other illness, and then consider the specific nature of the pain, along with associated symptoms. In the examination, **in all patients**, look for symptoms and signs of heart failure, PE, aortic dissection, and pulmonary sepsis. Synthesize this data to reach a working diagnosis, then prove it.

ACS

The key to the diagnosis is to ascertain whether historically the pain is myocardial ischaemia; if it is, and it occurs at rest, then the diagnosis is likely to be an ACS; if it lasts longer than 20 minutes, it is likely there is myocardial infarction. How is myocardial ischaemia diagnosed from the history? In some patients this is easy—half of patients with infarction have preceding angina (retrosternal chest pain, not present at rest, provoked by effort, building up and necessitating discontinuation of effort, relieved within 1–2 minutes of rest). These patients now present with pain similar to their effort angina (although more intense and prolonged) but occurring at rest. These patients are easy to diagnose. Another group easy to diagnose are those with previous proven symptomatic coronary disease such as myocardial infarction. Ask if their current pain is similar to their previous pain (this is most helpful when they have had previous proven and unambiguous infarction). Beware, however, that what patients felt may have been proven symptomatic coronary disease may not, in fact, have been this (e.g. a remote diagnosis of angina made by a non-cardiologist without specialist review or supportive data). Accordingly, always ask how the previous diagnosis of angina or infarction was made,

Table 9.1 Short-term risk of death or non-fatal myocardial ischaemia in patients with unstable angina

Feature	High Risk (At least 1 of the following features must be present)	Intermediate Risk (No high-risk feature but must have 1 of the following features)	Low Risk (No high- or intermediate-risk feature but may have any of the following features)
History	Accelerating tempo of ischemic symptoms in preceding 48 hrs	Prior MI, peripheral or cerebrovascular disease, or CABG; prior aspirin use	
Character of pain	Prolonged ongoing (>20 min) rest pain	Prolonged (>20 min) rest angina, now resolved, with moderate or high likelihood of CAD Rest angina (<20 min or relieved with rest or sublingual NTG)	New-onset CCS Class III or IV angina in the past 2 wk with moderate or high likelihood of CAD
Clinical findings	Pulmonary edema, most likely related to ischemia New or worsening MR murmur S ₃ or new/worsening rales Hypotension, bradycardia, tachycardia Age >75 y	Age >70 y	
ECG findings	Angina at rest with transient ST-segment changes >0.05 mV Bundle-branch block, new or presumed new Sustained ventricular tachycardia	T-wave inversions >0.2 mV Pathological Q waves	Normal or unchanged ECG during an episode of chest discomfort
Cardiac markers	Markedly elevated (eg, TnT or TnI >0.1 ng/mL)	Slightly elevated (eg, TnT >0.01 but <0.1 ng/mL)	Normal

Abbreviations: CABG, coronary artery bypass graft surgery; CAD, coronary artery disease; CCS, Canadian Cardiovascular Society; MI, myocardial infarction; MR, mitral regurgitation; NTG, glyceryl trinitrate (nitroglycerin).

and satisfy yourself that you are comfortable with this diagnosis. You can also use this approach in reverse—if patients have had negative investigations for coronary disease in the past, for example, a normal coronary angiogram, and now present with symptoms identical to those that led to the negative investigations, then it is unlikely that they have myocardial ischaemia.

This approach then leaves a group of patients in whom one cannot early on from the history alone categorically state what the pain is due to. However, there are clues from the history and physical examination (Table 9.2).

Duration of pain: Pain lasting a few seconds is unlikely to be anything serious; conversely, pain lasting many hours **in the setting of a completely normal ECG and normal troponin levels** is also unlikely to be an ACS. Typical angina pain in an ACS lasts a number of minutes, up to 20–30, but rarely longer. In addition, recurrence of pain is usual in an ACS; this means that an isolated episode of pain is unlikely to be an ACS.

Radiation: ACS pain often—but not always—radiates. Radiation of pain to the right arm increases the probability of ACS more than radiation to the left arm although radiation to the right arm is less common than to the left.

Absence of posture dependence, or worsening with respiration: Either absence of posture dependence or worsening with respiration reduces the chance of ACS. Posture dependence (better lying down, worse sitting forwards) may suggest pericarditis, and respiration dependence indicates the pain is pleuritic, for which there is a differential diagnosis (see 'PE').

Associated symptoms: Nausea, sweating, or sense of impending doom—all these increase the chance of infarction.

Physical examination in suspected ACS

The physical exam is rarely productive in ACS, but should always be carried out thoroughly. Look for signs of risk factors such as age, nicotine staining to the hands, lined face indicating smoking status, evidence of hyperlipidaemia (tendon xanthomata especially), high blood pressure, and bruits or lost pulses (feel all pulses, listen over the carotids and femorals), and perform a fundoscopy (for hypertensive and/or diabetic damage) and a urine dipstick test (for glucose and protein). Look for evidence of complications of an ACS—especially heart failure (e.g. jugular venous pressure, peripheral oedema, convincing lung crepitations), and especially a heart operating more stiffly (a third heart sound, probably the most reliable of all signs in ACS, provided the patient is listened to during pain). Look for murmurs, which are occasionally relevant to an ACS (e.g. indicating mitral regurgitation) but are usually more relevant to the overall management (e.g. indicating bystander aortic valve disease in a patient with an ACS).

The key diagnostic test in suspected ACS

The key diagnostic test in suspected ACS (see 'Key diagnostic tests') is an ECG that is initially diagnostically unambiguous (rare) or (more likely) one that changes sequentially in a pattern characteristic of an ACS. The latter characteristic means that ECGs should be repeated frequently. Furthermore, an ECG must always be taken whenever a patient has pain, as some ACSs only show changes, such as transient ST depression (common) or ST elevation (less likely, but indicating a need for immediate angiography), at that time. Ongoing chest pain with a resolutely normal ECG decreases greatly the chance of an ACS (although beware that circumflex territory ischaemia can be electrocardiographically silent—so, if the standard 12-lead ECG is normal, always ask for posterior leads (leads V7, V8, and V9) to be taken). In this situation, consider alternative serious diagnoses such as PE or aortic dissection.

PE

PE is a very common diagnosis. The key to diagnosis is eliciting risk factors from the history, such as recent (within 4–6 weeks) long-distance travel, age, female sex, use of the oral contraceptive pill, immobility, recent surgery, obesity, and cancer (although many patients have none of these factors), and then diagnosing one of the three distinct syndromes with which PE can present:

Table 9.2 Likelihood of myocardial infarction in patients presenting to the Emergency Dept with acute chest pain unrelated to trauma and unexplained by the chest radiograph, based on analysis of data from multiple studies

Finding	Sensitivity (%)	Specificity (%)	Likelihood Ratio* if Finding Is	
			Present	Absent
History				
Male sex	59–72	24–61	1.3	0.7
Age				
<40 years	4	81	0.2	—
40–59 years	34	—	NS	—
≥60 years	47–74	54–68	1.5	—
Sharp pain	8–16	59–70	0.3	1.3
Pleuritic pain	3–6	74–82	0.2	1.2
Positional pain	3–11	75–87	0.3	1.1
Relief of pain with glyceryl trinitrate	35–92	12–59	NS	NS
Physical Examination				
Hand gestures				
Levine sign (placing a clenched fist against the sternum)	7	87	NS	NS
Palm sign (placing the extended palm against the sternum)	32	63	NS	NS
Arm sign (gripping the left arm)	18	83	NS	NS
Pointing sign (pointing to a single point on the chest with 1 or 2 fingers)	2	95	NS	NS
Chest wall tenderness	3–15	64–83	0.3	1.3
Diaphoretic appearance	28–53	71–94	2.2	0.7
Pallor	70	49	1.4	0.6
Systolic blood pressure <100 mm Hg	6	98	3.6	NS
Jugular venous distention	10	96	2.4	NS
Pulmonary crackles	20–38	82–91	2.1	NS
Third heart sound	16	95	3.2	NS
Electrocardiogram				
Normal	1–13	48–77	0.2	1.5
Nonspecific ST changes	5–8	47–78	0.2	1.4
ST elevation	31–56	97–100	22.3	0.6
ST depression	20–62	79–96	3.9	0.8
T wave inversion	9–39	84–94	2.0	NS

NS, not significant. *For interpretation of Likelihood Ratios (LR), see Chapter 1. LR if finding present = positive LR; LR if finding absent = negative LR.

The findings increasing the probability of myocardial infarction the most are new ST elevation (LR = 22.3) or ST depression (LR = 3.9) on the ECG. The only findings decreasing the probability of myocardial infarction in these studies are pain that is pleuritic (LR = 0.2), positional (LR = 0.3), or sharp (LR = 0.3); a normal electrocardiogram (LR = 0.2); chest wall tenderness (LR = 0.3); and age younger than 40 years (LR = 0.2).

Reprinted from *Evidence-Based Physical Diagnosis*, Third Edition, McGee S, Diagnosing Myocardial Infarction, EBM BOX 47-2, pp. 416-417, Copyright 2012, with permission from Elsevier.

Pleuritic chest pain, laterally (retrosternal pleuritic chest pain is more likely due to pericarditis): Fever and cough increase the chance of pneumonia causing the pleurisy; their absence increases the chance of PE being the cause (or, possibly, viral pleurisy being the diagnosis).

Breathlessness as the dominant feature (with or without pleuritic chest pain): Breathlessness, often with a tachycardia, no wheeze or reduction in peak flow, and a clear chest X-ray, is the hallmark of a PE. Finding hypoxaemia and an increase in the alveolar–arterial gradient further increases the probability of PE. Remember that many patients with underlying diseases making them breathless—such as heart failure or COPD—can have a PE complicating their underlying illness. It is easy, when such patients come in to hospital more breathless, to assume that it is a deterioration in their underlying illness; have a low threshold for ordering PE-directed investigations in these patients, unless there is unambiguous evidence that their breathlessness reflects their underlying illness (e.g. increasing airflow obstruction in COPD—more wheeze and lower peak flow—and radiological left heart failure in chronic heart failure patients).

Haemodynamic collapse: Haemodynamic collapse is usually of sudden onset, with marked breathlessness and, on examination, pallor (from reduced cardiac output), sinus tachycardia (a key finding) or atrial fibrillation, reduced blood pressure, hypoxaemia, raised venous pressure, possibly a right ventricular heave, clear lung fields, and an ECG showing sinus tachycardia (or atrial fibrillation), and some rightward shift in the QRS axis. There is no postural blood pressure drop (no volume loss; part of the differential diagnosis of shock), usually no fever (no sepsis), the lungs are clear, and lying flat is not an issue (no left heart failure, so cardiogenic shock unlikely). Any patient with haemodynamic collapse requires an immediate diagnosis and appropriately directed treatment. If the diagnosis is not immediately obvious, a cardiac ultrasound is likely to help direct therapy (see ‘Introduction to therapy’); in PE causing shock, a dilated poorly functioning right heart is found, sometimes with a thrombus still present in the right atrium. The left heart is often small and compressed by the septum, which then is operating as a right ventricular structure.

Aortic dissection

The diagnostic clues are observing risk factors (features of Marfan syndrome or related connective tissue illness; hypertension; age; family history), and pain that is consistent with the diagnosis (retrosteral pain, sometimes tearing, often not, often radiating up to the neck and then into the back). The pain is persistent (i.e. lasts many hours). Examination may be normal (common), only show hypertension, or show complications of dissection, such as tamponade (**the key sign to look for**), aortic regurgitation, or damage from the intimal flap blocking the arterial blood supply to organs—hemiplegia (carotid artery), paraplegia (spinal artery), abdominal pain (mesenteric ischaemia), flank pain (renal ischaemia), or leg pain (femoral ischaemia). A chest X-ray is usually unhelpful (most dissections do not have widened mediastina, and most widened mediastina on chest X-ray are due to other causes, principally obesity), although occasionally diagnostic changes are seen, such as aortic dilatation, or left pleural effusion (suggesting aortic leak into the left pleural space). The ECG is often normal, or shows left ventricular hypertrophy (from long standing hypertension); occasionally a dissection presents as a myocardial infarct (usually inferior, as dissection of the left main stem is usually instantly fatal). The diagnostic test is a CT aortogram with contrast; occasionally, a transthoracic echo is diagnostic in showing the aortic flap, although more usually it ‘only’ shows pericardial fluid, or nothing. A transoesophageal echo has **no role** outside a cardiothoracic centre in diagnosing acute dissection (it is an invasive procedure that can result in transient hypertension and extension of the dissected aortic flap—it should only be carried out in cardiothoracic centres in the anaesthetic room with the surgical team standing by to proceed if positive).

Pneumothorax

The key here is sudden-onset, unilateral, pleuritic chest pain, often with breathlessness. The physical examination is usually unrewarding; in tension pneumothorax hypotension occurs, with tracheal deviation (away from the side with the pneumothorax). The chest X-ray is diagnostic.

Pneumonia

Most patients present with a clear pneumonic syndrome—unwell for a few days, with perhaps a preceding flu-like illness or viral sore

throat, fever, cough, malaise, and pleuritic chest pain. By definition, those that end up causing diagnostic doubt in the assessment of chest pain may have atypical features, such as no fever (more likely in the elderly, or immunosuppressed) or no cough (elderly, those on opiates, or with advanced cerebrovascular disease). The clue to the diagnosis in these cases is the chest X-ray, along with blood tests, particularly markers of inflammation.

Oesophageal pain

Oesophageal pain typically occurs in two different manifestations:

Oesophagitis, often in the presence of gastro-oesophageal reflux: Symptoms include a retrosternal burning discomfort that is worse on lying down and is relieved by antacids, including milk; reflux (burning discomfort passing from the epigastrium upwards) may also be present. There are no diagnostic tests, although cardiac investigations obviously are normal. Endoscopy is usually not useful, as oesophagitis can coexist with coronary disease, and so proving the diagnosis by itself does not exclude the more serious diagnosis of an ACS (see ‘Musculoskeletal chest pain’).

Oesophageal spasm: Oesophageal spasm provokes a pain remarkably similar to myocardial ischaemia (retrosternal tightness, of an unpleasant quality, persistent). The first clue indicating that the pain is due to oesophageal spasm rather than myocardial ischaemia is the demographics being against myocardial ischaemia; the second clue is there being no preceding angina, as there is **never** any preceding angina in the case of oesophageal spasm; the third clue is patients having had recurrent attacks of similar pain always at rest over the years (often with repeated negative cardiac investigations); and the fourth clue is that the ECG and the troponin level remain normal, despite prolonged pain. There can, however, be diagnostic doubt, and in some cases coronary angiography may be indicated to rule out a cardiac cause for symptoms.

Musculoskeletal chest pain

Typically, musculoskeletal chest pain occurs in the setting of unusual or prolonged effort using the arms, or prolonged coughing. However, often there is no preceding unusual effort. Pain is unilateral and often left-sided (as patients worry more about pain in the left chest, and so seek medical help more frequently). It may be sharp (‘like a knife’) or dull. Typically, it lasts for hours, and is often exacerbated by turning the chest round. There may be point tenderness. All of these features increase the chance of the diagnosis being musculoskeletal pain; however, even if clinically the diagnosis is musculoskeletal pain, coronary-artery-directed tests may be necessary, as occasionally an ACS and musculoskeletal pain coexist (perhaps as patients with an ACS may repetitively rub their chest wall in a fruitless attempt to relieve their cardiac symptoms, thereby provoking a musculoskeletal component to their symptoms).

Chest pain of uncertain aetiology

Chest pain of uncertain aetiology is a not-uncommon diagnosis, where the historical features share some of the features of several different diagnostic groups. In this situation the pragmatic approach is (1) determine the risk of coronary disease from the extant risk factors and (2) if there is a significant risk, risk stratify the patient (see ‘Philosophical approach’) and then proceed along a pathway to exclude both an ACS and PE (see ‘Key diagnostic tests’ and ‘Other diagnostic tests’).

Philosophical approach

As one proceeds along this journey, diagnoses are thrown up, and the key to reaching the correct diagnosis is not just to use the clues from the individual features, but to combine them so that the combination of data is more powerful than any individual factor (Hurst Step 2; see ‘Approach to diagnosis’). The key question to ask as you proceed with data gathering is ‘Does the new information increase or decrease the chance of my first (and other) diagnoses?’. For example, take a 56-year-old patient with new retrosternal chest pain, being seen in the A & E department, and whose examination shows some chest wall tenderness. Chest pain in A & E has a 30% chance of being an ACS; this chance is increased by age (for most patients the dominant risk factor) and male sex, along with coronary risk factors.

Our patient is younger than most, so the incidence is lower (use the demographics—they are a powerful diagnostic tool). Chest wall tenderness lessens this chance (it is not necessary to know by how much new data adjust, probably, merely the direction of change). Now, factor in a normal presentation ECG, and a normal ECG at 12 hours (further lessening the chance of ACS). The probability that the patient has an ACS is now very small. Although this is a simple example, you should get used to using data in this fashion, and not blindly going to the one positive test (e.g. troponin), believing that it has made the diagnosis for you, as it rarely has!

Table 9.2 shows features of the history that increase or decrease the probability of acute infarction.

Key diagnostic tests

The key to diagnosing the cause of acute chest pain is to use the following simple tests, to understand them, and, where necessary, to repeat them often:

The 12-lead ECG: This is the most important test. This must be done at presentation and then at least four times over a 12-hour period, which is probably the minimum duration for admission for anyone with any realistic chance of having an ACS. There are many features to look for:

ECG changes at presentation: ST elevation of a typical shape (convex upwards) in the distribution of a coronary artery usually indicates ST-elevation myocardial infarction (STEMI) and often trumps other findings; however, bear in mind that not all ST elevation is due to a STEMI (pericarditis, physiological ST elevation, bundle branch block, and Brugada syndrome are all in the differential). ST depression, particularly if marked and not in the lateral leads (where it may indicate left ventricular hypertrophy, digoxin use, or ischaemia) has a high chance of indicating ischaemia. Tachycardia is an important but non-specific finding—always think PE, left ventricular failure, or sepsis (the clinical exam and chest X-ray help distinguish these diagnoses).

Dynamic ECG changes: Dynamic ECG changes are a hallmark of an ACS, and **must** be looked for—all patients should have ECGs at regular intervals (how frequently is unclear; certainly, however, every 4 hours, and whenever pain recurs). The interpretation of fluctuating ECGs over time is not unambiguous, although most will have an ACS. However, be aware that there are many ACSs where dynamic ECG changes do not occur, and bear in mind that not all dynamic ECG changes mean an ACS—for example, a large PE can over a few hours give rise to T-wave inversion anterolaterally, looking remarkably similar to a left anterior descending (LAD) syndrome ECG.

Tachycardia: Tachycardia could indicate left heart failure, pulmonary embolism, sepsis, anxiety, or volume depletion, or just be a non-specific response to pain.

Left ventricular hypertrophy: left ventricular hypertrophy greatly increases the risk of a serious cause underlying the pain, such as coronary disease, aortic syndromes, or aortic valve disease.

Old Q waves: Old Q waves likewise usually indicate established coronary disease, and raise the probability that current symptoms reflect a new coronary event.

Troponin: Troponin is a sensitive marker of cardiac damage or stress. While sequential rises in troponin are the hallmark of an ACS, many patients with severe coronary disease have normal troponins, and many patients with small rises in troponin do not have coronary disease but rather one of the following:

- renal failure, a very common cause of small troponin rises
- a PE, where the extent of troponin rise relates to prognosis
- a cardiac arrhythmia—many patients with atrial fibrillation or a supraventricular tachycardia develop a small rise after prolonged tachycardia
- myocarditis
- stress ('takotsubo') cardiomyopathy

The clues to all these other causes of troponin rise are usually fairly obvious—the one that is most difficult to diagnose can be a PE, and it is worth noting that, if a patient with chest pain and a troponin rise has a coronary angiogram that is normal, this certainly does not

mean that they have a healed ruptured coronary plaque; they may have a PE. The moral is, don't stop the diagnostic process at angiography; if the angiogram is normal, often the diagnosis of acute decompensated coronary disease has been disproved and you must restart the diagnostic process with the following:

D-dimer levels: This test can be used to decrease the chance of PE (if the level is normal), but is rarely useful in increasing the chance of PE.

Chest X-ray: A chest X-ray is the key investigation (along with the ECG) in evaluating chest pain. Common abnormalities have already been described in 'PE', 'Aortic dissection', 'Pneumothorax', and 'Pneumonia'. Some key points, however, should be made:

1. If the chest X-ray is normal, consider PE or early pneumonia, in addition to considering the result to be genuinely normal.
2. Do not use the chest X-ray to alter the probability of aortic dissection; many dissections do not have widened mediastina, and virtually all widened mediastina are not due to dissection (obesity is the common explanation).
3. A chest X-ray is useful in diagnosing pneumonia, but a normal chest X-ray does not rule the diagnosis out; it merely decreases the chance of the diagnosis being pneumonia.
4. Always, if possible (using digital technology), compare the current chest X-ray with previous ones.

Nuclear cardiology imaging techniques: In many units, this is the mainstay of diagnosis and risk stratification in chronic stable angina. However, nuclear cardiology has a role in the assessment of acute chest pain:

Standard SPECT MPS: The SPECT (single-photon emission computed tomography) MPS (myocardial perfusion scan) is the standard nuclear scan, done both at rest (which allows remote infarction to be diagnosed) and with stress (from exercise—the preferred method—or by pharmacological methods, using adenosine or its analogues, or dobutamine), which provides quantification for the volume of inducible ischaemia present. The test is done on an expedited basis, within a few days of presentation with acute chest pain. The test is fairly reliable in diagnosing infarction and ischaemia, and provides data on prognosis.

Immediate rest SPECT MPS: In this version of the test, a radioactive isotope is injected during or within 2 hours of chest pain. If the scan is completely normal, by implication no infarction or volume ischaemia is present and the risk of immediate (1–2 weeks) events is low enough to allow hospital discharge. The patient returns for the stress component of the study, which provides data on risk stratification and the need for angiography.

Immediate scanning using infarction-seeking isotopes: This test remains largely investigative.

CTPA: CTPA is a crucial test that is increasingly useful in the assessment of acute chest pain. It should be ordered immediately as soon as PE is suspected, and preferably carried out with a few hours of acute hospital admission. Not only does it establish whether PE is present, but it assesses the quantity of PEs, thereby establishing the risk of haemodynamic collapse and thus determining how aggressive therapy should be (thrombolysis vs heparin alone) and where the patient should be monitored. CTPA also provides data on the presence of pneumonia, concomitant lung disease (e.g. emphysema), aortic disease, and the extent of coronary calcification, a strong predictive factor for coronary disease. Accordingly, even if CTPA excludes PE, it often moves the management forwards.

Coronary angiogram: A coronary angiogram is the key test in ACS, and very useful diagnostically in those in whom non-invasive investigations have failed to firmly establish the diagnosis. Most patients with an ACS have a coronary angiogram, to risk stratify and as a prelude to revascularization (percutaneous or surgical). However, many physicians underestimate its role in diagnosis. If there are significant risk factors for coronary disease, and the pain could be cardiac, and no alternative explanation has emerged, often a coronary angiogram provides a quick and **relatively** safe means of determining whether coronary disease is present. The risks are about 1 in 1000 of a serious adverse complication (heart attack, stroke, death).

Other diagnostic tests

All patients admitted with chest pain should have:

- a full blood count; anaemia can provoke angina, a raised white-cell count may indicate infection (e.g. pneumonia) or PE, and a high platelet count may indicate a haematological process giving rise to an ACS
- a full biochemical profile, to assess renal function, which is always critical in all hospitalized patients, and liver function, which may be abnormal because of complications of cardiac or respiratory illness or because the prime pathology is subdiaphragmatic (e.g. gall bladder disease)
- tests for inflammatory markers, such as C-reactive protein (CRP) and the erythrocyte sedimentation rate
- tests for lipid levels (especially cholesterol) and random glucose

Introduction to therapy

The aim of therapy is to improve prognosis, and relieve symptoms. It is easy to give directed therapy once you know what the diagnosis is, what the exact nature of any comorbidities are, and how they impact therapy, but it can be extremely difficult when the differential diagnosis remains broad and when therapies for some possible diagnoses can easily exacerbate other possible diagnoses (e.g. dual antiplatelet therapy if an ACS is top of the differential but an aortic dissection is Number 2!). How does one approach this?

- First, use the quickest means possible to establish the diagnosis: frame your question (see Hurst's steps in 'Approach to diagnosis'), think of the single test required to establish the diagnosis, and then get this test **immediately** if the condition could be life-threatening. For example, if you think the diagnosis is PE, order CTPA to be done then and there—that is, the afternoon of admission, not routinely, in a few days' time.
- Perform a clinical and investigative screen for comorbidities, especially falls, dementia, COPD, renal failure, and anaemia; establish in your own mind how these impact both diagnosis and therapy.
- If your definitive investigative tool is not available (e.g. out-of-hours CTPA is rarely available, and the same is true for coronary angiography for most chest pain, except STEMI), then use what imaging you have (e.g. out-of-hours cardiac ultrasound often provides useful data on diagnosis and risk both for ACS and PE).
- Do not believe that you **MUST** give therapy; if you do not know what the diagnosis is, then risk assess the patient **as if** they had an ACS or PE using standard scores (e.g. TIMI for ACS; for PE, the absence of tachycardia, with significant hypoxaemia and ECG changes, indicates lower—although not low—risk). If your risk stratification establishes low risk, and comorbidities substantially raise the risk of empiric therapy, withhold therapy until you can establish the diagnosis.
- Give empiric therapy for your Number 1 diagnosis—if it does not conflict with other possible diagnosis, give full treatment as appropriate. ACS will benefit from dual antiplatelet therapy if there are ECG changes or raised troponin; if neither is present, give mono-antiplatelet therapy (and low-molecular-weight heparin (LMWH) thromboprophylaxis as appropriate). Do not rush in with aspirin/clopidogrel/LMWH in chest pain with a normal ECG and negative troponin, as even if they have an ACS they will not benefit, and the potential to do harm is significant given that the diagnosis may easily not be an ACS (negative early investigations).
- Modify your treatment using common sense; for example, profound dementia and frequent falls implies you should not rush in with aggressive antiplatelet and anticoagulant therapy.
- If you think the diagnosis could be an ACS or PE but anaemia is present, and you cannot get diagnostic imaging (CTPA), then use what information you have and adopt a sensible approach to treatment.

Prognosis

Prognosis in chest pain depends on the diagnosis. Therein lies the problem; if you know the diagnosis, all well and good; risk prediction scores for each illness are available and give you the outcome. However, if you don't know the diagnosis, you have more limited data on prognosis. As most chest pain whose cause is not immediately apparent is either benign or due to an ACS, most strategies in A & E concentrate on excluding an ACS. This is entirely valid, but one must consider the alternative diagnoses, as these strategies are unhelpful in risk stratifying, for example, aortic dissection, pneumonia, or cancer causing rib pain. This emphasizes the need to always think about the diagnosis (e.g. benign chest pain), not the syndrome (e.g. troponin-negative chest pain). Most A & E strategies are designed to identify low-risk patients who can be safely discharged, for outpatient workup if necessary. What strategies are helpful?

- Consider the diagnosis using a standard history/examination/simple investigation approach. Often, this will allow one to be guided away from a chest-pain algorithm.
- All patients with chest pain must have an ECG (done immediately, and then frequently, e.g. at hourly intervals for the first 4–6 hours) and basic blood tests (full blood count, biochemistry, CRP). All patients need chest X-rays. Some patients need D-dimer tests. Do a highly selective troponin at presentation, and one 3 hours later.
- If the diagnosis is not clear after a few hours observation, you will be in a position to risk stratify even if you do not have a diagnosis. If patients are well (no arrhythmias or haemodynamic compromise) and oxygenated normally (no evidence of PE), with all pulses intact, no aortic regurgitation (no evidence of aortic dissection), no evidence of heart failure (from exam and chest X-ray), a normal ECG that remains normal, two negative highly selective troponins, and one negative CRP, then they fall into a low-risk category and they may be discharged with reasonable safety, provided, of course, that you have organized appropriate outpatient follow-up and investigation (this is the responsibility of the A & E clinician).
- Pitfalls in risk stratifying patients with chest pain in A & E include failing to address key factors in the history, failing to notice mild hypoxaemia (PE), failing to recognize that the ECG must be normal or near normal for low risk (fixed ECG abnormalities immediately raise the risk profile, sometimes massively, as in fixed, deep, anterolateral T-wave inversion, which often indicates a high-risk proximal LAD stenosis), failing to look at the chest X-ray (pneumothorax, heart failure)—and, above all, failing to consider a diagnosis of aortic dissection.
- Handling uncertainty in the diagnosis of this symptom is often not easy; however, remember that the greatest risk a patient with a life-threatening condition causing their chest pain faces is being sent home from A & E. Hence, if you have diagnostic doubt about the cause of the chest pain, it is always reasonable to admit the patient for further observation and investigation.

10 Chronic chest pain

Jonathan Timperley and Sandeep Hothi

Definition

Chronic chest pain constitutes pain (or discomfort, or indeed any sensation recognized by the patient as being 'not normal') in the chest; the hallmark is that it has been present for a significant time, usually months (to allow differentiation from acute chest pain and acute coronary syndromes (ACSs)). The main question to answer in the management of chronic chest pain is 'Are we dealing with chronic stable angina?'. The aim of having an arbitrary time period in the definition is to try and separate out patients with ACSs (see Chapter 9); this is not always possible in practice and, not infrequently, a diagnosis of an ACS (or other life-threatening condition) is made in those presenting with chronic chest pain—in other words, you need to keep your diagnostic wits about you when approaching chronic chest pain.

Differential diagnosis

Table 10.1 lists the usual causes that are included in the differential diagnosis.

Context

Chronic chest pain is common and may present in primary or secondary care. In both settings, it is important to determine whether chest pains relate to ischaemic heart disease (IHD), another life-threatening cause, or another illness. While IHD is the commonest life-threatening cause, it is not the only life-threatening cause (e.g. chronic pulmonary emboli), so do not restrict your differential diagnosis to the heart alone.

Approach to diagnosis

In thinking of the diagnosis, it is helpful to approach the differential diagnosis systematically:

- First, **think demographically**: 'What are the common causes of chest pain for the age/sex of the patient in front of me?'; in particular, use age and sex to estimate the probability of coronary disease, then adjust the probability by taking into account risk factors for coronary disease. Young females are unlikely to have coronary disease (they have musculoskeletal pains, gastrointestinal pains, breast pains, and, more rarely, pulmonary emboli), whereas older men who smoke and have diabetes are very likely to have coronary disease. Put another way, estimate a preclinical assessment probability of coronary disease (and other causes) using demographics and coronary disease risk factors. Always ask women if they are on the oral contraceptive pill; ask all patients about risk factors for thromboembolic lung disease.
- Second, as for all illness, **use the specific clinical features** to refine your differential diagnosis (see 'Specific clues to the diagnosis'). This is important; elderly patients commonly have coronary disease, but it is not responsible for their symptoms; so with all patients, you must answer the questions 'Do they have coronary disease?' and 'If so, is it relevant to the symptoms?' (in other words, 'do they have angina?').
- Third, **think anatomically**: 'What are the common causes for chest pain in the anatomical area that my patient experiences symptoms?'; for example, stable angina is usually felt retrosternally (as are many gastrointestinal causes of pain), whereas muscular pain is often felt around the left breast (pain sited here provokes more anxiety in lay patients than right-sided discomfort, and so lasts longer). Back pain radiating anteriorly is often due to

entrapment neuropathy. Ask whether the pain moves around—angina does not move between episodes, whereas musculoskeletal and non-cardiac chest pain does. Pain moving around the chest is described as 'flitting'; angina does not flit, nor does gastrointestinal pain. Most flitting chest pain is benign; rarely, it relates to pleurisy due to autoimmune disease.

- Fourth, **use an investigation (where possible) to confirm the diagnosis** (see 'Key diagnostic tests' and 'Other diagnostic tests') and, where relevant, to exclude the most likely serious diagnosis.
- Finally, **ask for all patients what their risk is of cardiac death**; if coronary disease is present, use standard models (e.g. Duke nomogram; see Chapter 89) to predict death. If you do not think coronary disease is present, ask the following questions:
 - **First**, what is the risk of a cardiac event occurring (using risk prediction charts based on standard risk factors (Table 10.2))?
 - **Second**, in those patients in whom you do not know if coronary disease is present, ask yourself the question 'If coronary disease were to be present, what would the prognosis be?'. This can then really clarify in your mind whether you should order an investigation with risk/cost (e.g. coronary angiography)—for example, if symptoms are infrequent (so there are no symptomatic grounds for intervention), and prognosis, if coronary disease were present, is good, there may be no grounds to undertake coronary angiography, and the patient can be managed medically.

The specific clinical features are ascertained by taking a careful history. The following should be determined:

The character of the pain, including its quality and location/radiation: Angina has a deep-seated quality that, once experienced, is rarely forgotten. If patients have had a previous myocardial infarct, specifically ask if the current symptoms, while differing in severity, have the same quality as the infarct.

The location of the pain: This is helpful, but not as diagnostic as many patients and doctors think. In most cases, angina is felt retrosternally, but this is not true for all cases; in some, angina is felt laterally or, indeed, in the shoulder alone. In most cases, pleurisy is felt laterally, gastrointestinal pain is felt retrosternally, and musculoskeletal pain is felt in the left chest—these are all generalizations and there are many exceptions. Nonetheless, location is a clue as to aetiology although do not use it to the exclusion of other factors.

Time course of symptoms: Inquire about the frequency, severity, and duration of the symptoms (pain lasting seconds is never serious)—first, to determine how intrusive the problem is to the patient and, if so, how important symptom relief is as opposed to diagnosis (clarity in this area is crucial for subsequent management); and, second, to estimate risk—infrequent anginal symptoms often indicate a low risk process, whereas intrusive symptoms are more likely to indicate severe coronary disease, placing the patient at higher risk of infarction and early death. A change in symptoms is also of relevance, as a worsening of chronic angina symptoms (becoming more severe, more frequent, or more easily provoked) often indicates progressive pathology warranting escalation of investigation and management (see Chapter 9).

Provoking and relieving factors: Crucially, one must be quite clear about the relationship with effort, but also ascertain any relation with food or lying flat (suggesting a gastrointestinal pathology), and upper arm movement (suggesting a musculoskeletal problem). It is above all the relationship with effort that allows chest pain to be diagnosed as angina in character, and you must completely understand this in all patients you see with chronic chest pain (see 'Stable angina').

	Condition	Frequency	Specific clinical clues	Diagnostic test	Traps
Cardiac	Chronic stable angina	Very common in specific groups	See text; a syndrome of chest pain provoked by effort and rapidly and totally relieved by rest; if the relationship with exercise is absent, the pain is not chronic stable angina	Confirmation of coronary disease, angiographically or by functional study	Stable angina can be caused by (1) coronary disease, (2) aortic stenosis, (3) pulmonary hypertension, or (4) (rarely) syndrome X (inadequate coronary vasodilator reserve)
	ACS	Common	Similar quality pain to stable angina, occurring at rest	Evidence of myocardial necrosis (enzymes) and coronary angiography	Myocarditis and takotsubo cardiomyopathy may present in a fashion similar to ACS; do not label troponin rises due to renal failure, or tachyarrhythmia (e.g. AVNRT) as an ACS
	Pericarditis	Not rare	Retrosternal pain, worse on inspiration, and on lying	None; typical ECG changes sometimes help	Exclude significant pericardial effusion by cardiac ultrasound; most but not all pericarditis is benign
Respiratory	Pleurisy	Common	Lateral pain, worse with inspiration	None	Always actively diagnose the cause of pleurisy—usually infection—but you must actively exclude pulmonary embolus
	Airways pain	Common	Deep internal discomfort, often associated coughing, worse on effort	Spirometry	Airways discomfort due to COPD may coexist with angina due to coronary disease (smoking causes both)
Gastrointestinal	GORD	Common	Retrosternal burning pain (reflux)	OGD, relief with PPIs	Oesophageal spasm can have symptoms identical to ACS, and this may need to be excluded
	Dyspeptic syndromes	Very common	Epigastric discomfort	Usually relief with PPIs	
	Peptic ulcer disease	Very common	Intrusive epigastric discomfort	OGD, relief with antacids	
	Gallbladder disease	Common	Pains usually occur episodically, felt in the epigastrium (bile duct pain), or right upper quadrant (cholecystitis)	Abdominal ultrasound	Beware: gall bladder stones are very common, and other pathologies may coexist with them
	Chronic pancreatitis	Rare	Severe epigastric pain	CT abdomen	Alcohol excess is very common; such patients often have multiple comorbidities and are at risk of coronary disease
Musculoskeletal pain	Arthritis	Common	Position or movement dependence to pain	No diagnostic test	Often improves with time or NSAIDs
	Non-specific musculoskeletal pain	The most common cause of pain	Many features; most commonly pain moving around chest, of variable duration, sometimes tender	No diagnostic test	May coexist with coronary disease, which usually therefore needs excluding in those at risk
Neurological	Entrapment neuropathy	Common	Back pain radiating anteriorly, lasts for hours at a time, not effort dependent	No diagnostic test; supportive data from finding spinal arthritis	As there is no diagnostic test for this, such patients may also need to have coronary disease ruled out
	Zoster	Rare	Very severe pain, usually only present for a few days	Rash, once it has occurred!	Usually not in the differential diagnosis of chronic chest pain; post-herpetic neuralgia, rarely; the history is diagnostic
Other	Cancer	Rare	Usually severe, localized pain	Imaging and histology	All patients with chest pain MUST have a chest X-ray, mainly to rule out malignancy

Abbreviations: ACS, acute coronary syndrome; AVNRT, atrioventricular nodal re-entrant tachycardia; CT, computed tomography; ECG, electrocardiogram; GORD, gastro-oesophageal reflux disease; NSAIDs, non-steroidal anti-inflammatory drugs; OGD, oesophagogastroduodenoscopy; PPIs, proton-pump inhibitors.

Table 10.2 Clinical pretest probabilities in patients with stable chest pain symptoms

Age	Typical angina		Atypical angina		Non-anginal pain	
	Men	Women	Men	Women	Men	Women
30–39	59 [†]	28 [†]	29 [†]	10 [*]	18 [†]	5 [*]
40–49	69 [‡]	37 [†]	38 [†]	14 [*]	25 [†]	8 [*]
50–59	77 [‡]	47 [†]	49 [†]	20 [†]	34 [†]	12 [*]
60–69	84 [‡]	58 [†]	59 [†]	28 [†]	44 [†]	17 [†]
70–79	89 [§]	68 [‡]	69 [‡]	37 [†]	54 [†]	24 [†]
>80	93 [§]	76 [‡]	78 [‡]	47 [†]	65 [†]	32 [†]

Note: Probabilities of obstructive coronary disease shown reflect the estimates for patients aged 35, 45, 55, 65, 75, and 85 years.

[†] Patients with a pretest probability <15% can be managed without further testing.

[‡] Patients with a pretest probability of 15%–65% could have an exercise ECG, if feasible, as the initial test. However, if local expertise and availability permit a non-invasive imaging-based test for ischaemia, this would be preferable, given the superior diagnostic capabilities of such tests. In young patients, radiation issues should be considered.

[§] Patients with a pretest probability of 66%–85% should have a non-invasive imaging functional test for making a diagnosis of stable coronary artery disease.

[§] For patients with a pretest probability >85%, one can assume that stable coronary artery disease is present. They need risk stratification only.

Specific clues to the diagnosis

Stable angina

The absolute key to diagnosing chronic stable angina is its relationship to effort (Table 10.3); pains must not be present before effort, must occur reliably on similar levels of effort (earlier if going uphill, when the weather is cold, or after eating), must build up such that continued effort at the same intensity becomes increasingly difficult, and must resolve completely within a minute or so of rest. Pain with these characteristics is termed 'anginal chest pain'. It often means angina due to obstructive coronary disease, but may indicate aortic stenosis, pulmonary hypertension, asthma (a common cause of this symptom), and, very rarely indeed, the very much over-diagnosed syndrome X. Thus, the diagnosis of anginal chest pains is an **interim** diagnosis until the pathological substrate can be determined. In many regards, therefore, it is analogous to **fever**; no one has a final diagnosis of fever. Likewise, no one should have a final diagnosis of angina; rather, the diagnosis should be 'angina due to obstructive coronary disease (or whatever)'. How can you discriminate between the different causes of angina? The following all help: coronary disease risk factors; typicality, or otherwise, of the pain (see Table 10.3, for obstructive coronary disease); physical examination (aortic stenosis, sometimes pulmonary hypertension); and cardiac ultrasound (pulmonary hypertension— aortic stenosis is diagnosed prior to the ultrasound). Chronic chest pain is often classified according to its similarity, or otherwise, to angina, which NICE defines as chest pain which:

- presents as a constricting discomfort in the front of the chest, or in the neck, shoulders, jaw, or arms
- is precipitated by physical exertion
- is relieved by rest or glyceryl trinitrate tablets within about 5 minutes

Table 10.3 Clues to the diagnosis of effort angina using the presence and nature of effort-dependent symptoms

	Present before effort	Leads to effort stopping	Time to resolution following effort
Angina	No	Yes	1–2 minutes
Musculoskeletal chest pain	Often	Sometimes	>20 minutes
Non-cardiac chest pain	Often	No	Substantial, sometimes days

Chest pain exhibiting all three of these features is defined as **typical angina**; chest pain exhibiting two of these features is defined as **atypical angina**; and chest pain exhibiting only one or none of the features is defined as **non-anginal chest pain**.

Unstable angina/acute coronary syndromes

Half of patients with an ACS (see Chapter 90) have preceding-effort angina: they have clear-cut effort-dependent symptoms, now occurring at rest. The diagnosis here is easy. In half, the ACS comes out of the blue; however, in these patients their symptoms, at most, have only been going on for a few weeks—which, by definition, excludes patients with chronic chest pain (where symptoms need to have been present for a few months). Have a high index of suspicion that episodic new chest pain (<2 weeks) in someone at risk of coronary disease could be an ACS—and beware: in these patients, there may be little or no effort dependence to the pain. Age and other coronary risk factors increase the chance that new chest pain is an ACS, whereas multiple previous contacts with physicians and many current symptoms decrease the chance of ACS.

Musculoskeletal pain

Surprisingly, a history of onset clearly related to musculoskeletal injury is rarely present. Upper body movement exacerbates pains, and so may using a particular limb (e.g. the left arm). Pains last a long time, not the minutes that stable angina does, and can last days. The chest wall may be tender to palpation, although this is far from universal. Ninety-nine per cent of musculoskeletal pains are benign and no underlying pathology is found; however, very rarely, musculoskeletal chest pains are due to a cancer eroding a rib or similar structure—the clue here is the localized area of the pain, the unremitting severity of the pain, and systemic features (e.g. malaise and weight loss). A history of previous malignancy is clearly a clue that should not be ignored. One reason for carrying out a full blood count and full biochemical profile in those with chest pain is to look for clues to such systemic illness. As rib metastases are difficult to see on plain chest X-ray, if their presence remains possible despite negative plain film imaging, consider ordering a bone scan.

Neuropathic pain

This is typically a sharp, shooting pain, often with a dermatomal or peripheral nerve distribution. There may be a history of onset after surgery, herpes zoster, and other causes of peripheral neuropathy, such as diabetes mellitus.

Gastrointestinal pains

Gastrointestinal pains may be due to the following:

Peptic ulcer disease: This may cause epigastric pain before eating, or at night (said to occur with duodenal ulcers), or pain related to meals (said to indicate gastric ulcers).

Gastroesophageal reflux disease: This causes a burning sensation which is felt in the retrosternal area or epigastrium, or regurgitation of acid or bile. Oesophageal spasm can be identical to the pain of myocardial ischaemia—a severe retrosternal pain lasting many minutes, and associated with diaphoresis and sometimes fear. The pain is not effort dependent (so the differential is an ACS rather than chronic stable angina). The clue is that, by the time patients present, they have often had many episodes going back years, unlike the case with ACS.

Biliary disease: In this case, symptoms are usually restricted to being subdiaphragmatic; rarely, they may be prominent above the diaphragm.

Respiratory causes of chest pain

Airways disease and pleurisy (infective or thromboembolic in origin) are common causes of abnormal chest sensations. In patients with chest pain due to airways disease, symptoms may be worse on effort ('tightness in the chest'), leading to confusion with angina due to coronary disease—one clue in favour of airways disease is the presence of marked breathlessness (patients usually mention this first rather than the chest tightness), which is rare in angina unless:

- there is severe, multivessel coronary disease—multiple risk factors are usually present, and the standard exercise test is usually very abnormal

- in those with impaired left ventricular function, which can be suspected from the history (previous myocardial infarction) and abnormal resting ECG
- in those with diabetes, in whom, de facto, there is a high pretest probability of coronary disease, indicating a preexisting need for high-level coronary-directed investigations

Other clues are:

Asthma: This is episodic wheeze, with breathlessness. The clue is usually the demographics, together with the prominence of breathlessness as a symptom.

Chronic obstructive pulmonary disease: In the history, the long progressive history of increasingly intrusive breathlessness is a good clue, backed up by the demographics, smoking history, and examination (hyperinflated lungs, poor air entry, wheeze) and confirmed by spirometry.

Non-cardiac chest pain

By this vague term, cardiologists mean ‘pain that doesn’t come from the heart, and doesn’t have specific features allowing a more specific diagnosis’ (so it is not musculoskeletal pain, which is diagnosed using the features previously outlined). It is a useful term for medical professionals, although patients find its use challenging. Cardiologists mean by its use ‘pain that historically is not anginal (no effort dependence) and for which appropriate coronary (and other cardiac) investigations have been negative’. It means pain that is benign prognostically and does not require cardiac drugs for treatment, or cardiologists for management. Patients with frequent hospital attendances due to non-cardiac chest pain benefit from cognitive behavioural therapy.

Key diagnostic tests

Blood tests

A full blood count, biochemical profile, thyroid function, cholesterol (and HDL/LDL subfraction), glucose, and triglyceride tests are all mandatory.

Resting ECG

In most patients with chronic chest pain, the resting ECG is normal and neither increases nor decreases the post-test probability of IHD. In a very few, there are diagnostic changes—evidence of an old Q-wave infarction, or ST/T-wave changes strongly associated with coronary disease (such as symmetrical pan-anterior T-wave inversion). Minor ECG changes in the elderly are rarely of any diagnostic utility. Occasionally, the ECG raises the possibility of another pathology—gross left ventricular hypertrophy suggests hypertension (usually obvious from the history and examination—and, of course, strongly correlated with the development of coronary disease), aortic stenosis (in this case, the exam is diagnostic), or, if neither are present, hypertrophic cardiomyopathy. A normal resting ECG does not exclude coronary artery disease, and this is the category into which most patients fall.

Chest X-ray

A chest X-ray is mandatory for all presenting with chronic chest pain, although this test rarely helps diagnostically. Usually normal (post-test IHD probability unchanged), it occasionally shows an increase in the size of the cardiac silhouette (in high-BMI individuals, this is not associated with cardiomegaly whereas, in thin patients, a large cardiac silhouette may indicate poor ventricular function or a pericardial effusion). Rarely, it shows a neoplasm, often caused by the same risk factors as coronary disease (smoking, age), as the cause of the chest pain.

Exercise ECG

In an exercise ECG, patients are exercised using a standard protocol on a motorized treadmill while an ECG is recorded. The test has varying specificity and sensitivity (see Table 10.3 and Figure 10.1), being least accurate in young women without typical angina, and most accurate in older men with typical angina. While conduction blocks on the ECG, and pacemakers, make the ECG difficult to interpret, the most helpful aspect of the exercise ECG is the accurate documentation of

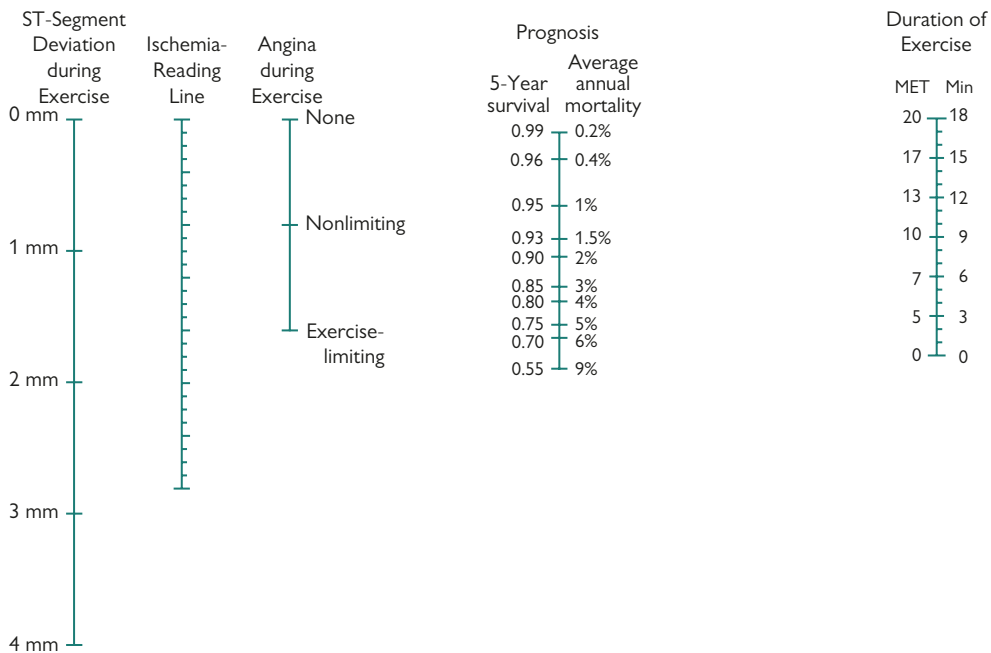

Figure 10.1 Nomogram of the prognostic relations embodied in the treadmill score. Determination of prognosis proceeds in five steps. First, the observed amount of exercise-induced ST-segment deviation (the largest elevation or depression after resting changes have been subtracted) is marked on the line for ST-segment deviation during exercise. Second, the observed degree of angina during exercise is marked on the line for angina. Third, the marks for ST-segment deviation and degree of angina are connected with a straight edge. The point where this line intersects the ischaemia-reading line is noted. Fourth, the total number of minutes of exercise in treadmill testing according to the Bruce protocol (or the equivalent in multiples of resting oxygen consumption (METs) from an alternative protocol) is marked on the exercise-duration line. Fifth, the mark for ischaemia is connected with that for exercise duration. The point at which this line intersects the line for prognosis indicates the 5-year survival rate and average annual mortality for patients.

exercise capacity, a variable strongly associated with prognosis. Thus, even where the ECG is unreliable, useful data can emerge from a well-conducted treadmill test.

Resting echocardiography

A resting echocardiography is rarely helpful by itself in diagnosing the cause of chest pain (very occasionally, it shows regional wall motion abnormalities suggestive of coronary disease), but often is very helpful in determining prognosis in a range of different diagnostic possibilities (the key measure is left ventricular function). Rarely, it shows unsuspected defects (aortic stenosis, hypertrophic cardiomyopathy).

Functional and anatomical imaging

Imaging used to investigate coronary artery disease may be **functional**, in which case it is used to assess possible reductions in myocardial perfusion and function in response to exertion or pharmacologically induced stress. Imaging may also be **anatomical**, in which case it is used to look for radiographic evidence of coronary artery obstruction. The advantage of functional imaging is that it permits detection of physiologically relevant obstructions, in contrast to anatomic imaging (see Chapter 87).

Stress echocardiography

Stress echocardiography uses echocardiography to examine the heart after it has been stressed by a pharmacological agent (usually dobutamine). Abnormal features are stress-induced decreases in wall thickening, regional wall motion hypokinesia/akinesia/dyskinesia, or compensatory hyperkinesia. Obesity and lung disease degrade the quality of the echocardiographic windows and may render the test unusable, though ultrasound contrast agents may circumvent this. Data shows that stress echocardiography is more accurate than the exercise ECG alone in detecting coronary disease, and about as accurate as myocardial perfusion scintigraphy.

Myocardial perfusion scintigraphy

Myocardial perfusion scintigraphy uses a radioactive tracer (thallium-201 or technetium-99) to determine myocardial perfusion at rest (defects may indicate previous infarction) and during stress (exertional or pharmacological), when inducible defects not present on the rest scan usually indicate myocardial ischaemia. Areas of inducible ischaemia represent areas at risk for future infarction, and their extent correlates to the prognostic benefit and hence need for revascularization. This test offers superior prognostic information, compared to exercise testing, and is also diagnostically useful where resting ECG abnormalities degrade exercise ECG interpretation. Patients with a negative myocardial perfusion scintigraphy result are at low risk for significant coronary artery disease events, although this result does not exclude coronary artery disease being present.

CT calcium scoring

This uses CT scanning to assess the degree of calcification of the coronary arteries (expressed as the Agatston score). A negative test (zero calcium) has a 96%–100% negative predictive value. The more calcium there is, the greater the chance of flow-limiting coronary disease; however, because of this probabilistic relationship, the test cannot positively diagnose coronary disease; it can only estimate the chance of coronary disease, and this is rarely sufficient in clinical practice.

CT coronary angiography

CT coronary angiography, where intravenous contrast is detected by CT imaging, is used to assess the patency of the coronary lumen. It requires a regular heart (so atrial fibrillation is an exclusion) and bradycardia (which is achieved with beta blockers, or ivabradine in patients with reversible airways disease); good luminal images are only obtained in those without extensive coronary calcification (so old age, renal failure, and diabetes are relative exclusions). It is likely to be useful in selected subgroups, although its exact role is still to be determined.

Coronary angiography

Currently, coronary angiography is the gold standard for diagnosing coronary artery disease. The test is invasive (a catheter is passed through the radial or femoral artery to the aortic root) and costly; risk and cost must be balanced against benefit. The risk is about a 1 in 1000 chance of a major adverse complication, including stroke, myocardial infarct, and death (higher in the elderly, diabetics, those with previous stroke, and those with extensive vascular disease). A significant stenosis is $\geq 70\%$ obstruction of an epicardial coronary artery. All coronary disease carries an adverse prognosis, although in many the risk is surprisingly small and best approached medically. In the few with chronic stable angina with extensive disease (left main disease, disease in all three major epicardial coronary arteries, or disease in the proximal portion of the left anterior descending coronary artery), the prognosis is less good, and improved by early revascularization—for many, the main aim of angiography is to diagnose and treat such severe coronary disease.

Oesophago-endoscopy

Investigations aimed at identifying gastrointestinal causes of chest pain include oesophago-endoscopy. This test enables the direct visualization of inflammation, ulcers, strictures, and both benign and malignant lesions. It also allows tissue sampling for histology. A trial of a proton-pump inhibitor may constitute a diagnostic test for gastro-oesophageal reflux disease (GORD). Ambulatory oesophageal pH monitoring can aid in the diagnosis of GORD. In suspected dyspepsia with no alarm features suggesting malignancy, a positive serology for *Helicobacter pylori* may influence antimicrobial therapy.

Other diagnostic tests

Cardiac magnetic resonance imaging is increasingly used for the assessment of cardiac structure, tissue characterisation, prior infarction, as well as functional assessment during a stress MRI.

Introduction to therapy

Stable angina

Lifestyle advice, such as recommending that the patient attain an ideal weight and engage in high-intensity exercise programmes, together with dietary advice (e.g. consumption of oily fish, low amounts of animal fats, and modest amounts of alcohol) should be provided. Medical therapy is through the use of aspirin (or clopidogrel), lipid-lowering drugs (statins), and angiotensin-converting enzyme (ACE) inhibitors. Symptomatic relief is through the reduction of myocardial oxygen demands via beta blockers, and coronary vasodilatation with nitrates. In three-vessel or left main-stem disease, CABG is the preferred choice for revascularization. Patients with other discrete lesions may be treated with percutaneous coronary intervention if symptoms are refractory on maximum medical therapy.

Musculoskeletal pain

Musculoskeletal pain should be treated with reassurance and very occasionally analgesia.

Gastrointestinal pain

Gastrointestinal pain often responds to proton-pump inhibitors.

Prognosis

Prognosis depends on the diagnosis and extent of the problem. Patients with a negative myocardial perfusion scintigraphy, exercise ECG, stress MRI or stress cardiography result are at a lower risk of future cardiac events than those with a positive result. However, it must be noted that, as with many tests, the sensitivity and specificity of these tests is not 100%, and so an understanding of the probabilistic nature involved in their interpretation is important in determining

the relevance of a test result for a particular patient. Where non-invasive investigations are performed but the results are equivocal, formal angiography should be considered to assess for coronary artery disease.

How to handle uncertainty in the diagnosis of this symptom

In this area, more than in most, uncertainty can and does occur, to the frustration of both the patient and clinician. Uncertainty can revolve around diagnosis, response to treatment, and prognosis. For diagnostic uncertainty, depending on the situation, always clarify in your own mind whether you think angina is present on the basis of the history, as this is the key to management. It is entirely permissible to diagnose non-cardiac chest pain, and still undertake coronary-directed tests to clarify cardiac prognosis. However, be clear with patients as to why you are doing tests, particularly if the tests are invasive, as confusion can easily arise and patients may subsequently not understand that, while they have coronary disease and chest pain, the two are not related, something you thought was the case from the outset. Inform patients when you think symptoms are non-cardiac but the investigations to date haven't ruled out severe coronary disease and you need to know more. Be very clear with patients that you believe that, even if you find coronary disease, it does not relate to symptoms. If you find coronary disease, but cannot decide clinically if it is relevant to symptoms, demonstrate myocardial ischaemia (e.g. via myocardial perfusion scintigraphy, fractional flow reserve—see Chapter 87) before proceeding to revascularization. In a very few patients, you may have to undertake revascularization to see if it helps their symptoms; again, be clear with patients that there is a significant possibility that symptoms are non-cardiac

before revascularization so that, if revascularization fails to improve symptoms, your patients are not surprised. If patients do not respond to treatment, re-evaluate the history so that you are clear as to whether you have been barking up the wrong tree—are you treating angina with proton-pump inhibitors? Are you treating musculoskeletal chest pain with nitrates? The clue to treatment failure is usually in a thorough re-evaluation of the history; occasionally, you may have to introduce empiric therapy as a therapeutic trial, but be clear with patients that this is what you are doing. Cardiac prognosis is usually easy to estimate from the demographics, a knowledge of left ventricular function, and functional (e.g. exercise stress testing (see 'Key diagnostic tests')) or anatomic (e.g. coronary angiography) data. However, you should be very clear with patients that cardiac prognosis is a probabilistic issue, and this is the main difficulty that patients have in understanding outlook—they may have an extraordinary good prognosis, but still die tomorrow, or a terrible prognosis, but live 10 years—you must convey this probabilistic aspect. This comes down to good doctoring.

11 Hypotension

Jonathan Timperley and Sandeep Hothi

Definition of symptoms

Hypotension is defined as a systolic arterial blood pressure of less than 90 mm Hg, or a diastolic arterial pressure of less than 60 mm Hg. Hypotension may lead to shock (the hallmark of which is clinical evidence of inadequate blood supply to critical organs), but does not inevitably do so.

Differential diagnosis

The causes of hypotension may be broadly divided by their pathophysiological mechanism and are shown in Table 11.1.

Context

There is substantial inter-individual variability in mean arterial blood pressure and the range of tolerated blood pressures. Thus, while hypotension has multiple possible causes, its effects will depend on the rapidity of onset, the absolute blood pressure, and the difference between the patient's usual blood pressure and its current level. Bearing this in mind, mild hypotension may be observed in the outpatient setting due to drug therapy and not warrant hospital admission. At the other extreme, hypotension may result in organ hypoperfusion and failure, causing critical illness.

Approach to diagnosis

The first issue is to decide whether the person with hypotension is stable and can be investigated and managed slowly, or unstable with signs of organ hypoperfusion ('shock'). For the latter, the diagnostic approach is made simultaneously with management; the priority is to support the circulatory system and affected organs while the diagnosis is established. Diagnostic features are elicited from the history, examination, and investigations, while circulatory and organ support are provided as needed. Assessment typically follows an ABCDE approach, which often identifies life-threatening causes requiring immediate treatment (e.g. tension pneumothorax) and, if not, will usually give strategic direction to further investigation and therapy.

In any acute illness, the presence of hypotension is a poor prognostic sign, and as such, is a feature of many early warning scores. If hypotension induces organ hypoperfusion, then the condition of shock exists. Organ hypoperfusion results in abnormal organ function, as follows:

Cerebral hypoperfusion: anxiety, aggressiveness, altered mental state, altered level of consciousness

Renal hypoperfusion: reduced urine output, acute kidney injury

Cardiac hypoperfusion: may result in myocardial ischaemia if there is preexisting coronary disease

Liver hypoperfusion: ischaemic hepatitis

Skin hypoperfusion: pallor, poor capillary return; sweating is a marker of sympathetic activation and often occurs in hypovolaemic or cardiac causes of shock

As shock can rapidly progress to irreversible organ failure and death, it is critically important to treat immediately according to the most likely cause. Diagnostic testing should be done if this does not delay treatment (e.g. echocardiography, if it can be performed immediately at the bedside) but, if waiting for diagnostic tests will lead to an unacceptably delay (e.g. in situations occurring in the middle of the night), you may have to treat 'blindly' if you feel the patient is deteriorating rapidly and time does not allow your preferred investigation to be performed. This means that treating shock, while distressing for patients, who are critically unwell and may die, and their relatives, can also be very stressful for clinicians, as your level of diagnostic certainty is often much lower than usual, magnifying your anxiety.

Specific clues to the diagnosis

In the stable patient, run through the usual diagnostic possibilities; however, many cases relate to an interaction between age, drugs, and possibly autonomic failure. Elicit whether the hypotension relates to posture, for example, occurs when the patient is standing upright (orthostatic hypotension), or after the patient has been standing still for a prolonged period of time (e.g. neurocardiogenic syncope). Always establish the drug history. Ask about recent weight loss (as this often leads to lowered blood pressure)—and, if present, determine the reason for the weight loss. Determine whether conditions giving rise to autonomic neuropathy are present (e.g. age, diabetes, neurodegenerative conditions).

In the acute setting, the history often provides the best clues as to cause and indicates whether this is likely to be sepsis (fever; pain in appropriate organs; travel history; etc.), hypovolaemia (often obvious blood or excess fluid coming from an orifice), or cardiac (e.g. known cardiac disease, or major risk factors for ischaemic heart disease/pulmonary embolism).

Examination of those in shock

Those in shock have a reflex sinus tachycardia; determine if the heart rate is proportionate to the clinical state, and, if not, consider whether tachy- or bradyarrhythmias are contributing. Sustained ventricular tachycardia is a not uncommon cause of shock; atrial fibrillation rarely causes shock unless the heart rate is very high (>220, as in pre-excited atrial fibrillation in Wolff-Parkinson-White syndrome), or severe left ventricular dysfunction is present. Look for evidence of valvar heart disease in the pulse—slow rising (aortic stenosis) or collapsing (aortic regurgitation). A raised jugular venous pressure may indicate heart failure, but can indicate pericardial tamponade, pulmonary embolism, and, rarely, pneumothorax (although here the signs are dominated by gross respiratory distress). The apex beat, if displaced, gives information about the chronicity of heart failure (it takes time for the heart to enlarge). For those with keen ears, a third or fourth heart sound may be heard in those with left ventricular dysfunction. A pericardial rub is rarely heard in tamponade; bibasal crepitations often indicate heart failure, although they sometimes indicate bronchopneumonia (bronchial breathing is a more reliable guide to lobar pneumonia), reduced air entry (in asthma or COPD), or pulmonary oedema. In severe pulmonary oedema, it may be impossible to hear the heart sounds because of the loud chest sounds. Cardiac

Table 11.1 Causes of hypotension

Hypovolaemia	Cardiac pump failure	Vasodilatation
Haemorrhage	Extrinsic (obstruction to inflow/outflow)	Sepsis
Intra-abdominal pooling	Tension pneumothorax	Anaphylaxis
Fluid loss (from kidney, gut, and skin)	Cardiac tamponade	Drug-induced
	Pulmonary embolism	Adrenal insufficiency
	Intrinsic	Autonomic failure
	Ischaemic heart disease	
	Cardiomyopathy	
	Valve disease	
	Arrhythmia	

murmurs may be present and reflect valvar heart disease underlying shock (e.g. critical aortic stenosis, severe mitral regurgitation).

Specific clues to diagnosis

Myocardial ischaemia/infarction

There may be known angina or heart failure. Ischaemic chest pain is often (not always) present (retrosternal heavy chest pain); this must be differentiated from the pain of pleurisy (respiration-dependent breathing, lateralized), which may indicate a pulmonary embolus or pleural involvement in a pneumonic process (do not forget empyema in this situation). Examining those with shock due to ischaemic heart disease often reveals a cool patient with high heart rate, low blood pressure, weak (low volume) pulse, raised jugular venous pressure, quiet heart sounds, and bibasal crackles. The main clue to the diagnosis is provided by the ECG (myocardial ischaemia sufficient to cause shock is almost always manifest as gross ECG changes, although left bundle branch block can, of course, obscure them). Echocardiography, where available, is diagnostic.

Pulmonary embolism

There may be shortness of breath, pleuritic chest pain (may be absent), swollen tender calf, or risk factors for thromboembolism. The chest examination may be normal. The main clue is in the risk factors for venous thromboembolism (cancer, recent surgery, etc.), and the finding of a cool patient with high heart rate, marked tachypnoea, low blood pressure, sometimes a raised jugular venous pressure, hypoxaemia, but otherwise normal cardiorespiratory exam, a clear chest X-ray, and an ECG normal, aside from sinus tachycardia (sometimes atrial fibrillation).

Tension pneumothorax

Look for sudden onset pleuritic chest pain and breathlessness, chest trauma, mechanical ventilation, and deviated trachea, with absent breath sounds on the affected side.

Hypovolaemia

Look for loss of skin turgor, dry mucous membranes, and prolonged capillary refill time with cool peripheries. Postural hypotension (sit the patient forwards in their bed) may be marked. Signs of the underlying cause may be present, as follows:

Ruptured abdominal aortic aneurysm: This is indicated by abdominal tenderness with a pulsatile, central mass and bruising in the flanks.

There may be loss of peripheral pulses with aortic dissection

Gastrointestinal bleed: There may be a history of haematemesis, melaena, rectal bleeding, abdominal pain, and use of NSAIDs, steroids, or anticoagulants. Signs of anaemia on physical examination may be present. It is important to perform a rectal examination in suspected **gastrointestinal** bleeds, looking for melaena.

Dehydration: There may be a history of diarrhoea, vomiting, burns, or heat exhaustion. Often, however, the affected patients are elderly, and dehydration has crept up on them; the shock relates to this along with sepsis.

Sepsis

In septic shock, there is hypotension with vasodilation and warm peripheries. If shock is untreated and progresses, the peripheries may become cold as myocardial depression sets in. There may be features of the underlying infection.

Anaphylaxis

Anaphylaxis is characterized by shortness of breath, an urticarial rash, wheezing, and swelling of the tongue and lips. There may have been a clear trigger and a previous history of anaphylaxis and allergy. An allergy alert tag may be present.

Adrenal insufficiency

Adrenal insufficiency presents in a myriad of ways. Symptoms include fatigue, weight loss, nausea, vomiting, and postural hypotension. There may be increased pigmentation of the palmar creases, lips, scars, and mucous membranes. A history of long-term steroid use with sudden cessation may also be suggestive. Addisonian crisis is

severe adrenal insufficiency with profound hypotension or coma. However, no diagnostically useful signs may be present. **This means that, in all cases of undiagnosed shock, it is reasonable to give replacement steroids in case this is the first presentation of undiagnosed adrenal failure.**

Neurological clues

Recent spinal surgery suggests spinal shock. There may be a history of diabetes mellitus (autonomic neuropathy) or Parkinsonian features (multiple system atrophy).

Drug history

A full history of prescribed and non-prescribed medications and drugs must be elicited, along with the actual doses taken.

Key diagnostic tests

ECG

An ECG is a critically useful test in shock. It may indicate:

Arrhythmia: You must always ask yourself whether any arrhythmia is sufficient to cause shock, as arrhythmias can complicate many causes of shock (e.g. atrial fibrillation is common in cardiogenic shock, regardless of the cause, and also in pulmonary embolism). A tachycardia is a common physiological response in most cases of hypotension.

Myocardial ischaemia or infarction: If infarction is the cause, then usually the ST/T changes are gross. If the changes are subtle, you must decide whether myocardial ischaemia is genuinely causative, or a bystander.

Other features may be present with other causes. For instance, if gross left ventricular hypertrophy is present, you should urgently consider whether aortic stenosis is the cause. In pulmonary embolism, there may be evidence of right heart strain (right axis deviation, right bundle branch block, or anterior T-wave inversion), although, more commonly, the ECG only shows sinus tachycardia. With cardiac tamponade there may be low amplitude QRS voltages and sinus tachycardia.

Full blood count

Check for anaemia secondary to bleeding causing hypotension. With acute blood loss, the mean corpuscular volume will remain unchanged, while chronic blood loss causes iron-deficiency anaemia with microcytosis.

Partial thromboplastin time/activated partial thromboplastin time

In hypotension due to bleeding, the coagulation must be checked by using the partial thromboplastin time or the activated partial thromboplastin time test. Where these are abnormal, the fibrinogen level should also be checked.

Urea and electrolytes

Hypotension of any aetiology can cause prerenal failure. Hyponatraemia and hyperkalaemia, in the setting of hypotension, can be suggestive of adrenal insufficiency.

C-reactive protein level and white blood cell count

The C-reactive protein level and white blood cell count is often, but not always, elevated in sepsis. In severe rampant sepsis, these tests may initially be normal, only becoming rather dramatically abnormal hours or indeed days later, way beyond the time they would have been of diagnostic use. The central message is that, if you suspect sepsis, take blood cultures, give broad-spectrum antibiotics immediately, and do not be put off by finding initially normal inflammatory markers.

Chest X-ray

This may show the cause of shock (e.g. pneumothorax), be highly suggestive (the globular heart of pericardial effusion is very characteristic), or may offer pointers, such as findings of cardiac failure

(e.g. pulmonary oedema, cardiomegaly, Kerley B lines, upper lobe diversion, or pleural effusions, all of which would strongly suggest that cardiac disease underlies the shock). Hypotension due to chest sepsis may show consolidation and possibly a parapneumonic effusion. The chest radiograph may be normal with pulmonary embolism; very rarely, it reveals a reduction of vascular markings, a wedge-shaped infarction, or a small effusion.

Echocardiogram

This is perhaps the single most useful test in patients with shock of uncertain aetiology—while not always diagnostic, it can substantially increase (left ventricular dysfunction/valvar lesion, pericardial effusion) or lessen the chance of shock being cardiac in origin (vigorous left ventricular function without pericardial fluid greatly lessens the chance of cardiac shock—it does not remove it though; e.g. severe acute mitral regurgitation can present with shock and transthoracic echo appearances which are virtually normal), and it often offers clues to the presence of pulmonary embolus (right ventricular dilatation/dysfunction). It informs about right heart pressures (from inferior vena cava calibre and its change with respiration), which gives information about volume status. Table 11.2 shows typical echocardiographic findings in hypotension of different aetiologies.

Other diagnostic tests

Abdominal ultrasound

An abdominal ultrasound can reveal dilatation and rupture of the abdominal aorta, as well as free fluid in the abdomen. If a ruptured abdominal aortic aneurysm is seriously suspected, or if there is severe abdominal pain without a diagnosis, immediate CT is the investigation of choice, with the emphasis being on immediate.

Troponin T or I

Troponin T or I is elevated with myocardial necrosis (but also in pulmonary embolism, arrhythmias, and renal failure). Only rarely does the immediate troponin provide a categorical diagnosis; often, it provides pointers. However, most patients with shock have rapidly deteriorating renal function and widespread organ hypoperfusion (including of the heart), both of which may give rise to very non-specific, but large rises in troponin. Do not rely on troponin to establish the cause of shock.

D-dimers

D-dimer levels are elevated with thrombus, infection, pregnancy and malignancy; they are also elevated post-operatively and with an inflammatory response. A negative test is reassuring in patients with a low or moderate pretest probability of pulmonary embolism. Again, this test is rarely helpful in shock, as many sick patients, from whatever cause, have large rises in D-dimers. If a pulmonary embolus is seriously suspected, do the most immediately available test, a CT pulmonary angiogram if possible. If the patient is too sick, do a

transthoracic cardiac ultrasound instead. Treat until you can establish the diagnosis, with thrombolytics, if necessary.

Adrenocorticotrophic hormone stimulation test

Plasma cortisol is measured before and after injection of a synthetic form of adrenocorticotrophic hormone to assess for an appropriate release of cortisol by the adrenal glands. This test is of no use in the acute situation. If there is any possibility that hypoadrenalism underlies shock, immediately take a blood sample for cortisol and give intravenous hydrocortisone, continued until either an alternative diagnosis emerges or the patient is stable. Once the patient is stable, usually a few days later, perform a short synacthen test.

Introduction to therapy

There is a difference in the speed of investigation and treatment, depending on the clinical settings (e.g. an elderly patient with postural hypotension and mild symptoms on multiple blood-pressure-lowering agents, vs a patient with post-operative septic shock in secondary care).

In otherwise stable patients in primary care, treatment of the underlying cause is initiated. Thus, in the case of drug-induced hypotension, the offending drug dose may be stopped, reduced in dose, or changed to alternative treatment.

In treating shock, the aim is to maintain adequate tissue perfusion. A rapid assessment of the patient is required with assessment and securing of the airway, assessment of adequacy of breathing, and also of integrity of the circulatory system (the ABC approach; see 'Further Reading'). Oxygen is administered where required. A straight leg raise will help redistribute circulatory volume in hypovolaemia. Intravenous access is obtained and blood taken for analysis and group and save, or crossmatching. Intravenous fluid resuscitation is performed to restore circulatory fluid volume and central venous pressure (unless the patient is in cardiogenic shock). Monitoring should be instituted to include continuous ECG monitoring, urine output, pulse rate, blood pressure, respiratory rate, and pulse oximetry; this usually mandates that a patient, at a minimum, should be on a high-dependency ward, although transfer to an intensive care unit may be necessary. Urine output is a sensitive indicator of cardiac output and will aid management of fluid balance. In some cases, central venous pressure and invasive arterial pressure monitoring are required. The main stay of therapy in most cases of shock, except cardiogenic shock, is fluid replacement. This can be performed with by initially giving a rapid 250–500 ml fluid challenge of colloid or crystalloid fluid. If blood loss is the presumed cause, then blood should be used (the order of preference is crossmatched blood, type-specific blood, O-negative blood). Where there is coagulopathy and haemorrhage, the coagulopathy should be appropriately corrected.

In patients with cardiogenic shock, the heart cannot produce a blood pressure sufficient to maintain adequate tissue perfusion. Usually, there is an increased left atrial pressure and pulmonary oedema. Fluids given here will exacerbate the situation (except for

Table 11.2 Echocardiographic findings in hypotension

	IVC	LV size	LV contraction	RV size	RV contraction
Hypovolaemia	Flat	Small	Increased	Small	Increased
Sepsis	Flat	Normal or large	Normal or reduced	Normal or large	Normal or reduced
LV dysfunction due to ischaemia	Normal or dilated	Large	Reduced regionally or globally	Normal	Normal (unless associated RV infarction)
Acute major pulmonary embolism	Dilated	Normal or small	Normal or increased	Large	Reduced
Cardiac tamponade	Dilated	Normal	Normal or increased	Normal	Diastolic free wall collapse
RV infarction	Dilated	Normal or large if associated LV inferior MI	Normal or reduced if associated inferior MI	Large	Reduced

Abbreviations: IVC, inferior vena cava; LV, left ventricular; MI, myocardial infarction; RV, right ventricular.

those rare patients with predominant right ventricular infarction usually complicating an inferior infarct, as they do benefit from fluids). Instead, immediate treatment is with IV diuretics, opiates (also beneficial for myocardial infarction pain). The use of inotropes is controversial; they may have a place where there is reversible pathology or as a bridge to definitive treatment. There is no evidence that they improve outcome. Mechanical circulatory support (intra-aortic counterpulsation balloon pumping, left ventricular assist devices) has a role in highly selected patients with reversible pathology. In those with acute myocardial infarction, immediate percutaneous coronary intervention has an important role, improving the dreadful outcome, although the prognosis of cardiogenic shock remains poor, despite all therapies. Patients considered to have a reasonable outcome may also require ventilatory support.

In patients with anaphylaxis and hypotension, immediate intramuscular (IM) adrenaline is given, the legs elevated, hydrocortisone IV or IM, and chlorphenamine 10 mg IV or IM. The causal antigen should be removed, where possible, and intravenous fluids given. Nebulized bronchodilators are used if bronchospasm is present. Adrenaline IM can be repeated every 5 minutes, if required. Where the airway is threatened, formal intubation and ventilation may be required with rapid assistance from an anaesthetist and critical care; an ENT surgeon should be present to assist, if required.

In septic shock, a septic screen should be sent (blood, urine, and wound cultures, inflammatory markers, full blood count, and biochemical screen, and usually blood gases, for pH, lactate, and pO₂ and pCO₂ levels), IV resuscitation should be initiated, and broad-spectrum antibiotics should be given promptly. Vasoconstrictor agents (e.g. noradrenaline or adrenaline) should be used when appropriate.

Prognosis

The mortality is variable depending on the cause. Approximate figures of mortality for the major types of shock are 60% in cardiogenic

shock, 70% in ruptured aortic aneurysm, 30% in septic shock, and <1% in anaphylaxis. When hypotension is secondary to hypovolaemia, once this is corrected, the mortality is dependent on the underlying cause.

How to handle uncertainty

In the acute setting, the clinical presentation should provide clues to differentiate between cardiogenic shock and other types of shock. Echocardiography is a critically useful investigation, where available, if the diagnosis is unclear, and helps differentiate between acute severe pulmonary embolism, cardiogenic shock, valvular heart disease, and hypovolaemia. In non-cardiogenic shock, initial fluid resuscitation may be performed while the cause is being determined.

12 Acute breathlessness

Jonathan Timperley and Sandeep Hothi

Definition of the symptom

Acute breathlessness or dyspnoea is the new onset of an unpleasant awareness of breathing, at rest or at a level of exercise, which did not previously cause symptoms. It is often associated with other symptoms—including wheeze, cough, chest pain, and palpitation—which, together with the patient's comorbidities, help shape the differential diagnosis.

Differential diagnosis

The differential diagnosis of acute dyspnoea may be organized by system; some common causes are given in Table 12.1.

Context

Acute breathlessness is a frequent reason for presentation to the emergency department, and a common problem complicating the

hospital course of inpatients. Decompensated heart failure, exacerbations of asthma or COPD, pneumonia, and pulmonary embolism account for 80% of diagnoses. In older patients, acute breathlessness often results from multiple interrelated pathologies (e.g. pneumonia on a background of COPD, triggering acute atrial fibrillation).

Approach to diagnosis

Acute breathlessness may herald diseases which can lead to death in minutes or hours. It is therefore crucial to assess if the patient is critically ill using simple physiological variables, such as blood pressure, heart rate, respiratory rate, arterial oxygen saturation, and conscious level, as described in detail in Chapter 149. If these observations indicate critical illness, the approach to the diagnosis and management should follow the methods outlined in Chapter 149.

If the patient is not critically ill and there are no immediate threats to life, then a focused history should be taken (see Box 12.1), followed

Box 12.1 Focused history taking in acute breathlessness

- context and time-course of breathlessness
- associated symptoms: wheeze, cough, chest pain, palpitation, orthopnoea (seen in heart failure, diaphragmatic paralysis, ascites, morbid obesity)
- usual effort tolerance and recent change (e.g. distance walked on the flat, number of stairs climbed without stopping, ability to manage activities of daily living unaided; see MRC dyspnoea scale)
- known cardiorespiratory disease
- previous acute exacerbations of chronic obstructive pulmonary disease (COPD) or asthma requiring hospital admission/non-invasive ventilation/mechanical ventilation
- requirement for home-nebulized bronchodilator and/or long-term oxygen therapy
- previous diagnosis of heart failure, coronary artery disease, myocardial, or valve disease
- risk factors for venous thromboembolism
- other major comorbidities
- current medications
- smoking history
- occupational/environmental exposure to smoke, fumes, toxins/animals, or birds
- travel history

by clinical examination and appropriate investigations. Nonetheless, it may be appropriate to initiate some treatment and investigations simultaneously with the history and examination. High-flow oxygen may be given by mask. Further oxygen therapy should be administered in accordance with British Thoracic Society guidelines. It should be remembered that, although many acutely dyspnoeic patients are hypoxic, hypoxia per se does not correlate with dyspnoea. Patients may remain breathless despite correction of hypoxia. If there is wheeze, or a history of asthma/COPD, peak flow should be measured and compared to the patient's predicted or known normal reading, and a beta-2 agonist given by oxygen-driven nebulizer. If not already done, the patient should be attached to a pulse oximeter to measure

Table 12.2 The DECAF Score

Variable	Score
Dyspnoea eMRC5 5a	1
eMRC5 5b	2
Eosinopenia ($<0.05 \times 10^9/l$)	1
Consolidation	1
Acidaemia (pH <7.3)	1
Atrial fibrillation	1
Total DECAF Score	6

Abbreviations: DECAF, dyspnoea, eosinopenia, consolidation, acidaemia, and atrial fibrillation; eMRC5, extended MRC dyspnoea scale.

Note: The extended MRC dyspnoea scale dichotomizes Stage 5 according to whether the patient can wash and dress independently (5a) or not (5b).

arterial oxygen saturation, ECG and blood pressure monitors, and IV access obtained. Arterial blood gases, pH, and lactate should be measured, and 12-lead ECG and chest radiography performed.

Key diagnostic tests

All patients with acute breathlessness should have a chest radiograph, 12-lead ECG, and measurement of arterial blood gases, including lactate concentration. A full blood count and biochemical profile (including glucose) should be measured. If sepsis is suspected, blood culture should be taken and C-reactive protein or procalcitonin levels measured. Additional culture samples should be taken according to the suspected diagnosis and clinical findings.

The **chest radiograph (CXR)** establishes if the patient has pleural disease (effusion or pneumothorax) or pulmonary parenchymal disease, which may be focal or diffuse. Marked enlargement of the cardiac silhouette may reflect pericardial effusion or advanced valve/myocardial disease. Acute breathlessness with a clear CXR is seen in upper and lower airways disease, pulmonary embolism, sepsis, and metabolic acidosis.

Abbreviations: DECAF, dyspnoea, eosinopenia, consolidation, acidaemia, and atrial fibrillation.

Reproduced from *Thorax*, John Steer, John Gibson, Stephen C Bourke, The DECAF score: predicting hospital mortality in exacerbations of chronic obstructive pulmonary disease, volume 67, pp.970–6, copyright © 2012 with permission from BMJ Publishing Group Ltd.

The **12-lead ECG** may reveal signs of acute myocardial ischaemia or infarction (ST depression or elevation, new left bundle branch block), or evidence of structural heart disease. Sinus tachycardia is the most common ECG abnormality associated with pulmonary embolism; features of right heart strain (right axis deviation, new right bundle branch block, anterior T-wave inversion) may not be present despite major embolism. The ECG may also demonstrate arrhythmia, acute atrial fibrillation being the most commonly encountered.

The **arterial blood gases and pH** establish if the patient has type 1 or type 2 respiratory failure, and also characterize the acid–base status, which carries diagnostic and prognostic information. Please see chapters 135 and 149 for further information on the assessment and management of respiratory failure.

Other diagnostic tests

Ultrasonography of the lungs, heart, and inferior vena cava

Ultrasonography of the lungs, heart, and inferior vena cava can identify pleural and pulmonary parenchymal disease, exclude cardiac tamponade, and provide evidence for or against a diagnosis of heart failure or acute major pulmonary embolism (see Figure 12.1). Pocket-sized ultrasound devices (e.g. Vscan, GE Healthcare) are now available which allow a screening ultrasound examination to be done in a few minutes, as part of the clinical assessment.

Plasma brain natriuretic peptide

Plasma brain natriuretic peptide (BNP) is an important test in the diagnosis of chronic heart failure, but is less helpful in the patient with acute breathlessness. A raised plasma BNP level by itself cannot discriminate between acute, acute-on-chronic, or chronic heart failure, or between left or right ventricular dysfunction. Cor pulmonale and right ventricular dysfunction from acute pulmonary embolism are both causes of a raised BNP, with plasma levels in cor pulmonale typically in the range of 100–500 pg/ml. A patient with chronic heart failure may be acutely breathless because of acute non-cardiac (rather than cardiac) disease. Accepting these limitations, measurement of plasma BNP is a useful

screening test in the patient acute breathlessness, levels <100 and >500 pg/ml having high negative and positive predictive values for heart failure.

Plasma D-dimer

Plasma D-dimer is a degradation product of cross-linked fibrin and gives a measure of endogenous fibrinolysis. A normal level of plasma D-dimer excludes pulmonary embolism in patients in whom the clinical probability is low to moderate. A raised level is seen in a wide range of conditions including sepsis and aortic dissection, and is therefore not diagnostic of venous thromboembolism.

Plasma cardiac troponin I or T levels

Plasma cardiac troponin I or T levels are often measured to exclude acute coronary syndrome as the cause of acute breathlessness. However, troponin release may also occur in pulmonary embolism, myocarditis, stress cardiomyopathy, supraventricular arrhythmias, and sepsis, amongst others conditions, and the plasma troponin level therefore must be interpreted in the light of clinical, ECG, and echocardiographic features.

CT of the chest

CT of the chest will often be diagnostic in acute breathlessness, and has a greater yield than plain radiography. However, the need to lie flat for the scan may not be possible for some patients, and this should be considered when requesting CT, particularly if the same information can be obtained from other modalities performed at the bedside, such as chest ultrasonography or echocardiography.

Further investigation will be guided by the differential diagnosis.

Introduction to therapy

Supportive therapy for the critically ill patient is discussed in Chapter 149. Specific therapy is directed by the working diagnosis.

Prognosis

This depends on the diagnosis, its severity, the patient's comorbidities, and initiation of prompt appropriate therapy. Prognostic scores have

Demographics	Past medical history	Vital signs	Laboratory	ECG	Radiography

13 Chronic breathlessness

David Spriggs, Andrew Jeffrey, Phil Barber, and Nigel Clayton

Definition

The act and sensation of breathing are at the interface between the conscious and the subconscious mind; breathing is an unconscious process, but one which enters consciousness in healthy people in some circumstances, notably during and after exercise. Chronic breathlessness (dyspnoea) can be defined as an unpleasant awareness of breathing at a level of exercise which would not cause symptoms in a healthy person of the same age (or which did not previously cause symptoms), persisting for more than 1 month. It can be graded according to the Medical Research Council dyspnoea scale (Table 13.1). Breathlessness may be accompanied by other symptoms such as chest tightness, cough, or wheeze, which, together with the patient's comorbidities and risk factors for specific diseases, help shape the differential diagnosis.

Differential diagnosis

The differential diagnosis, organized by system, is given in Table 13.2.

Context

Chronic breathlessness is highly prevalent—a survey of people aged 70 and over living at home in a South Wales town found that almost one-third had breathlessness of MRC grades 3–5—and one of the commonest presenting symptoms in primary and secondary care. It usually reflects cardiopulmonary disease, but a broad range of disorders, from anaemia to neuromuscular disease, needs to be considered (Table 13.2). More than one disorder is present in around 20% of patients (e.g. the combination of COPD and heart failure). In addition, obesity and physical deconditioning are often contributory factors, and may be the sole cause of exertional breathlessness. Anxiety states may cause breathlessness and other somatic symptoms, but psychogenic breathlessness is a diagnosis of exclusion and may, of course, coexist with organic disease. Breathlessness is also a major symptom in the terminal phase of many cardiorespiratory diseases.

Approach to diagnosis

Asthma, COPD, heart failure, and interstitial lung disease (ILD) are the final diagnoses in around 80% of patients presenting with chronic breathlessness. One approach is therefore to consider these four

diagnoses, together with an additional category of 'Something else', in all patients. Initial probabilities of these disorders, based on age, sex, and risk factor profile, are then adjusted up or down in the light of further information derived from the history and examination, to yield a judgement as to whether each diagnostic category is probable, possible, or unlikely. These assessments are further revised when the results of screening investigations are known. As an example, Table 13.3 summarizes the information relevant to the probabilities of asthma and COPD in a patient with chronic breathlessness associated with wheeze.

Specific clues to the diagnosis

There is considerable overlap between clinical features of the many diseases which can cause chronic breathlessness, and the symptom may reflect the cumulative effect of more than one disease. Consequently, clinical diagnosis should be regarded as provisional, with its aim being to establish a differential diagnosis which can be tested and refined by investigation.

Important clues to the diagnosis are the mode of onset of breathlessness; its duration, pattern, and periodicity; precipitating or aggravating factors; and accompanying symptoms. Breathlessness of psychogenic origin tends to be 'patternless', occurring unpredictably and often at rest. Breathlessness of organic origin is more predictable, and the pattern clinically coherent, often closely and reliably linked to exertion but sometimes variable or episodic, especially in asthma. Orthopnoea (breathlessness in the recumbent position) and nocturnal dyspnoea are characteristic of heart failure (although their absence does not exclude the diagnosis) but are also common in COPD. Orthopnoea is also found in diaphragmatic paralysis, severe ascites, and morbid obesity.

Other relevant aspects of the history in suspected cardiac, respiratory, or neuromuscular disease are covered in detail in Chapters 87, 126, and 220. The psychological status of the patient should also be assessed. This will include asking about significant stressors in the patient's life, and the disability caused by the symptoms. Fear generated by the sensation of breathlessness, and frustration at the associated disability, can significantly worsen symptoms.

The examination findings define the physiological status of the patient and allow diagnostic hypotheses suggested by the history to be tested (Chapter 1). General examination should include an overall impression of the patient's health, assessment of muscle bulk and nutrition, and thyroid status. The presence or absence of conjunctival pallor, cervical lymphadenopathy, finger clubbing, and peripheral oedema are all relevant. Respiratory rate and pattern, arterial oxygen saturation by pulse oximetry, peak flow rate, heart rate and blood pressure, and height and weight (with calculation of body mass index) should be measured.

Features to note in the respiratory examination are the quality of the voice and cough, the tracheal position, and the presence of chest wall abnormalities such as kyphosis, scoliosis, or hyperinflation. Percussion and auscultation may reveal signs of pleural disease, and focal or diffuse crackles and wheezes. Breathlessness due to asthma or COPD typically causes a wheeze audible with the stethoscope but this can be absent even in severe airflow limitation, so that objective measurements (by peak flow rate and spirometry) are essential.

The cardiac examination should include assessment of the jugular venous pressure, palpation of the carotid pulse and precordium, and auscultation of the heart. A raised jugular venous pressure and a displaced apex beat both increase the likelihood of an elevated left ventricular end-diastolic pressure and impaired left ventricular systolic function (positive likelihood ratios 4–8). However, the absence

Table 13.1 Medical Research Council dyspnoea scale

Grade	Degree of breathlessness related to activities
1	Not troubled by breathlessness except on strenuous exercise
2	Short of breath when hurrying or walking up a slight hill
3	Walks slower than contemporaries on level ground because of breathlessness, or has to stop for breath when walking at own pace
4	Stops for breath after walking about 100 m or after a few minutes on level ground
5	Too breathless to leave the house, or breathless when dressing or undressing

		Psychogenic factors	Chapter 241

of these signs and others (e.g. third heart sound, lung crackles) does not significantly reduce the likelihood of heart failure. In summary, abnormal cardiac signs are diagnostically useful if present, but normal cardiac function cannot be inferred from their absence.

Neuromuscular disorders such as myasthenia gravis or myopathies are rare and easily missed causes of chronic breathlessness: they should be considered in the patient with an unexplained restrictive defect.

Key diagnostic tests

Investigation for chronic breathlessness has three stages (Table 13.4). All patients should have Stage 1 or screening tests—chest radiography, electrocardiography, spirometry, and blood tests. When combined with clinical information, the data from these tests should allow the organ system responsible for symptoms to be identified with reasonable accuracy, and provide the basis for an intelligent selection of further tests.

Table 13.3 Features supporting a diagnosis of asthma or COPD in the patient with chronic breathlessness and wheeze

Consider asthma	Consider COPD
Age <40 years	Age >40 years
Smoker or non-smoker	Smoker, with >20 pack-years consumption
Symptoms following exposure to allergens such as grass pollen or animals	Gradual onset of symptoms
Intermittent or seasonal variation in symptoms	Symptoms including cough present on most days
Cough at night or on exercise	Cough worse in morning
Family history of asthma, eczema, hay fever	Industrial exposure to coal/cotton dust
Occupational exposure to dusts, chemicals, or fumes	Pursed lip breathing/prolonged expiration
Variability in serial peak flow measurements >15%	Barrel-shaped chest
FEV ₁ improves >12% and >200 ml following bronchodilator or steroid therapy	PEF <85% predicted with little variability in serial measurements
	Little or no improvement in FEV ₁ following bronchodilator or steroid therapy

Stage 1 tests

Chest radiography

The site of pathology is frequently evident on the chest radiograph (CXR), which may reveal structural abnormalities in extra-pulmonary tissues (e.g. deformities of the thoracic cage, rib fractures, diaphragmatic weakness); pleural pathology (pneumothorax, pleural effusion), and gross disease of the pulmonary parenchyma (ILD), consolidation, pulmonary oedema, soft tissue growth).

A CXR is often unhelpful in characterizing airways disease, subtle pathology of the lung parenchyma, and pulmonary vascular disease. Although disease at these sites may be suspected from the clinical assessment, the absence of abnormal findings on the CXR should alert the clinician to consider these diseases more carefully.

Electrocardiography

The ECG defines the cardiac rhythm: tachyarrhythmias (e.g. atrial fibrillation or flutter) and bradyarrhythmias (e.g. sinus bradycardia due to sinus node dysfunction, complete heart block) may be the sole cause of chronic breathlessness or may exacerbate other causes. The ECG also gives indirect information about cardiac structure which shapes the differential diagnosis: relevant abnormalities include pathological Q waves (indicative of previous myocardial infarction), evidence of right ventricular hypertrophy (which may reflect congenital heart disease or pulmonary hypertension) or left ventricular hypertrophy (seen in hypertrophic cardiomyopathy or aortic valve disease), and left bundle branch block (often present in dilated cardiomyopathy). In essence, any ECG arrhythmia or other abnormality warrants transthoracic echocardiography.

Spirometry

Basic spirometry requires the patient to take a maximal breath in, followed by a forced and complete expiration into the spirometer, yielding a volume–time curve. The most common indices recorded are the forced expiratory volume in 1 s (FEV₁), the vital capacity (FVC), which is the volume of air exhaled from the point of maximum inspiration, and the ratio of FEV₁ to FVC (FEV₁/FVC). Psychogenic breathlessness typically produces an effort-limited and variable configuration, while the spirometry of organic disease is usually highly reproducible.

Spirometry allows the categorization of lung disease into obstructive, restrictive, or mixed physiology. Airflow obstruction,

Table 13.4 Investigation in chronic breathlessness		
Stage 1: Screening tests	Stage 2: Further tests to confirm, refine, or reject possible diagnoses	Stage 3: Additional tests which may be needed in individual cases
Chest radiography	Transthoracic echocardiography	Bronchoscopy
Electrocardiography	High-resolution CT of the chest	Lung biopsy
Spirometry	Pulmonary function testing	Cardiac catheterization

	Non-invasive tests for coronary artery disease	Transoesophageal echocardiography
		MRI of the heart
		Tests for chronic pulmonary thromboembolism
		Cardiopulmonary exercise testing
		Tests for neuromuscular disease

diagnosed when the FEV₁/FVC ratio falls below the lower limit of normal (Figure 13.1), is due to airway narrowing or obstruction. Common causes of airflow obstruction are COPD, asthma, bronchiectasis, cystic fibrosis, endobronchial tumour, vocal cord dysfunction, and goitre.

Restrictive physiology is characterized by reduced lung volumes. Common causes of restrictive physiology are pulmonary fibrosis, obesity, kyphoscoliosis, neuromuscular disease, and heart failure.

Spirometry typically demonstrates a proportionally reduced FVC and FEV₁, with normal or even increased FEV₁/FVC ratio, indicating reduced lung volume with no airflow obstruction. Most desktop spirometers use a simple algorithm to interpret test data. An FVC below the lower limit of normal will usually be interpreted as restrictive disease (reduced lung volume). In patients with COPD and asthma, a forced expiration is usually accompanied by airway collapse, resulting in a significantly reduced FEV₁ and FVC. The spirometer will

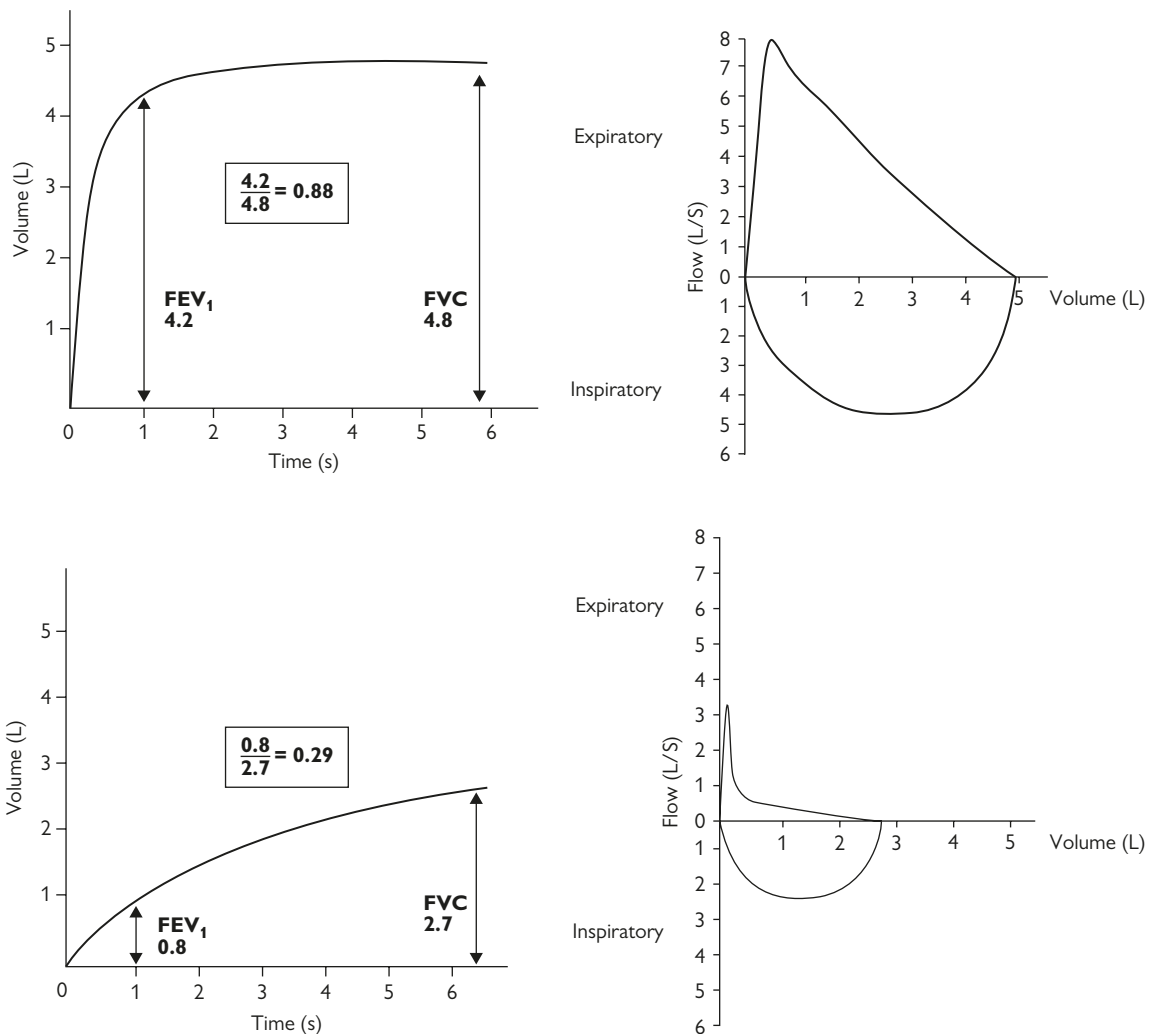

Figure 13.1 Spirograms in a normal subject (a) and a patient with severe airflow obstruction (b), showing scooping of the expiratory side of the flow/ volume curve due to airway collapse. It is often stated that airflow obstruction is diagnosed when the FEV₁/FVC ratio falls below 0.7. This is misleading and can lead to over-diagnosis of obstructive physiology in elderly patients, and under-diagnosis in young patients, as the FEV₁/FVC ratio is dependent on age, height, and sex.

often interpret this as mixed disease (small lungs with obstruction) which can be misleading. In COPD, the total lung capacity (TLC) may well be within normal limits, or even increased due to reduced elastic recoil. A measurement of TLC will correctly identify restriction, normal lung volume, or hyperinflation. Where TLC is below the lower limit of normal, then restrictive disease should be considered. Where TLC is above the upper limit of normal, but the FEV₁/FVC ratio is below the lower limit of normal, hyperinflation should be considered. Determination of TLC and other derived lung volumes requires referral to a specialist lung function laboratory.

In diaphragmatic weakness, the restrictive defect is more severe when the patient is supine. With mild diaphragmatic weakness or unilateral paralysis, seated FVC is typically 10%–30% greater than supine FVC; with bilateral diaphragmatic paralysis, it is 30–50% greater.

Blood tests

Given the limitations of clinical assessment of haemoglobin concentration, all patients should have a full blood count done. A biochemical profile should be done to screen for chronic kidney and liver disease, and as a baseline before therapy. If heart failure is possible, plasma brain natriuretic peptide (BNP) (or the equivalent NT-pro-BNP) should be measured. Thyrotoxicosis and hypothyroidism can cause or contribute to chronic breathlessness, and measurement of plasma thyroid stimulating hormone level as a screen for these disorders should be done in patients over 50 or with clinical features of, or risk factors for, these diseases.

Full blood count

Exertional breathlessness is a common symptom of anaemia, although its degree depends on the severity of the anaemia, the time course of its development, and the cardiorespiratory status of the patient. Interpretation of the full blood count is discussed in detail in Chapter 278.

BNP

BNP was so named as it was first isolated from brain tissue. However, the primary source of BNP in plasma is the heart. Ventricular wall stress is the stimulus to synthesis of pre-pro-BNP in cardiomyocytes. After synthesis, the peptide is cleaved first to pro-BNP, then to the biologically active BNP and the inactive amino-terminal fragment, NT-pro-BNP. Measurement of plasma BNP or NT-pro-BNP concentrations substantially improves the accuracy of the diagnosis of chronic heart failure. A plasma BNP level of <100 pg/ml makes heart failure very unlikely (<2%). At levels between 100 and 400 pg/ml, the probability of heart failure is around 75%; judgement as to a diagnosis of heart failure depends on clinical features (e.g. previous myocardial infarction, raised jugular venous pressure, symptoms improved by diuretic). A level of >400 pg/ml gives a probability of heart failure of >95%. Plasma BNP concentration is higher in men than women, increases with age and the degree of chronic kidney disease, and is decreased by obesity.

Further diagnostic tests

Stage 2 tests

Stage 2 tests (Table 13.4) are those typically needed to confirm, refine, or reject possible diagnoses: these include echocardiography, measurement of transfer factor, and high-resolution CT of the chest.

Echocardiography

Transthoracic echocardiography (TTE) provides extensive information about cardiac structure and function and also allows estimation of right atrial and pulmonary artery systolic pressures (Box 13.1). TTE can therefore identify many of the cardiac disorders which may cause chronic breathlessness, and screen for pulmonary hypertension. An important limitation of TTE is that high-quality images cannot be obtained in all patients (e.g. those with body mass index >30, chest wall deformities, or severe COPD). The quality of the images, and the accuracy of their interpretation, also depends on the skill of the operator. A complete study typically takes around 30 minutes to perform. Pocket-sized ultrasound devices (e.g. Vscan, GE Healthcare) are now available which allow a screening echocardiogram to be done in a few minutes, as a component of the physical examination.

Box 13.1 Information derived from transthoracic echocardiography

- presence or absence of congenital abnormalities (e.g. atrial septal defect)
- left ventricular systolic function (global and regional)
- left ventricular diastolic function (inferred from the pattern of mitral inflow, tissue Doppler data, and left atrial size)
- evidence of right ventricular pressure- or volume-overload (indicative of pulmonary hypertension and/or a left-to-right shunt)
- valve function
- estimation of right atrial pressure and pulmonary artery systolic pressure (derived from the size and respiratory change in the inferior vena cava, and the velocity of tricuspid regurgitation)
- pericardial function and the presence of pericardial effusion
- presence and characteristics of pleural effusion

Measurement of transfer factor (diffusing capacity)

When spirometry does not identify the cause of chronic breathlessness, further information may be gained from measuring the transfer factor for carbon monoxide (TLCO). TLCO reflects the function of the alveolar capillary membrane. The patient is required to exhale completely, followed by a maximal inhalation of 0.3% CO, 0.3% CH₄ (or 14% helium), 21% O₂, and balanced N₂. The breath is held for 10 s to allow diffusion of inhaled CO. During exhalation, the expired gas concentration is continuously monitored, and the plateau of expired alveolar gas concentrations measured once dead space has been cleared. Comparing inspired and expired CO and CH₄ concentrations allows the determination of TLCO and effective alveolar volume (V_A). Dividing TLCO by V_A gives the KCO or transfer coefficient. Component parts of the diffusion equation can be used to determine the likely disease process (Table 13.5).

High-resolution CT of the chest

CXR is a useful screen for parenchymal lung disease, but has limited accuracy in the detection and categorization of ILD (false-negative and false-positive rates around 20%). High-resolution CT of the chest (HRCT) has greater accuracy (false-negative and false-positive rates <5%) for ILD, and should be done if the chest radiograph suggests ILD, or if the features on clinical assessment or lung function testing point to ILD, but the CXR is normal (e.g. inspiratory crackles; restrictive physiology on spirometry; normal spirometry but exercise-induced fall in oxygen saturation). Findings on HRCT, when integrated with clinical

Table 13.5 Typical disease changes in the transfer factor for carbon monoxide (TLCO) and its components

data, have high diagnostic accuracy as regards the specific cause of ILD, and can guide the type and site for lung biopsy if indicated.

Stage 3 tests

Stage 3 tests are the additional tests which may be needed in individual cases, but would generally not be done before Stage 2 tests. Further discussion of investigation in suspected cardiovascular, respiratory, and neuromuscular disease can be found in Chapters 87, 126, and 220, respectively.

Introduction to therapy

Most patients with chronic breathlessness will have one or more long-term conditions, and need evidence-based management of the underlying cause or causes, ideally delivered by an integrated clinical network that spans primary and secondary care. They are typically vulnerable to acute exacerbations (e.g. from disease flare, super-added infection, arrhythmia, or pulmonary embolism), and should have ready access to specialist care to deal with these. Other elements of management may include immunization against influenza and pneumococcal infection, help with smoking cessation, long-term oxygen therapy, optimization of nutritional state, cardiopulmonary rehabilitation, and psychological support. Opioids can be used to relieve breathlessness of any cause, if the underlying disease cannot be alleviated.

Prognosis

This depends on the specific disease or diseases responsible and their severity and response to treatment. Models to predict prognosis have been constructed for some diseases (e.g. Seattle Heart Failure Model, available online at <https://depts.washington.edu/>

[shfm/?width=1093&height=615](https://www.mdcalc.com/bode-index-copd-survival); the BODE index for COPD, <https://www.mdcalc.com/bode-index-copd-survival>; and the GAP risk assessment system for idiopathic pulmonary fibrosis <https://www.mdcalc.com/gap-index-idiopathic-pulmonary-fibrosis-ipf-mortality>).

How to handle uncertainty

If the cause of breathlessness remains unclear, the history should be retaken and the patient re-examined. The CXR and other imaging should be reviewed. Any Stage 2 tests that have not already been done should be requested. Diagnoses that can easily be missed include ILD, atrial septal defect, constrictive pericarditis, pulmonary hypertension, and neuromuscular disorders.

Cardiopulmonary exercise testing (CPET) provides detailed respiratory data in addition to the clinical and cardiovascular data obtained from the standard exercise test. CPET is useful if the cause of chronic breathlessness is still obscure despite Stage 1 and Stage 2 tests, or if multiple possible causes are present and quantification of the contribution of each (including physical deconditioning) is needed.

14 Peripheral oedema

Jonathan Timperley and Sandeep Hothi

Definition of the symptom

Peripheral oedema is a palpable swelling caused by increased interstitial fluid in soft tissues.

Differential diagnosis

Peripheral oedema can be due to local or systemic disease. Fluid distribution between capillaries and the interstitium is governed by Starling forces. The lymphatic system returns excess fluid and protein from the extracellular, interstitial space to the blood stream. Thus, interstitial oedema may arise from factors that increase capillary pressure or permeability, factors that reduce plasma colloid osmotic pressure, factors that impede lymphatic drainage, or a combination of these causes (Table 14.1).

Context

Peripheral oedema may be acute or chronic, and unilateral or bilateral. Mild bilateral ankle oedema may frequently be due to chronic venous disease or benign causes, including gravitational force (e.g. after a long-haul flight); pregnancy; drugs (e.g. dihydropyridines); and obesity. At the other end of the spectrum, peripheral oedema may be due to severe acute or chronic illness.

Approach to diagnosis

Causes needing urgent treatment, such as venous obstruction or thrombosis, organ failure, pre-eclampsia, compartment syndrome, obstruction of the superior vena cava, and necrotizing fasciitis, must be identified. Additionally, a distinction must be made between obesity, lymphoedema, lipoedema, and lipolymphoedema (Table 14.2).

Cause	Examples
Increased capillary pressure due to renal retention of sodium and water	Primary renal disorders (including nephrotic syndrome) Heart failure Cirrhosis Drug-induced (e.g. NSAIDs, steroids) Pregnancy and pre-eclampsia
Increased capillary pressure due to increased venous pressure	Heart failure Compression of superior or inferior vena cava, or of iliac veins Deep vein thrombosis Chronic venous insufficiency
Increased capillary permeability	Allergic reaction Infection (e.g. cellulitis) Trauma Burn
Decreased plasma oncotic pressure	Malabsorption syndrome Nephrotic syndrome Critical illness Liver failure
Impaired lymphatic drainage	Lymph node damage from surgery or radiotherapy Lymphatic or lymph node involvement by cancer or infection Primary lymphoedema

Lymphoedema may be primary or secondary to a number of causes, including regional lymph node dissection, neoplastic infiltration of lymphatic channels, radiotherapy-induced fibrosis, surgery involving the removal of lymph nodes or channels, and filariasis. Lipoedema is a disorder of adipose tissue with fat distribution that differs from that seen in obesity, and differs from lymphoedema in a number of ways. It is usually bilateral, spares the feet, is painful, bruises easily, is orthostatic, and resolves after rest until the late stages.

Specific clues to the diagnosis

Specific clues to the diagnosis are as follows:

- Rapid onset of oedema is seen with venous thrombosis, infection, allergy, and compartment syndrome.
- Pre-eclampsia needs urgent identification and management and is suspected in a pregnant female with proteinuria and hypertension.
- A history of ischaemic heart disease or of liver or renal disease suggests heart, liver, or renal failure, respectively. A history of malignancy or radiotherapy raises the possibility of secondary lymphoedema.
- The drug history may reveal changes in medication (e.g. dihydropyridine antagonists, beta blockers, corticosteroids, oestrogen, progesterone, NSAIDs, glitazones) associated with the onset of oedema.
- The physical examination may also reveal diagnostic clues. On general inspection, there may be features of hypothyroidism (see Chapter 186). An elevated BMI and large neck may exist in sleep apnoea with pulmonary hypertension. The skin has brawny induration in chronic lymphoedema, and haemosiderosis in venous insufficiency.
- Examination of the lower extremities should document the presence or absence of pitting oedema. Both limbs should be compared for any asymmetry, epidermal and dermal changes, ulcers, discoloration, tenderness, cords, and venous prominence. The extent of oedema may be assessed by its height.
- The urine dipstick will show significant proteinuria in nephrotic syndrome, and proteinuria or haematuria in glomerulonephritis.
- Cardiovascular examination may reveal bradycardia, tachycardia, a raised jugular venous pressure, murmurs of valve disease, or third or fourth heart sounds of heart failure. A tender, swollen calf suggests deep vein thrombosis (DVT).
- Pitting oedema occurs with DVT and venous insufficiency. Myxoedema and lymphoedema are non-pitting.
- Respiratory examination may reveal coarse crepitations of underlying lung disease (such as COPD or bronchiectasis) that may result in cor pulmonale. It may also demonstrate fine inspiratory crepitations of either pulmonary fibrosis or pulmonary oedema.
- Abdominal examination may demonstrate ascites, a pelvic mass, a palpable kidney (consider polycystic kidney disease), hepatomegaly, and stigmata of chronic liver disease.

Key diagnostic tests

Where a local cause is suspected (because of unilateral limb swelling or abnormal skin), request a duplex scan and a D-dimer test, to investigate for DVT.

A suspected systemic cause may be detected by the following:

Biochemical profile: urea and electrolytes, a liver function test (LFT), and a thyroid-stimulating hormone test, to assess renal, liver, and thyroid function, respectively; the LFT will provide the serum albumin level
Urinalysis: for detection of proteinuria; if significant proteinuria is present on urinalysis, a 24-hour urinary collection permits

Table 14.2 Differentiating between obesity, lipoedema, lymphoedema, and lipolymphoedema

	Obesity	Lipoedema	Lymphoedema	Lipolymphoedema
Gender	Male or female	Almost always female	Male or female	Almost always female
Time at onset	Childhood onwards	Typically age 10–30 years	Childhood (primary), adult (secondary)	Usually age 30 years onwards
Family history	Common	Common	Only for primary	Occasionally
Effect of dieting	Positive	None	None	None
Effect of elevation	None	Minimal	None	Helpful until fibrosis occurs
Pitting oedema	Absent	Minimal	May stop as fibrosis develops	Usually present to some extent
Easy bruising	No	Yes	No	Yes
Pain	None	In legs	None in early stages	In legs
Area	Generalized	Bilateral legs, sometimes arms	Feet first then legs, often unilateral	Usually bilateral lower limbs, feet eventually affected, Stemmer's sign positive
Positive Stemmer's sign	Absent	Absent	Present	Present

A positive Stemmer's sign is the inability to lift a thickened fold of skin at the base of the second toe or finger.

Adapted from *Advances in Skin & Wound Care*, Fife CE, Maus EA, Carter MJ. Lipoedema: a frequently misdiagnosed and misunderstood fatty deposition syndrome, volume 23, pp. 81–92, copyright ©2010 Wolters Kluwer Health, Inc.

quantification of urinary protein loss; measurement of the albumin-to-creatinine ratio will also be important

Albumin-to-creatinine ratio: to quantify the degree of urinary albumin loss

ECG: may suggest cardiovascular disease

Chest X-ray: may demonstrate cardiorespiratory disease

Plasma BNP: will be elevated in heart failure

Echocardiography: to assess for evidence of ventricular dysfunction, tricuspid valve disease, pulmonary hypertension, and pericardial effusion; this will permit diagnosis of heart failure as well as assess for possible causes (e.g. valve disease, regional wall motion abnormalities)

Chest X-ray: to assess for cardiomegaly, malignancy, and coexisting pulmonary oedema

D-dimer test: useful where a DVT is suspected, unless the clinical probability of DVT is high, in which case, definitive imaging should be performed

Other diagnostic tests

Other diagnostic tests include:

Serum lipids: in suspected nephrotic syndrome

Ultrasound: essential in a unilaterally swollen leg in which a DVT is suspected; ultrasound or other imaging of the abdomen is indicated where a pelvic mass is suspected

Computed tomography: this may be used to search for evidence of malignancy, local venous obstruction, and pulmonary disease

Lymphoscintigraphy: where lymphoedema is suspected, this test seeks to identify abnormalities of lymphatic drainage; it involves the administration of radiolabelled large molecules (macromolecules or colloids) into the interstitial space; their movement through lymphatics and lymph nodes is characterized by external gamma cameras

Right heart catheterization: may rarely be required in investigation of suspected pericardial restriction or restrictive cardiomyopathy

Introduction to therapy

Therapy is as follows:

- Venous insufficiency is treated with elevation of the leg and compression stockings. Compression stockings are contraindicated in the presence of arterial insufficiency.

- Lymphoedema is difficult to treat. Options include exercise, elevation, compression, manual lymphatic drainage, and surgery.
- The mainstay of initial treatment for heart failure is diuretic therapy. The underlying cause of heart failure will need directed treatment (e.g. consideration of surgery for valve disease; secondary prevention and possible revascularization in ischaemic heart disease).
- Renal failure will require referral to a nephrologist to treat the specific disorder.
- Liver failure is treated by general and specific principles (see Chapters 209 and 210 on liver failure).
- A DVT is treated with anticoagulation—initially with heparin (usually subcutaneous low molecular weight) and then with warfarin.
- Cellulitis is treated with appropriate antimicrobial therapy.
- Pre-eclampsia requires urgent obstetric involvement to achieve blood pressure control and consideration of early delivery.
- Compartment syndrome requires urgent fasciotomy and debridement.

Prognosis

The prognosis is dependent on the underlying aetiology. An untreated DVT is dangerous due to the risk of pulmonary embolus (PE). Approximately 29%–50% of patients with untreated DVT will develop a PE. The prognosis in heart, liver, and renal failure is generally poor, as described in Chapters 91 and 92, 209 and 210, and 162, respectively.

How to handle uncertainty in the diagnosis of this symptom

Where the aetiology is unclear, it is important to exclude acutely serious conditions (DVT, cellulitis, compartment syndrome, necrotizing fasciitis, pre-eclampsia, acute heart/renal liver failure) in the first instance. Chronic systemic conditions must also be considered.

15 Murmur

Jonathan Timperley and Sandeep Hothi

Definition

A murmur is an abnormal sound heard on auscultation of the heart or great vessels due to turbulent blood flow in or near the heart. A bruit is an abnormal sound arising from turbulent flow in a blood vessel.

Aetiology

Murmurs arise from turbulent flow in the heart or great vessels. This may occur because of a structural abnormality of the heart, or increased flow across normal cardiac structures (e.g. innocent flow murmur in pregnancy; the tricuspid flow murmur which may be heard in atrial septal defects with a large left-to-right shunt). Turbulence occurs when laminar blood flow is disrupted. The point at which this occurs is when the velocity exceeds the Reynolds number (Re), predicted by

$$Re = \frac{(\bar{v} \cdot D \cdot \rho)}{\eta},$$

where \bar{v} = mean velocity, ρ = density, D = the diameter of the vessel, and η = viscosity. Thus, high blood velocities and reduced viscosity promote turbulence and hence murmurs.

Murmurs are classified by their timing in relation to the cardiac cycle as systolic, diastolic, or continuous (Box 15.1).

Systolic murmurs are due to:

- obstruction to outflow from the right or left ventricle, at the sub-valvar, valvar, or supra-valvar level
- mitral or tricuspid regurgitation
- ventricular septal defect

Box 15.1 Timing of murmurs in relation to the cardiac cycle

Systolic murmur

Mid-systolic murmur

- aortic stenosis

Pansystolic murmur

- mitral regurgitation
- tricuspid regurgitation
- ventricular septal defect

Late systolic murmur

- mitral valve prolapse

Diastolic murmur

Early diastolic murmur

- aortic regurgitation
- pulmonary regurgitation

Mid-diastolic murmur

- mitral stenosis
- tricuspid stenosis

Continuous murmur (rare presentation)

- patent ductus arteriosus
- arteriovenous fistula
- venous 'hum'

Diastolic murmurs are due to:

- aortic or pulmonary regurgitation
- abnormal flow across the mitral or tricuspid valves (stenotic valve or increased diastolic flow)

Continuous murmurs, heard in systole and diastole, are due to:

- an abnormal connection between the aorta and the pulmonary artery (e.g. patent ductus arteriosus)
- an abnormal connection between an artery and a vein (e.g. arteriovenous fistula)

Context

Murmurs are a common finding on examination. Murmurs may be organic, functional, or innocent. Organic murmurs are caused by intrinsic cardiac disease. Functional murmurs are due to perturbations which are present in the circulation but which are due to non-cardiac causes. Innocent murmurs can arise from cardiac or non-cardiac sources but are not due to a recognized disease. Systolic murmurs are heard in up to 50% of adults. More than 90% of young adults and around 50% of older adults with a systolic murmur have a structurally normal heart on echocardiography (i.e. an innocent murmur). Diastolic or continuous murmurs always indicate structural disease. The finding of a diastolic murmur, or a new systolic murmur, in an ill patient with fever raises the possibility of infective endocarditis. Anaemia, pregnancy, and thyrotoxicosis may result in a high-output state with a functional (flow) murmur. A pericardial rub can be mistaken for a heart murmur.

Approach to diagnosis

The findings on auscultation need to be placed in relation to the history, other features of the examination, and the ECG. Key examination findings relevant to interpretation of the murmur are:

- pulse rate and rhythm
- arterial blood pressure and pulse pressure
- carotid pulse upstroke and volume
- location and quality of apex beat (note that the apex beat is impalpable in 50% of patients)
- presence of left parasternal lift
- signs of heart failure
- arterial oxygen saturation
- heart sounds
- assessment of JVP
- palpation of liver
- presence of peripheral oedema

The technique of auscultation typically begins with the patient recumbent. The murmur of mitral stenosis is best heard with the patient lying on their left side, using the bell of the stethoscope. Aortic regurgitation is heard best with the patient sitting forwards with their breath held in expiration.

A careful analysis of the characteristics of the murmur aids diagnosis. Key features are:

- timing, in relation to the cardiac cycle (see 'Aetiology')
- intensity, graded from very soft to very loud (e.g. using the Levine grading system, which grades the intensity of murmurs from 1 to 6)
- pitch: high, low, or mixed
- location where the murmur is loudest, and its radiation
- effects of dynamic manoeuvres: various physical manoeuvres can bring about characteristic changes in some murmurs

Murmurs vary with respiration. Murmurs that arise from right-sided lesions increase in intensity with inspiration, while left-sided murmurs are unaltered or decrease in intensity. In expiration, the opposite changes occur. Deep expiration brings the base of the heart closer to the chest wall and makes auscultation of aortic regurgitation and pericardial rubs easier.

The strain phase of a Valsalva manoeuvre reduces the intensity of most murmurs but increases the intensity of murmurs due to hypertrophic cardiomyopathy (HCM). Moving from standing to squatting produces an increase in venous return and increases arterial blood pressure. As a result, most murmurs increase in intensity, except those due to HCM; these reduce in intensity because of increased ventricular size and reduced obstruction to flow. Moving from squatting to standing produces the opposite changes. Handgripping (an isometric exercise) increases systemic vascular resistance and increases the intensity of mitral regurgitation, but reduces the intensity of aortic stenosis because of reduced pressure gradient across the aortic valve. The murmur of HCM becomes softer.

Specific clues to the diagnosis

See Table 15.1 for specific clues to the diagnosis.

Key diagnostic tests

All patients with a murmur should have an ECG. If the murmur has the characteristics of an innocent murmur and the ECG is normal, echocardiography is not mandatory. In all other patients with a murmur, transthoracic echocardiography (TTE) should be performed.

Other diagnostic tests

Other diagnostic tests are as follows:

Transoesophageal echocardiography: This allows better ultrasound imaging where TTE gives inadequate imaging due to limited windows.

Chest X-ray: This may demonstrate cardiomegaly, pulmonary oedema, aortic root dilatation, valvar or valve-related calcification, and prosthetic heart valves.

Blood tests: Where infective endocarditis is suspected, multiple sets of blood cultures should be taken. In addition, a full blood count,

C-reactive protein, ESR and biochemical profile should be checked. BNP will be elevated where a valve lesions results in heart failure. Thyroid function tests should be checked where a high-output flow murmur of thyrotoxicosis is suspected.

Contrast TTE/transoesophageal echocardiogram: Echocardiography with contrast permits the assessment of intra-cardiac shunts, including patent foramen ovale or an atrial septal defect.

Cardiac MRI: This permits assessment of cardiac structure, haemodynamics, and function. It permits higher spatial resolution than echocardiography.

Cardiac catheterization: This permits assessment of coronary artery disease in patients being considered for valvular surgery, as well as enabling the measurement of valve gradients and saturation measurements that might identify the site of intra-cardiac shunts.

Introduction to therapy

The management of specific valve and congenital heart lesions is addressed elsewhere. Innocent murmurs need no specific treatment. Mild to moderate valve lesions may be managed by surveillance echocardiography.

In the UK, routine antibiotic prophylaxis for patients with valvular or congenital heart disease is no longer recommended by NICE for dental procedures, or procedures involving the genitourinary, gastrointestinal, or respiratory tracts. They do recommend appropriate antibiotics if a procedure involves a potentially or actually infected gastrointestinal or genitourinary tract.

Prognosis

The prognosis is that of the cause of the murmur. For instance, innocent flow murmurs have a good prognosis, while symptomatic aortic stenosis without intervention has a poor prognosis.

How to handle uncertainty in the diagnosis of this symptom

Transthoracic echocardiography is the key diagnostic test. Occasionally, this can be non-diagnostic, and further information is required. In this case, transoesophageal echocardiography will usually provide the required information.

Table 15.1 Characteristics of different murmurs

Murmur	Cardiac abnormality	Examination findings	Specific clues to the diagnosis
Mid-systolic	None: innocent murmur	–	–
Mid-systolic	Aortic stenosis	Narrowly split or reversed S2, harsh mid-systolic murmur, loudest upper right sternal edge radiating to carotids, quiet second heart sound; intensity increased by squatting	Slow rising pulse, slow volume pulse, narrow pulse pressure, left ventricular hypertrophy on 12-lead ECG; exertional chest pain/dyspnoea/syncope
Mid-systolic	Hypertrophic cardiomyopathy with left ventricular outflow tract obstruction	Mid-systolic murmur loudest at apex and left lower sternal edge; intensity decreased by squatting; does not usually radiate to the neck; may be pansystolic murmur at apex (associated mitral regurgitation)	There may be a family history; ECG: left ventricular hypertrophy; septal hypertrophy; ventricular ectopics
Early diastolic	Aortic regurgitation	A2 may be soft; decrescendo, high-pitched early diastolic murmur loudest at left sternal edge; its duration is increased by increasing severity of aortic regurgitation; there may be an Austin–Flint murmur (low-pitched, mid-diastolic, apical murmur); collapsing pulse, wide pulse pressure	–
Mid-diastolic	Mitral stenosis	Mitral facies, signs of pulmonary hypertension with loud P2; loud S1, opening snap, then low-pitched, mid-diastolic murmur, loudest at apex with patient in left lateral position, with presystolic accentuation if in sinus rhythm; murmur intensity increased by exercise	On 12-lead ECG, may have atrial fibrillation, right bundle branch block, right axis deviation
Pansystolic	Mitral regurgitation	Soft or absent S1, pansystolic murmur loudest at the apex, radiating to the axilla; there may be an S3	Hyperdynamic apex, may be displaced with chronic regurgitation
Pansystolic	Tricuspid regurgitation	Pansystolic murmur loudest at lower left sternal edge, increasing with respiration	Giant 'v' wave and rapid 'y' descent in jugular venous pressure, pulsatile liver, peripheral oedema

16 Cough

Jacky Smith

Definition of the symptom

A cough is an explosive forced expiratory manoeuvre, usually against a closed glottis and gives rise to a characteristic sound. Acute cough is defined as a cough of less than 3 weeks duration, and chronic cough, of more than 8 weeks duration.

Differential diagnosis

Coughing is a symptom of broad range of upper and lower respiratory tract diseases. Common causes in patients presenting to secondary care with cough as an isolated symptom are shown in Box 16.1.

Context

Acute cough is the commonest presenting symptom in primary care and by far the most frequent cause is viral respiratory tract infection. Most sufferers do not seek medical care; it has been estimated that 50% self-medicate with over-the-counter therapies and only 50% of these consult with their general practitioner, most often because of persistent/severe coughing or concern about a more serious illness.

The prevalence of chronic cough has been estimated as between 11% and 20% of the general population. Women are more frequently affected than men and associations have been reported with smoking, a diagnosis of asthma and symptoms of gastro-oesophageal reflux disease. The main effect of coughing is on quality of life and this is particularly prominent in chronic cough patients who not infrequently develop physical complications such as chest pain, retching and vomiting, hoarseness, incontinence, sleep disturbance, and syncope. In addition psychological distress and social embarrassment are often features.

Approach to diagnosis

Acute cough

The majority of patients presenting to primary care will have an acute cough and the diagnosis is made based upon a symptoms typical of

Box 16.1 Common causes of cough seen in secondary care

Acute cough

- acute bronchitis
- pneumonia
- inhaled foreign body

Chronic cough

- cough-variant asthma
- gastro-oesophageal reflux disease
- rhinosinusitis
- eosinophilic bronchitis
- COPD
- bronchial carcinoma
- bronchiectasis
- angiotensin-converting-enzyme inhibitor therapy
- pulmonary tuberculosis
- interstitial lung disease
- heart failure

a viral upper respiratory tract infection. Such cases are benign and self-limiting and require no specific investigation or treatment; there is insufficient evidence to suggest that over-the-counter cough medicines are effective. The key is to identify the very small number of individuals in whom acute coughing indicates a serious underlying illness. Further investigation is required if there is a suspicion from the history or examination of an inhaled foreign body or a neoplasm, or if a prominent systemic illness is present. Specific symptoms requiring further investigation are:

- haemoptysis
- fever
- breathlessness
- chest pain
- weight loss

The remainder of this chapter will deal with chronic cough.

Chronic cough

The overall approach to patients should consist of:

1. the diagnosis and treatment of underlying conditions that may explain cough
2. investigations and trials of therapy targeting the known common conditions associated with chronic cough
3. interventions to help control coughing in unexplained or treatment-resistant cough

Several respiratory societies have produced specific detailed algorithms to aid diagnosis and management of chronic cough (see 'Further reading').

Specific clues to the diagnosis

Chronic cough

Specific clues to the diagnosis of chronic cough are as follows:

- Many patients report coughing on minor exposure to environmental irritants and temperature changes and in relation to eating, talking, or laughing; however, there is little evidence to support the notion that these features are suggestive of any particular diagnosis.
- Expectoration of sputum suggests a primary pulmonary pathology.
- Additional symptoms of asthma, gastro-oesophageal reflux, or rhinosinusitis may suggest the diagnosis and should direct trials of therapy.
- Responses to previous therapeutic trials might help narrow possible diagnoses.
- Physical examination may identify signs suggestive of specific conditions associated with chronic cough, such as chronic obstructive lung diseases, bronchiectasis, interstitial lung disease, heart failure, or lung cancer. However, often there are no specific findings.

Key diagnostic tests

Key diagnostic tests are as follows:

Chest radiography: This is mandatory in all patients with chronic cough or with acute cough with atypical symptoms or signs. In respiratory clinics, up to 31% of chest X-rays are abnormal and help establish the diagnosis.

Spirometry: This is mandatory in chronic cough.

Bronchoscopy: This is mandatory in patients with chronic cough where a foreign body or neoplasm is suspected.

If the history/examination and these key diagnostic tests reveal abnormalities that could account for the cough, then these abnormalities should be appropriately investigated to establish a diagnosis, and treatment commenced. Should no abnormality be identified or the cough prove resistant to therapy for the established diagnosis (assuming a response is expected), then subsequent investigations and therapeutic trials should be targeted at the known common causes of chronic cough (see 'Other diagnostic tests').

Other diagnostic tests

The identification of the cause of a chronic cough often hinges on the success of specific therapeutic trials. Diagnostic testing can be useful, but access to some of these specialist tests varies, and approaches should be adapted to local circumstances. The following therapeutic trials/investigations can be helpful in diagnosing and managing chronic cough.

Asthma syndromes

Cough-variant asthma is defined as asthma presenting with an isolated cough; classical symptoms of wheezing and breathlessness are absent.

Investigations

Spirometry may show evidence of airway obstruction reversible with bronchodilators. If spirometry is normal/near normal, then bronchial provocation testing with methacholine or histamine is more useful; a negative test excludes cough-variant asthma but mildly positive tests are common in chronic cough in the absence of other features of asthma.

Induced sputum examination for eosinophilic inflammation contributes to the diagnosis but is rarely available outside of the research setting. If a bronchoscopy is performed, washing of the proximal airways may identify such inflammation. Eosinophilic inflammation in the absence of a positive bronchial provocation test suggests a diagnosis of eosinophilic bronchitis.

Therapeutic trial

Asthma syndromes generally respond well to treatment with corticosteroids, and the cough should resolve following a 2-week course of 30 mg prednisolone. It must be remembered that asthma syndromes are not the only steroid-responsive causes of cough and therefore, if the symptoms return when treatment is converted to inhaled corticosteroids, an alternative diagnosis should be sought.

Gastro-oesophageal reflux disease

Some patients with chronic cough respond well to acid-suppressing therapy; however, it remains unclear how such patients can be prospectively identified.

Investigations

Although reflux disease may be assessed by gastroscopy, 24-hour pH monitoring, and 24-hour pH/impedance monitoring, currently no particular parameter from any of these investigations has been shown to predict a positive response to a particular therapy. Laryngeal appearances to diagnose reflux are also of questionable value in chronic cough.

Therapeutic trial

Proton-pump-inhibitor treatment (the equivalent of 20–40 mg omeprazole twice daily for 8 weeks, before meals) is well tolerated and improves cough in some patients, although randomized controlled trials have been disappointing. The role of more aggressive acid suppression such as the addition of H₂ receptor antagonists or the use of prokinetic agents and baclofen is less clear, as is the role of anti-reflux surgery.

Rhinosinusitis

Upper airways diseases are also a common cause of chronic cough. In the past, these were referred to as 'post-nasal drip syndromes', based on the suggestion that secretions dripping into the larynx provoked coughing, but there is little evidence supporting this mechanism.

Investigations

ENT referral/examination and sinus imaging may be useful in patients with prominent upper airway symptoms and where chronic sinus disease is suspected. Examination of the throat may also reveal tonsillar hypertrophy, which can contribute to chronic cough.

Therapeutic trial

Although evidence from randomized controlled trials is lacking, a 1-month trial of topical nasal corticosteroids is recommended in patients where rhinitis is suspected. Antibiotic therapy and decongestants may also be helpful for sinusitis.

In patients in whom targeted investigations and/or therapeutic trials have been unhelpful, the following investigations should be considered:

High-resolution CT of the thorax: This may reveal interstitial lung disease or bronchiectasis not visible on the chest X-ray. Scanning should be performed at the outset, however, if auscultation of the chest suggests such a diagnosis.

Bronchoscopy: This may find rare causes of chronic cough such as tracheomalacia, tracheobronchopathia osteochondroplastica, and endobronchial amyloidosis, which are difficult to diagnose without airway examination.

Sleep studies: Obstructive sleep apnoea (OSA) patients commonly report chronic coughing, and case reports suggest that, in patients presenting with chronic cough and found to have OSA, positive airway pressure therapy might improve coughing.

Introduction to therapy

Generally, therapy for chronic cough should be the appropriate treatment of the underlying cause and may be established as part of the diagnostic process. However, it is increasingly recognized that many patients have either unexplained cough (no identifiable cause) or treatment-resistant cough (no response to therapy for identified potential causes). Unfortunately, effective, well-tolerated anti-tussive therapies are lacking. Some patients benefit from low-dose amitriptyline (10 mg daily) or low-dose morphine sulfate (5–10 mg twice daily) but side effects (especially with morphine) are common. Supportive therapies, such as speech and language therapy to teach cough control/suppression, incontinence services, and treatment of anxiety and depression, should also be considered.

Prognosis

Little is known about the prognosis of chronic cough. However, data from one specialist clinic showed that, over a 7-year follow-up, 14% of patients with chronic cough resolved and 40% had a significant improvement.

How to handle uncertainty in the diagnosis of this symptom

Patients with chronic cough can be challenging to manage, especially where no cause or multiple potential causes of cough are identified. These patients benefit from review in a specialist cough clinic.

17 Wheeze

Andrew A. Jeffrey

Definition of the symptom

A wheeze is a high-pitched musical sound which reflects airflow obstruction. It may be monophonic or polyphonic, and may be heard during inspiration, expiration, or both phases of respiration. Stridor is the term used to describe wheeze which is louder over the neck than the chest, and may be audible without a stethoscope.

Differential diagnosis

The differential diagnosis of wheeze is given in Table 17.1.

Context

Wheezing is typically associated with breathlessness, and may present as an acute or chronic problem. It is most often due to asthma or chronic obstructive pulmonary disease.

Approach to diagnosis

If wheezing is associated with respiratory distress or other evidence of critical illness, the approach to the diagnosis and management should follow the method outlined in Chapter 126.

In stable patients, a detailed history should be taken, with particular attention to the speed of onset of wheezing, trigger factors, and history of atopy. The clinical features, measurement of peak expiratory flow, and spirometry will usually differentiate between possible diagnoses.

Specific clues to the diagnosis

Asthma

The commonest cause of wheeze is bronchospasm in the context of asthma. The patient, or those around them, may be aware of noisy breathing occurring usually in association with laboured breathing and a sensation of chest tightness or heaviness. In asthma this symptom occurs at rest and in response to specific triggers as well as on exertion. Asthma usually starts in childhood or early adult life, although it can present at any age. The peak expiratory flow rate (PEFR) is significantly reduced when wheeze is present. There is usually a rapid response to short-acting bronchodilator therapy.

Table 17.1 Causes of wheeze by anatomical site of airflow obstruction

Extra-thoracic upper airway (nose, mouth, pharynx, larynx, and upper trachea)	Intra-thoracic upper airway (lower trachea, and bronchi >2 mm in diameter)	Lower airways (bronchi <2 mm in diameter, and bronchioles)
Anaphylaxis	Tracheal disorders	Asthma
Vocal cord disorders	Foreign body aspiration	Chronic obstructive pulmonary disease
Laryngeal disorders	Mucus deposits in large airways	Pulmonary oedema
Tracheal disorders, including extrinsic compression by large goitre	Endobronchial tumours	Bronchiectasis
	Bronchomalacia	Cystic fibrosis

Pulmonary oedema

So-called cardiac asthma results from the narrowing of small airways by mucosal oedema caused by high pulmonary-capillary pressure. This is a relatively uncommon presentation of pulmonary oedema, as other symptoms normally predominate. However, wheeze can occasionally be a dominant feature and hard to differentiate from bronchial asthma. In its character, the wheeze in pulmonary oedema is almost identical to that caused by bronchospasm. As it can occur at rest, particularly in bed at night, the history shares features with asthma as well. The onset of wheeze in an older patient should trigger a search for risk factors, symptoms, and signs of cardiac disease, as well as for asthma. The PEFR can be reduced in pulmonary oedema and so a single low reading is not diagnostic; however, the classical diurnal variation in PEFR is not seen. A raised level of plasma BNP will be found in a patient with wheeze due to cardiogenic pulmonary oedema.

Chronic obstructive pulmonary disease

Wheezing can be found in airflow obstruction, which is usually due to chronic bronchitis. It occurs frequently on exertion or during exacerbations when a degree of bronchospasm is also present due to mucosal oedema. Patients often report frequent 'winter bronchitis'. Onset is later in life and almost invariably in cigarette smokers. No diurnal variation in PEFR occurs.

Vocal cord dysfunction

Vocal cord dysfunction (VCD) is a relatively common problem resulting from an involuntary increase in muscle tone in the laryngeal muscles. In some, this can result in paradoxical narrowing of the laryngeal opening during inspiration, resulting in **inspiratory** wheeze. It occurs relatively commonly in patients with asthma and can be interpreted by the patient as part of the symptoms produced by their asthma, but one that does not respond to bronchodilator therapy and is often not associated with chest tightness. They can present with difficult to control asthma. It is vital in taking the history to establish where in the respiratory cycle (i.e. during inspiration or expiration) that wheezing occurs and to consider VCD in all such patients. Flow-volume loops can sometimes show a characteristic 'flutter' pattern with VCD. Direct observation of the cords during breathing is essential to rule out more sinister laryngeal pathology and can be diagnostic in VCD, but, as the problem varies over time, the diagnosis can be difficult to prove.

Other causes

A simple whistling noise from mucus in airways occurs in the context of a productive cough and usually clears or changes with coughing. Bronchomalacia is a rare disorder in which the cartilage in the major airways softens, resulting in their collapse during expiration (intra-thoracic) or inspiration (extra-thoracic). Diagnosis is by bronchoscopy or CT chest with inspiratory and expiratory views

Key diagnostic tests

The key diagnostic tests are:

- measurement of PEFR, before and after inhaled bronchodilator
- spirometry, before and after inhaled bronchodilator (including measurement of the flow-volume loop if extra-thoracic or intra-thoracic upper airway obstruction is suspected)
- chest radiography

Other diagnostic tests

Other diagnostic tests are:

- nasendoscopy/laryngoscopy
- bronchoscopy
- CT of the chest/neck
- provocative tests for asthma

Introduction to therapy

Supportive therapy for the critically ill patient with respiratory failure is discussed in Chapter 135. Specific therapy is directed by the working diagnosis.

Prognosis

The prognosis depends on the cause.

How to handle uncertainty in the diagnosis of this symptom

If the clinical features suggest extra-thoracic upper airway obstruction, refer to an ENT surgeon for consideration of nasendoscopy/laryngoscopy. For suspected intra-thoracic disease, arrange bronchoscopy or a chest CT.

18 Haemoptysis

Rakesh Panchal

Definition of the symptom

Haemoptysis is the expectoration of blood or blood-stained sputum resulting from haemorrhage into the respiratory tract. Massive haemoptysis (5% of cases) is usually defined as >600 ml in 24 hours.

Differential diagnosis

See Table 18.1 for the differential diagnosis of haemoptysis.

Context

Haemoptysis is a common and non-specific symptom. It can vary from blood-streaked sputum to massive, life-threatening haemorrhage. Haemoptysis may originate from the bronchial arteries (90%), pulmonary arteries (5%), or non-bronchial collaterals. Haemoptysis causing haemodynamic instability and/or respiratory compromise is a medical emergency. Unexplained haemoptysis may herald a serious underlying lung condition and therefore requires a thorough diagnostic workup. The majority of patients can be safely investigated and managed as outpatients. Urgent workup or inpatient management will be determined by the rate and severity of bleeding, and knowledge of either the source of bleeding and/or the underlying condition.

Approach to diagnosis

It is important to distinguish haemoptysis from epistaxis or haematemesis.

A focused history is the key to diagnosis:

Demographics: In patients from the Indian subcontinent or sub-Saharan Africa, a diagnosis of tuberculosis or post-tuberculous bronchiectasis is more likely while, in the West, bronchiectasis or lung cancer is more common.

Smoking: A high-pack-year history of smoking in the context of haemoptysis and other red-flag symptoms such as cough, dyspnoea, chest pain, and weight loss is suggestive of lung cancer.

Volume of haemoptysis: Bronchiectasis and pulmonary haemorrhage typically present with moderate-to-severe bleeding, whereas lung cancer and bronchitis cause mild-to-moderate bleeding.

The clinical examination may be normal, but the following signs may be found:

Nasal signs: Nasal crusting or dried blood may be found in Wegener's granulomatosis (granulomatosis with polyangiitis).

Superior vena cava obstruction: Swelling of the face and neck with fixed elevation of the jugular venous pressure may be found in lung cancer.

Auscultation of the chest: Bronchial breath sounds may be heard in pneumonia or tuberculosis, while coarse crepitations may be heard in bronchiectasis.

Specific clues to the diagnosis

See Table 18.2 for specific clues to the diagnosis.

Key diagnostic tests

Key diagnostic tests are as follows:

Chest radiograph: This is the first investigation of choice, as it may help localize the bleeding site to, for example, a mass lesion, or regions showing consolidation, bronchiectasis, or diffuse interstitial shadowing in vasculitides. In approximately 20%–46% of cases, the chest radiograph will be non-diagnostic.

Blood tests: These should be taken to evaluate haemoglobin, platelet count, and clotting profile (full blood count, international normalized ratio, and activated partial thromboplastin time). If vasculitis or a pulmonary–renal syndrome is suspected, renal and liver function tests as well as antineutrophil cytoplasmic antibodies (ANCA), autoantibodies, and antiglomerular basement membrane (anti-GBM) antibodies should be requested. All patients should be grouped and saved.

Sputum: In patients at risk for lung cancer, sputum should be sent for cytology; in suspected tuberculosis or pneumonia, it should be sent for Gram stain, stain for acid-fast bacilli, and culture.

CT scan: This is now performed in the majority of unexplained causes of haemoptysis and should be done prior to bronchoscopy, as it directs the bronchoscopist to the likely source of bleeding and therefore increases the potential yield. High-resolution CT should be requested if bronchiectasis is suspected. Contrast-enhanced CT may help in identifying vascular lesions such as arteriovenous malformations. Request for a CT with bronchial artery circulation

Table 18.1 Differential diagnosis of haemoptysis

Primary care		Secondary care	
Infection	60%–70%	Bronchiectasis	38%
<ul style="list-style-type: none"> ● bronchitis (25%) ● pneumonia (10%) ● tuberculosis (8%) 			
Lung cancer	25%	Mycetoma/aspergilloma	16%
Cardiac haemoptysis (pulmonary venous or arterial hypertension; left ventricular failure, mitral stenosis, pulmonary embolism, and, more rarely, congenital heart disease with Eisenmenger syndrome)	5%	Lung cancer	10%
		Tuberculosis	8%
		Pneumonia	6%
		Pulmonary vasculitis	2%
		Others	8%

Note: Twenty per cent of haemoptyses are **cryptogenic**.

Table 18.2 Specific clues to the diagnosis

Clues	Likely diagnosis
Age	<40 years: bronchiectasis and mitral stenosis >40 years: lung cancer
Fever; rusty-coloured, purulent sputum	Pneumonia, especially <i>Streptococcal pneumoniae</i> , or tuberculosis
COPD, cachexia, smoker	Lung cancer
History of lung disease: childhood respiratory illness, tuberculosis, pneumonia, etc.	Bronchiectasis
Major risk factors for venous thromboembolism + haemoptysis	Pulmonary embolism
Fever, weight loss, sinus/nasal symptoms, haematuria, skin rash, eyes, joint, CNS involvement	Vasculitis, e.g. Wegener's granulomatosis (granulomatosis with polyangiitis).

will provide a 'road map' of dilated tortuous bronchial arteries that may be targeted by an interventional radiologist for embolization if a bronchiectatic cavity or aspergilloma is suspected (see 'Other diagnostic tests').

Bronchoscopy: Bronchoscopy, pending CT, is useful as both a diagnostic and therapeutic modality. It enables the anatomical source of the haemoptysis to be directly visualized and allows tissue biopsies or bronchial washes to be taken. From a therapeutic perspective, it allows injection of a bleeding tumour with a vasoconstrictor (e.g. adrenaline) or tamponade via a catheter (e.g. a Fogarty catheter). Many clinicians believe bronchoscopy should be performed in all cases of haemoptysis.

Urinalysis: Microscopic haematuria in the presence of frank haemoptysis should encourage investigations to confirm or refute pulmonary–renal syndrome.

Other diagnostic tests

Subsequent investigations will depend on the presumed underlying diagnosis:

CT pulmonary angiogram: Do this if pulmonary embolism is suspected.

Echocardiography: This will identify moderate/severe pulmonary hypertension or mitral valve disease if suspected as a cause of haemoptysis.

Bronchial artery angiography and embolization (BAE): This technique has both diagnostic and therapeutic benefits. If bleeding is from a bronchial artery, it will identify a mesh of dilated or tortuous vessels surrounding, for example, a bronchiectatic cavity or an aspergilloma. It is best performed during an episode of bleeding in order to maximize the chances of identifying the bleeding source. Abnormal vessel embolization is performed using glue or coils. This technique is only carried out in specialist centres, usually by experienced interventional vascular radiologists, with a success rate in the range of 73%–98%. Complications include transient chest pain which is often ischaemic in origin and, more seriously, a 1% risk of spinal cord ischaemia if the embolized bronchial artery gives rise to the anterior spinal artery.

Pulmonary function tests: In genuine causes of pulmonary haemorrhage, the gas transfer (KCO) will be elevated, reflecting the increased oxygen-carrying capacity of blood present in the alveoli. This may be useful in confirming haemoptysis, provided the other causes of a raised KCO are excluded.

Introduction to therapy

Non-massive haemoptysis is managed conservatively, provided there is no haemodynamic instability or respiratory compromise. The key is to identify and treat the source. If the haemoptysis is persistent or troublesome, then in the absence of severe renal failure an anti-fibrinolytic such as tranexamic acid may be prescribed either orally (500 mg three times daily, or 15–25 mg/kg two to three times daily) or intravenously (0.5–1.0 g three times daily).

Massive haemoptysis is a medical emergency and must be managed in the same manner as a gastrointestinal (GI) haemorrhage (e.g. variceal bleeding). Resuscitation (intravenous fluids) and airway

protection are the first priority. Early anaesthetic input is important, and the patient may need to be admitted to a high-dependency or intensive care unit. If the bleeding source is known, then the patient should be positioned with the bleeding side down to protect and prevent overspill into the unaffected lung. Nebulized adrenaline (5–10 ml of 1:10 000) acts as a vasoconstrictor and may be used under these circumstances. Patients with ongoing massive haemoptysis should be intubated with a large endotracheal tube to allow bronchoscopy and suction. Alternatively, a double-lumen endotracheal tube may be passed to protect the unaffected lung. Early bronchoscopy is advisable as it allows identification of the bleeding source and instillation of topical adrenaline (5–10 ml of 1:10 000) or lavage with iced 0.9% saline to induce vasoconstriction, or tamponade using a balloon catheter. Rigid bronchoscopy is preferable for balloon tamponade but is often done by thoracic surgeons in tertiary centres in the UK. It also allows laser or electrocautery treatment in endoscopically visible tumours.

If haemostasis is achieved, the most effective non-surgical treatment, depending on the likely cause, is BAE (see 'Other diagnostic tests'). However, for select cases (e.g. rebleeding despite BAE; localized bronchiectasis; trauma; hydatid cysts; arteriovenous malformations; thoracic aneurysm and aspergilloma) surgery (e.g. by lobectomy) remains the procedure of choice because it is curative.

Prognosis

In 20%–33% of cases, no source of bleeding is identifiable. This is called **cryptogenic haemoptysis** and has a good prognosis, with resolution of bleeding within 6 months of evaluation. Non-massive haemoptysis has a mortality ranging from 7%–30%. However, in massive haemoptysis the mortality can reach 80% and such an encounter is often a terrifying experience for both clinician and patient alike.

How to handle uncertainty in the diagnosis of this symptom

The majority of cryptogenic haemoptyses can be managed by reassurance; however, it is important to have considered and excluded vasculitides such as Wegener's granulomatosis, microscopic polyangiitis, or Goodpasture's if there is any evidence of systemic disease. Patients may occasionally state that 'blood appeared in my mouth'; if you believe the patient has had a bleed but are unsure if it is haemoptysis, then a thorough history for possible upper respiratory tract (e.g. epistaxis) or upper GI symptoms (dyspepsia, reflux, vomiting, melaena, etc.) should be sought, and referral to either an ENT or a gastroenterologist for possible nasal or upper GI endoscopy should be considered.

19 Pleural effusion

Seamus Grundy

Definition of the presentation

A pleural effusion is a collection of fluid within the space between the visceral and parietal pleura. Pleural effusions can be unilateral or bilateral, and differentiation of this can aid with creating a differential diagnosis.

Differential diagnosis

All unilateral pleural effusions require further investigation within a secondary care setting. Bilateral pleural effusions in the setting of known heart failure can be safely treated without further investigations unless the effusions are markedly asymmetric or there are symptoms suggestive of an alternative aetiology.

Context

Pleural effusion is a common clinical problem which can present both to primary and secondary care. In healthy individuals, the pleural space contains approximately 10–15 ml of pleural fluid. Pleural effusions can be caused by many different disease processes. However, the process by which fluid accumulates can be divided into transudative or exudative. Transudative effusions (Table 19.1) occur in the presence of normal pleura and are caused by increased oncotic or hydrostatic pressures. Exudative effusions (Table 19.2) are associated with abnormal pleura and are caused by either increased pleural fluid production due to local inflammation or infiltration or by decreased fluid removal which is caused by obstruction of the lymphatic drainage system.

Patients may be entirely asymptomatic or they may present with breathlessness, particularly if the effusion is large. Other symptoms include a cough and systemic symptoms such as weight loss, anorexia, and fever. Chest pain is suggestive of inflammation/infiltration of the parietal pleura and points towards malignancy or empyema.

It is crucial to illicit the underlying diagnosis rapidly with a minimum of invasive tests in order to allow appropriate management of the causative disease process.

Approach to diagnosis

The initial assessment of a patient with a pleural effusion requires a thorough medical history with particular attention to the following:

Systemic symptoms: High fevers are suggestive of parapneumonic effusion/empyema or tuberculosis. Weight loss/anorexia points towards malignancy or empyema.

Past medical history: In particular, look for previous malignancy or systemic diseases which can be associated with pleural effusion.

Occupational history: Asbestos exposure can cause both malignant mesothelioma and benign asbestos-related pleural effusion. The

Table 19.1 Transudative pleural effusions

temporal relationship with the asbestos exposure is important, with mesothelioma often having a lag time of decades whereas benign asbestos-related effusion normally presents within 10 years of asbestos exposure.

The patient should be examined with close attention being paid to the presence of any palpable lymph nodes, cachexia, and peripheral oedema suggestive of either congestive cardiac failure or a low-protein state. Auscultation of the lungs will reveal diminished breath sounds over the pleural effusion, with stony dullness to percussion.

Specific clues to the diagnosis

Specific clues to the diagnosis are as follows:

Exudate vs transudate: Pleural fluid can be defined as exudative or transudative, according to the concentration of protein and/or lactate dehydrogenase (LDH) within the fluid. Light's criteria have a sensitivity of 97% and a specificity of 80% for diagnosing an exudate (Table 19.3).

Unilateral vs bilateral pleural effusion: A unilateral pleural effusion invariably requires further investigation to determine the underlying pathological process. Bilateral pleural effusions in the presence of a history consistent with left ventricular dysfunction can safely be managed with medical treatments for heart failure without further tests. However, if the effusions are treatment resistant, further investigations should be pursued.

Pleuritic chest pain: The presence of pleuritic chest pain implies involvement of the parietal pleura. This almost invariably suggests that the effusion is exudative in nature and most likely infectious or malignant, although pulmonary embolism with associated lung infarction is an important differential.

Key diagnostic tests

The diagnostic workup of a patient with a pleural effusion should be systematic and based upon clinical judgement and results of initial investigations (see Figure 19.1).

Pleural fluid

In most cases, a sample of pleural fluid should be obtained. This should be analysed for the following:

Biochemistry: Protein and LDH should be measured to define whether the effusion is transudative or exudative. The pH of the fluid should

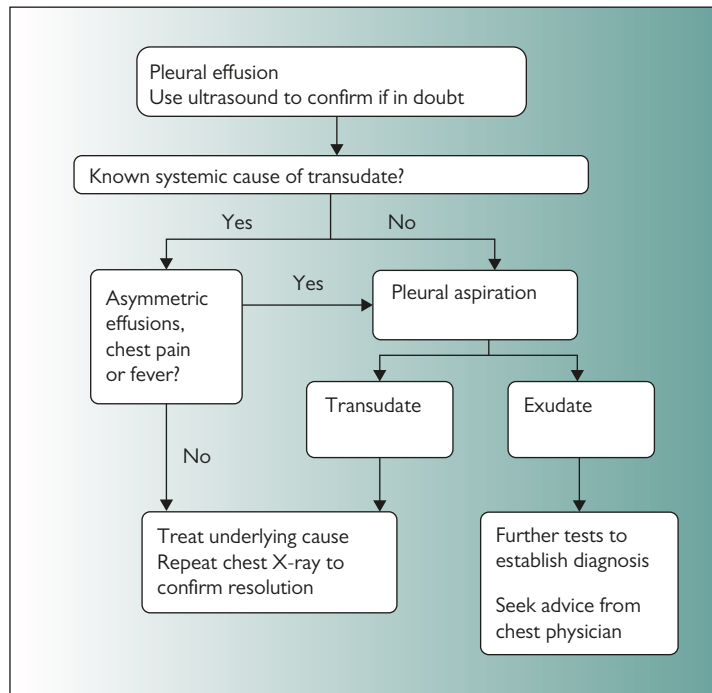

Figure 19.1 Management of pleural effusion.

Reproduced with permission from Spriggins D, Chambers JB. *Acute Medicine*, fourth edition, Wiley-Blackwell, Oxford, UK, Copyright © 2008.

be measured, particularly when pleural infection is suspected. If the pH is <7.2 , an intercostal drain should be inserted.

Microbiology: Routine bacterial culture and alcohol/acid fast bacilli should be performed to assess for the presence of bacterial infection or tuberculosis.

Cytology: A sample should be assessed for the presence of malignant cells. A differential cell count can also be helpful. A lymphocyte count $>80\%$ is suggestive of tuberculosis. If initial tests are non-diagnostic, a repeat cytology sample can improve the sensitivity for malignant effusions.

See Tables 19.3 and 19.4 for overview of pleural fluid analyses.

Table 19.3 Pleural fluid analysis (1)	
Test	Comment
Visual inspection	Blood-stained effusion (pleural fluid hematocrit 1–20% of peripheral hematocrit) is likely to be due to malignancy, pulmonary embolism or trauma Purulent fluid signifies empyema
Protein and lactate dehydrogenase (LDH)	These are the only tests needed if the effusion is likely to be a transudate Pleural fluid LDH correlates with the degree of pleural inflammation Exudative pleural effusions have a protein concentration >30 g/L If the pleural fluid protein is around 30g/L, Light's criteria are helpful in distinguishing between a transudate and exudate. An exudate is identified by one or more of the following: <ul style="list-style-type: none"> • Pleural fluid protein to serum protein ratio >0.5 • Pleural fluid LDH to serum LDH ratio >0.6 • Pleural fluid LDH more than two-thirds the upper limit of normal for serum LDH

Reproduced with permission from Spriggins D, Chambers JB. *Acute Medicine*, fourth edition, Wiley-Blackwell, Oxford, UK, Copyright © 2008.

Table 19.4 Pleural fluid analysis (2): Additional tests for exudative pleural effusion

Test	Comment
Pleural fluid pH and glucose (check these if a parapneumonic or malignant pleural effusion is suspected. Send sample in heparinized syringe for measurement of pH in blood gas analyzer)	Low pH (<7.3)/low glucose (<3.3 mmol/L) pleural fluid may be seen in: <ul style="list-style-type: none"> • Complicated parapneumonic effusion and empyema • Malignancy • Rheumatoid or lupus pleuritis • Tuberculosis • Esophageal rupture
Cytology (total and differential cell count; malignant cells)	Neutrophilia ($>50\%$ cells) indicate acute pleural disease Lymphocytosis is seen in malignancy, tuberculous pleuritis and in pleural effusions after CABG The yield of cytology is influenced by the histological type of malignancy: $>70\%$ positive in adenocarcinoma, 25–50% in lymphoma, 10% in mesothelioma
Microbiology (Gram stain and culture; markers of tuberculosis (TB))	Send fluid for markers of TB if TB is suspected or there is a pleural fluid lymphocytosis
Other tests depending on the clinical setting (e.g. amylase, triglyceride)	Elevated pleural fluid amylase is seen in acute pancreatitis and esophageal rupture Check triglyceride level if chylothorax is suspected (opaque white effusion); chylothorax (triglyceride >1.1 g/L) is due to disruption of the thoracic duct by trauma or lymphoma

CABG, coronary artery bypass graft.

Reproduced with permission from Spriggins D, Chambers JB. *Acute Medicine*, fourth edition, Wiley-Blackwell, Oxford, UK, Copyright © 2008.

Pleural biopsy

If the initial tests do not provide a firm diagnosis, then a pleural biopsy should be obtained. This can be taken 'blind' with an Abrams needle; under radiological guidance, with a cutting biopsy needle; or at thoracoscopy. The only indication for Abrams biopsy is a suspected tuberculous effusion, as the sensitivity for malignant effusions with a blind biopsy is almost half that with either radiologically guided biopsy or thoracoscopy.

Introduction to therapy

The management strategy for a pleural effusion is aimed at relieving symptoms and treating the underlying pathology. In the case of transudative effusions, effective treatment of the causative process is normally all that is required.

Removal of pleural fluid can be achieved in two ways: therapeutic thoracentesis or intercostal drain insertion. An intercostal drain should only be inserted once a diagnosis has been achieved, as complete drainage of the pleural space may inhibit the ability to perform thoracoscopy. The only urgent indication for intercostal drain is empyema or parapneumonic effusion with a pleural fluid pH <7.2. If a patient is very breathless, and a diagnosis has not been made, then withdrawal of up to 1 litre of pleural fluid by thoracentesis will relieve symptoms. The vast majority of pleural procedures should be performed at times when the hospital is well staffed and by experienced practitioners. If an effusion is recurrent or the patient has trapped lung, making effective pleurodesis impossible, a long-term indwelling pleural catheter can be sited. This allows the patient to drain off fluid on a regular basis to relieve symptoms.

Malignant pleural effusions, both mesothelioma and metastatic, require a management strategy aimed at reducing symptoms and optimising quality of life. Pleural fluid can be controlled with pleurodesis via intercostal drain, talc poudrage via thoracoscopy or insertion of in-dwelling pleural catheter. There is currently no clear evidence to define the optimal approach and so patients should be given a choice.

Pleural infection should be treated initially with empirical antibiotics guided by local policy. The bacteriology of pleural infection

differs between community acquired and hospital acquired infection. Anaerobes often co-infect the pleural space thus anaerobic antibiotic cover should be continued even if an aerobic bacteria is cultured.

Prognosis

The prognosis of a patient with a pleural effusion is dependent upon the underlying pathology. The life expectancy for patients with malignant pleural effusion or mesothelioma is poor, with a 2-year survival rate of approximately 20%, whereas most patients with a parapneumonic effusion or empyema will make a full recovery with appropriate antibiotics.

Dealing with diagnostic uncertainty

Even if the comprehensive investigation pathway previously described in this chapter is followed, there will always be a small proportion of cases in which a definitive diagnosis cannot be made. It is crucial in cases like these to review thoroughly the case history and revisit any possible symptoms which could suggest malignancy outwith the pleural space. If no underlying pathology is found, a diagnosis of idiopathic pleural effusion is made. Most idiopathic pleural effusions follow a benign course, although some will later turn out to be malignant and so all cases should receive regular follow-up.

A particular challenge can be differentiating the histology of mesothelioma from other tumours such as adenocarcinoma. Often, despite extensive immunohistochemical stains, it is impossible to say with certainty what the primary tumour is. In this situation, a multidisciplinary approach is essential to conclude the final diagnosis and management plan.

20 Chylothorax

Anjali Crawshaw

Definition of the disease

Chylothorax is an accumulation of lymphatic fluid in the pleural space due to obstruction or injury of the thoracic duct.

Aetiology of the disease

Malignant disease causing obstruction of the thoracic duct accounts for more than 50% of cases; lymphoma is the most common cause. Non-malignant causes are rare. Trauma to the thoracic duct can result from mediastinal surgery, most commonly oesophagectomy. The causes of chylothorax are given in Box 20.1.

Typical symptoms of the disease, and less common symptoms

Dyspnoea and tachypnoea are common, as with pleural effusion of any aetiology. Pleuritic pain and fever are uncommon unless due to underlying disease, as chyle does not irritate the pleural surface.

Demographics of the disease

Chylothorax can occur at any age. There is no gender difference.

Natural history and complications of the disease

Malnutrition and immunocompromise (T-cell deficiency) result from the loss of chyle, which is rich in proteins, fats, electrolytes, bicarbonate, fat-soluble vitamins, and lymphocytes.

Approach to diagnosing the disease

Clinical examination and chest radiography should suggest the presence of pleural fluid. A pleural-fluid triglyceride level >110 mg/dl is diagnostic of chylothorax. A low pleural-fluid cholesterol level, the presence of chylomicrons, and a high lymphocyte count support the diagnosis. The appearance of the fluid may be misleading, resulting in under-diagnosis of chylothorax: the classic milky appearance is seen in around 50% of cases.

Other diagnoses that should be considered

Empyema is an important differential requiring early recognition and treatment. The pleural-fluid pH will be low (<7.2). Although the fluid may appear cloudy, when centrifuged, the supernatant is clear.

Pseudochylothorax occurs in more chronic pleural effusion and is characterized by a high cholesterol level (typically >200 mg/dl, although it may exceed 1000 mg/dl). The effusion is usually sterile and requires no treatment unless large enough to cause respiratory

Box 20.1 Causes of chylothorax

Congenital

21 Difficulty swallowing

Satish Keshav and Alexandra Kent

Definition of the symptom

Dysphagia is a difficulty in the process of swallowing.

Common causes

Dysphagia is an alarm symptom, and therefore requires referral to secondary care for investigation. There are multiple causes, divided into oesophageal, neurological, surgical, and extrinsic obstruction, as shown in Table 21.1. Investigation and treatment of non-oesophageal causes is not covered in detail in this section.

Context

Swallowing is a complex process involving coordination of many nerves and over 50 pairs of muscles and can be divided into oral, pharyngeal, and oesophageal phases. It is important to ascertain whether patients have a problem initiating the swallow (suggesting

a neurological cause) or describe a sensation of ‘food sticking’ (suggesting oesophageal causes). Dysphagia can lead to weight loss and malnutrition; it also predisposes to aspiration pneumonia. Acute dysphagia has an annual incidence of ~13 per 100 000 population and is usually due to food impaction in obstructing lesions or eosinophilic oesophagitis.

Approach to diagnosis

The cornerstone to diagnosing the cause of dysphagia is a careful medical history. It is important to assess whether dysphagia is intermittent or progressive, and ask for associated symptoms, including heartburn, weight loss, haematemesis, coffee-ground emesis, anaemia, regurgitation of food particles, and respiratory symptoms. Furthermore, it is important to determine the type of food that produces dysphagia (solid vs liquid) and the temporal association to symptoms. For example, motility disorders may produce intermittent symptoms, whereas obstructing lesions (cancer, peptic strictures) will be progressive, involving solids before liquids.

Specific clues to the diagnosis

Specific clues to the diagnosis are as follows:

- Cancers causing obstruction will cause progressive dysphagia, from liquids to solids, with no relief from symptoms. Patients often have associated systemic symptoms including weight loss, anaemia, and chest pain, and risk factors such as smoking.
- Patients with peptic strictures will have an underlying history of gastro-oesophageal reflux.
- Achalasia is a progressive disease often developing over months to years, and may be associated regurgitation or chest pain.
- Motility disorders often have an intermittent history, and associated symptoms including chest pain, heartburn, and regurgitation. There may be symptoms of underlying disease, such as scleroderma, dermatomyositis, Sjögren’s syndrome, and so on.
- Pharyngeal pouches are slowly progressive and have associated regurgitation and gurgling.
- Patients with eosinophilic oesophagitis are often younger with a history of atopy.

Key diagnostic tests

Any patient suffering dysphagia requires an upper gastrointestinal (GI) endoscopy, to rule out obstructing lesions. Furthermore, this provides the opportunity to obtain oesophageal biopsies to exclude eosinophilic oesophagitis.

Other diagnostic tests

Patients who are felt to be at risk of complications from endoscopic procedures (comorbidities, such as severe heart or lung disease) should undergo a barium swallow, which will identify mucosal lesions and motility disorders such as achalasia. Oesophageal biopsies taken at the time of endoscopy are fundamental to the diagnosis of eosinophilic oesophagitis. In cases of a normal endoscopy and biopsies, patients should undergo oesophageal manometry to identify a motility disorder.

Patients who have a problem initiating swallowing may have a neurological cause. These patients should undergo CT head, assessment by speech and language therapists (SALT) and video fluoroscopy. Assessment by SALT is important to reduce the risk of aspiration.

		Incidence
Oesophageal	Tumours Oesophagitis Eosinophilic oesophagitis Peptic stricture Diverticulum Rings and webs Motility disorders Scleroderma Functional	Most common causes are peptic stricture and oesophagitis; with increasing age, the incidence of dysmotility increases; dysphagia in juveniles and young adults is more likely to be due to eosinophilic oesophagitis
Extrinsic compression	Aberrant subclavian artery Cervical osteophytes Enlarged aorta Enlarged left atrium Mediastinal mass	Rare
Surgical	Laryngectomy Pharyngectomy Oesophagectomy Head and neck surgery	Rare
Neurological	Stroke or traumatic brain injury Multiple sclerosis Myasthenia gravis Myopathy (dermatomyositis, myotonic dystrophy) Poliomyelitis Cervical brace Cervical spondylosis Motor neuron disease (e.g. amyotrophic lateral sclerosis) Parkinson’s disease and other degenerative disorders Cerebral palsy	Increasing with age
Other	Age, ventilator dependency	

Introduction to therapy

Therapy is dictated by the underlying diagnosis:

- Strictures can be treated with endoscopic balloon dilatation, although cancerous strictures have a significantly higher risk of perforation, compared to benign peptic strictures. Patients suffering with oesophageal cancers unsuitable for surgical resection or curative procedures may gain symptomatic relief from placement of an oesophageal stent.
- Oesophagitis and peptic strictures require high-dose therapy with proton-pump inhibitors.
- Achalasia is treated with smooth muscle relaxants, botulinum toxin, balloon dilatation, or surgical myotomy.
- Eosinophilic oesophagitis responds to elimination diets and/or topical steroids in the majority of patients.

Prognosis

Overall prognosis is highly dependent on the underlying diagnosis. However, in most conditions, relief of dysphagia is achievable.

How to handle uncertainty in the diagnosis of this symptom

It is important to take a detailed history, as patients may misinterpret their symptoms, for example, describing 'difficulty in swallowing' when their main symptom is pain on swallowing (odynophagia). Standard tests may yield no clear diagnosis. Dysmotility in the early stages can be subtle, and tests may be negative. However, with time, symptoms may worsen, and subsequent testing may reveal a diagnosis previously not established. Rarely, pseudoachalasia, which is caused by an infiltrating tumour in the gastric cardia, may be misdiagnosed or missed.

22 Haematemesis

Satish Keshav and Alexandra Kent

Definition of the symptom

Haematemesis is the vomiting of fresh or altered blood.

Common causes

Haematemesis is almost exclusively dealt with in the hospital setting, as it is a medical emergency (see Box 22.1). Mallory–Weiss tear, which typically occurs after prolonged vomiting and retching, usually is of small volume, without haemodynamic compromise, and is usually self-limiting, may be recognized as such and not always referred to secondary care. Rare causes of haematemesis are unlikely to be encountered by most general practitioners. No cause for the haematemesis is found in 17% of cases, despite investigation. Endoscopy in the emergency setting can be difficult, and lesions may be missed. The Mallory–Weiss tear may have healed by the time endoscopy is performed, and Dieulafoy lesions may only be transiently visible. Haemoptysis and vomiting of red-stained food can be mistaken for haematemesis, possibly accounting for some cases where a diagnosis is not established.

Context

Upper gastrointestinal haemorrhage (UGIH) has an incidence of 50–150 cases per 100 000 population. Upper gastrointestinal bleeds have a 10% mortality rate, and as such should be treated as a medical emergency. The airway, breathing, and circulation (ABC) should be **immediately** assessed in all patients, as this reflects intravascular volume and the presence of ongoing bleeding. However, the physiological response to blood loss can mask signs and symptoms until >40% of the intravascular volume has been lost. Despite the use of proton-pump inhibitors (PPIs), admission rates for peptic ulcer haemorrhage have increased in older age groups, probably related to increased use of antiplatelet agents and anticoagulants. Further reductions in mortality and morbidity may be prevented by the rising age of the population.

The commonest cause of haematemesis is peptic ulceration, accounting for nearly 50% of cases. Risk factors include the use of NSAIDs, including aspirin; *Helicobacter pylori* infection; smoking; and alcohol use. Ninety per cent of duodenal ulcers, and 70% of gastric ulcers, are associated with *H. pylori*, and eradication is integral to treatment. Excess alcohol consumption has doubled the incidence of variceal bleeding over the past 10 years; this condition carries a high mortality that is related to underlying portal hypertension and liver disease/cirrhosis.

Box 22.1 Causes of haematemesis

Common

- duodenal ulcer*
- gastric ulcer
- oesophageal varices*
- Mallory–Weiss tear

Infrequent

- vascular malformations:
 - Dieulafoy lesions
 - gastric antral vascular ectasia (GAVE)
 - angiodysplasia
- upper gastrointestinal cancer oesophagitis*
- gastroduodenal erosions

Rare

- haemobilia
- aortoenteric fistula

* Common with excess alcohol.

Rapid access to specialist care and emergency endoscopy are desirable, although this standard of care is not yet universally available in the United Kingdom. Integrated management by the acute medical and gastroenterology teams is, however, critically important, whatever the local service structure.

Approach to diagnosis

History and examination will often give clues to the underlying cause of bleeding. If possible, be certain that the blood was vomited rather than coughed up. Was it a large or small volume, and was there evidence of volume depletion, such as feeling faint, weak, sweaty, or unwell? The list of medications can identify precipitants (e.g. aspirin, NSAIDs), medications likely to worsen bleeding (e.g. aspirin, warfarin, clopidogrel), and medications that may mask signs of intravascular depletion (e.g. beta blockers).

Examination should ascertain the level of cardiovascular compromise: level of consciousness, breathing, pulse rate, blood pressure, and postural hypotension. It should also include a rectal examination to check for melaena, the presence of which confirms significant UGIH. Signs of chronic liver disease suggest that variceal bleeding is more likely. This can be torrential and life-threatening and therefore enhanced care is appropriate: for example, early referral to gastroenterology, rapid replacement of blood, attention to comorbidity such as sepsis, and intensive nursing care. Nonetheless, peptic ulceration remains a major cause of haemorrhage even in those with portal hypertension, accounting for 20–40% of bleeding episodes.

It is important to remember that the circulating haemoglobin level will not fall after haematemesis until the patient has replaced their lost circulating volume with plasma. Therefore, the first test in the emergency setting may be completely or nearly normal. This should not be regarded as reassuring!

Specific clues to the diagnosis

Establishing that haematemesis has occurred may require endoscopy if non-invasive tests are negative. There is no wholly satisfactory alternative to this, although passage of a nasogastric tube, followed by gastric lavage with a few hundred millilitres of saline, may be helpful in some circumstances. A negative lavage may allow the medical team to search more efficiently elsewhere for the cause of hypotension and anaemia, for instance. Endoscopy also allows a diagnosis to be made of the cause of haematemesis. Clues to the underlying diagnosis are shown in Table 22.1. The advantage of rapid or immediate endoscopy is that it also enables therapy to be administered.

Table 22.1 Causes of upper gastrointestinal haemorrhage

Diagnosis	Symptoms, signs, clues
Peptic ulcer disease	Dyspepsia Smoking/alcohol/caffeine Medications: aspirin, NSAIDs
Varices	Excess alcohol consumption Signs of chronic liver disease or portal hypertension
Mallory–Weiss tears	Vomiting prior to haematemesis
Upper gastrointestinal cancers	Weight loss, dysphagia, early satiety, anaemia, older age (>50 years)
Haemobilia	Recent endoscopic retrograde cholangiopancreatography Gallstones
Aortoenteric fistula	Aortic aneurysm surgery, signs of endovascular infection

Table 22.2 Rockall score								
Variable	Score							
	0	1	2	3				
Age	<60	60–79	>80					
Shock	No shock Systolic BP >100 Pulse <100	Systolic BP >100 Pulse >100	Systolic BP <100					
Comorbidity	None	None	Cardiac failure Ischaemic heart disease Any major comorbidity	Renal failure Liver failure Disseminated malignancy				
Diagnosis	Mallory–Weiss tear No lesion and no SRH	All other diagnoses	Malignancy of GI tract					
Major signs of recent haemorrhage	None or dark spot		Blood in upper GI tract Adherent clot Visible or spurting vessel					
<i>Mortality rates (%) as related to initial Rockall score</i>								
Initial risk score	0	1	2	3	4	5	6	7
Mortality	0.2	2.4	5.6	11	24.6	39.6	48.9	50

Key diagnostic tests

Upper GI endoscopy can be used to diagnose the cause of bleeding and provide therapy for ongoing bleeding. The risk of endoscopy must be weighed against the benefit, especially in the elderly and those with underlying cardiorespiratory disease. As a rule, the patient should have adequate fluid resuscitation with a haemoglobin level above 8 g/dl before endoscopy is attempted. Aspiration of gastric contents including blood can cause life-threatening aspiration pneumonia, and therefore the airway must be adequately safeguarded in all patients, and this may necessitate prophylactic endotracheal intubation and ventilation in some cases.

Other diagnostic tests

Visceral angiography and radionuclide scanning rely on rapid bleeding to identify the source. These are an alternative or adjunct to endoscopy, particularly where the endoscopy has not provided a diagnosis. If angiography is performed, it should be performed in a setting that allows therapeutic intervention, such as embolization of a bleeding vessel.

Introduction to therapy

Immediate therapy includes assessing, protecting, and maintaining the airway, breathing, and circulation; fluid resuscitation; and replacement of blood. Postural hypotension may be the first sign of intravascular depletion. Once the patient's condition has been stabilized and their condition assessed, early upper GI endoscopy should be arranged and performed.

Patients thought to have bleeding varices should immediately receive intravenous terlipressin (a somatostatin analogue) prior to endoscopy. If varices are confirmed at endoscopy, terlipressin should be continued for 72 hours (2 mg four times daily).

Thrombocytopenia and coagulopathy should be corrected where necessary: aim to maintain platelets above 40, and administer 10 mg of vitamin K in addition to fresh frozen plasma where necessary. In portal hypertension due to liver disease it can be impossible to maintain normal coagulation status, which should not be pursued at all cost. Give broad-spectrum antibiotics in people with cirrhosis, as

non-specific bacteraemia is a recognized risk factor for variceal haemorrhage, possibly by increasing portal venous pressure.

PPIs are an important part of the treatment of non-variceal UGIH. PPIs raise the gastric pH, improving platelet function and coagulation. Patients requiring endoscopic therapy for bleeding ulcers should receive a PPI infusion (80 mg stat, then 8 mg/hour for 72 hours). All patients with peptic ulcers should be tested and treated for *H. pylori*.

Prognosis

The risk of death from UGIH is approximately 10%, and most deaths occur in the elderly with more than one medical condition. This reflects the fact that bleeding is usually self-limiting or can be controlled endoscopically and medically. However, depleted physiological reserves and comorbidity mean that an episode of UGIH can be fatal. These observations have been incorporated into a prognostic score that is general use and which allows some prioritization of the use of endoscopy and other resources (see Table 22.2).

The risk of recurrent peptic ulceration can be obviated by appropriate eradication of helicobacter infection, and by the use of acid suppressants in those on aspirin or NSAIDs. The risk of variceal haemorrhage remains high for as long as the underlying disease, such as liver cirrhosis, remains. Mallory–Weiss tears do not generally recur.

How to handle uncertainty in the diagnosis of this symptom

Haematemesis is potentially life-threatening, and early referral to specialist gastroenterology and endoscopy is advisable. A non-typical history in a patient without evidence of cardiovascular compromise allows time to check for a fall in haemoglobin after a period of a few days—if this does not occur, then significant UGIH is unlikely.

23 Acute abdominal pain

Satish Keshav and Alexandra Kent

Definition of the symptom

Acute abdominal pain is pain which is below the chest and above the pelvic brim and which has been present for ≤ 4 weeks. However, typically, patients present within hours of the onset of pain.

Common causes

Acute abdominal pain is a relatively frequent presenting complaint. The diagnosis of irritable bowel syndrome requires that abdominal pain or discomfort be chronic—however, every illness has to start at some point! The differential diagnosis does not differ much in primary and secondary care, although patients in hospital are probably more likely to be prone to iatrogenic illnesses such as pancreatitis, intestinal ischaemia, and *Clostridium difficile*-associated colitis. A list of differential diagnoses is presented in Table 23.1.

Context

Acute abdominal pain can be severe, and prompt patients to seek urgent medical attention. It can also be associated other symptoms that provide clues to diagnosis, such as vomiting, diarrhoea, haematuria, or vaginal discharge. All of these must be taken into account in planning diagnosis and therapy.

Abdominal pain can be separated into three types:

Visceral pain: This originates from the abdominal viscera, which is innervated by autonomic nerves. They respond to distension and contraction. Pain is usually poorly localized, with foregut structures causing upper abdominal pain, midgut structures causing periumbilical pain, and hindgut structures causing lower abdominal pain.

Somatic pain: This corresponds to pain in the parietal peritoneum, which is innervated by somatic nerves. Somatic pain is sharp

Table 23.1 Causes of acute abdominal pain

		Primary care	Secondary care
Common	Gastrointestinal disease	Gastroenteritis and food poisoning Dyspepsia/peptic ulcer disease Cholelithiasis and cholangitis Diverticulitis Pancreatitis Mesenteric adenitis (children) Appendicitis Hepatitis	Gastroenteritis and food poisoning Dyspepsia/peptic ulcer disease Cholelithiasis and cholangitis Diverticulitis Pancreatitis Mesenteric adenitis (children) Appendicitis Hepatitis
	Non-gastroenterological causes	Dysmenorrhoea Polycystic ovary syndrome Endometriosis Pelvic inflammatory disease Urinary tract infection Nephrolithiasis	Dysmenorrhoea Polycystic ovary syndrome Endometriosis Pelvic inflammatory disease Urinary tract infection Nephrolithiasis
Uncommon	Gastrointestinal disease	Intestinal obstruction, e.g. hernia, adhesions Inflammatory bowel disease Peritonitis Mesenteric angina	Intestinal obstruction, e.g. hernia, adhesions Inflammatory bowel disease Peritonitis Mesenteric angina
	Non-gastroenterological causes	Ischaemic heart disease Basal pneumonia Herpes zoster Abdominal cutaneous nerve entrapment syndrome (ACNES) Abdominal aortic aneurysm Diabetic or alcoholic keto-acidosis	Ischaemic heart disease Basal pneumonia Herpes zoster Abdominal cutaneous nerve entrapment syndrome (ACNES) Abdominal aortic aneurysm Diabetic or alcoholic keto-acidosis
Rare	Gastrointestinal disease	Sigmoid or caecal volvulus Liver abscess Intra-abdominal abscess Ischaemic colitis	Sigmoid or caecal volvulus Liver abscess Intra-abdominal abscess Ischaemic colitis
	Non-gastroenterological causes	Ectopic pregnancy Acute porphyria Opiate withdrawal Factitious abdominal pain (can be more common in e.g. children)	Ectopic pregnancy Acute porphyria Opiate withdrawal Factitious abdominal pain (can be more common in e.g. children)

and well localized, and is triggered by irritation, infection, or inflammation.

Referred pain: This is pain perceived in an area (usually a superficial area) which is different from the site of origin. This is thought to be due to the dermatome of the perceived pain arising from the same spinal segment that innervates the underlying abdominal structure.

It can be difficult to differentiate between pain arising from pelvic structures and pain originating from abdominal structures. Therefore, the physician should keep both in mind.

Approach to diagnosis

For information on how to approach the diagnosis, see Figure 23.1 for pain localization.

Specific clues to the diagnosis

A clear history can direct the physician to the underlying cause. Important characteristics include:

Localization and referred location: See Figure 23.1; gallbladder disease is commonly referred to the right shoulder/scapula, whereas splenic or pancreatic pain can be referred to the left shoulder. Pancreatitis, perforated duodenal ulcers, and ruptured aortic aneurysm are classically referred through to the back.

The nature of the pain: Renal and biliary colic are characterized by waves of severe constricting pain, whereas intestinal obstruction usually causes waves of dull pain, and both can be associated with vomiting. Dull colicky pain, which becomes increasingly severe, is common with pancreatitis, mesenteric ischaemia, and strangulated obstructions. Appendicitis characteristically starts with dull, periumbilical pain which localizes to the right iliac fossa when the parietal peritoneum is affected. Tearing severe pain is more in keeping with a ruptured aortic aneurysm.

Recurrent pain: Recurrent pain is more common with diverticulitis, gallstones, renal colic, biliary colic, or gynaecological problems, as these are often recurring problems.

Severity: Severe pain is more common with perforation, peritonitis, mesenteric ischaemia, or pancreatitis.

Onset: A sudden onset of pain is more in keeping with a sudden event, including perforated viscus, renal stone, ruptured aneurysm, ruptured ectopic pregnancy, or testicular or ovarian torsion.

Clinical examination will give important clues to the diagnosis, in particular, the severity of the condition. Serious conditions may be associated with tachycardia, hypotension, pallor, and sepsis. The abdominal examination is essential to check for signs of peritonism (tenderness,

guarding, rebound tenderness, rigidity) or obstruction (absent or tinkling bowel sounds, tympanic percussion note, distension).

Key diagnostic tests

Perforation and ruptured aortic aneurysms are rapidly fatal conditions unless treatment is instituted early. Other serious conditions, including obstruction, pancreatitis, and mesenteric ischaemia, also require rapid diagnoses. CT should be performed early and will be effective at diagnosing these and the majority of other abdominal conditions. Discuss whether or not enteral contrast is indicated or feasible. Intravenous contrast is usually administered. CT scanning has reduced the number of diagnostic laparotomies performed for acute abdominal pain.

Abdominal and pelvic ultrasound may be preferable to CT scanning in many cases—for example, for checking for gallstones, and to reduce the radiation dose in young people and potentially pregnant females. However, pregnancy should not preclude CT scanning in urgent or emergency situations.

Other diagnostic tests

Other diagnostic tests include the following:

Abdominal plain X-rays: These are particularly useful for patients with suspected obstruction (dilated bowel and air–fluid levels), perforation (free air seen under the diaphragm), and acute colitis (thickened bowel wall; check for toxic dilatation).

Urinalysis: This should be performed in all women of childbearing age, to exclude pregnancy (ectopic pregnancy). Renal colic normally causes haematuria. Acute porphyria is associated with urinary porphyrins.

Stool cultures: Stool cultures should be sent for bacterial pathogens, amoebiasis, *C. difficile* toxin, and parasites, ova, and cysts.

Blood tests: A greatly raised amylase or lipase level indicates acute pancreatitis, while upper gastrointestinal disease such as peptic ulcer may be associated with a minor elevation. Patients with acute or chronic pancreatitis may also only have modestly elevated pancreatic enzyme levels. A drop in haemoglobin can confirm a haemorrhagic cause of shock (e.g. ruptured aortic aneurysm, bleeding peptic ulcer).

Ultrasound scan: An ultrasound scan is often a more useful investigation for biliary disease, providing more detail about the biliary tree and presence of gallstones.

Endoscopy: This can aid in the diagnosis of dyspepsia and peptic ulcer disease.

Diagnostic laparoscopy: Diagnostic laparoscopy may be necessary where other tests do not provide a firm diagnosis, and where symptoms persist.

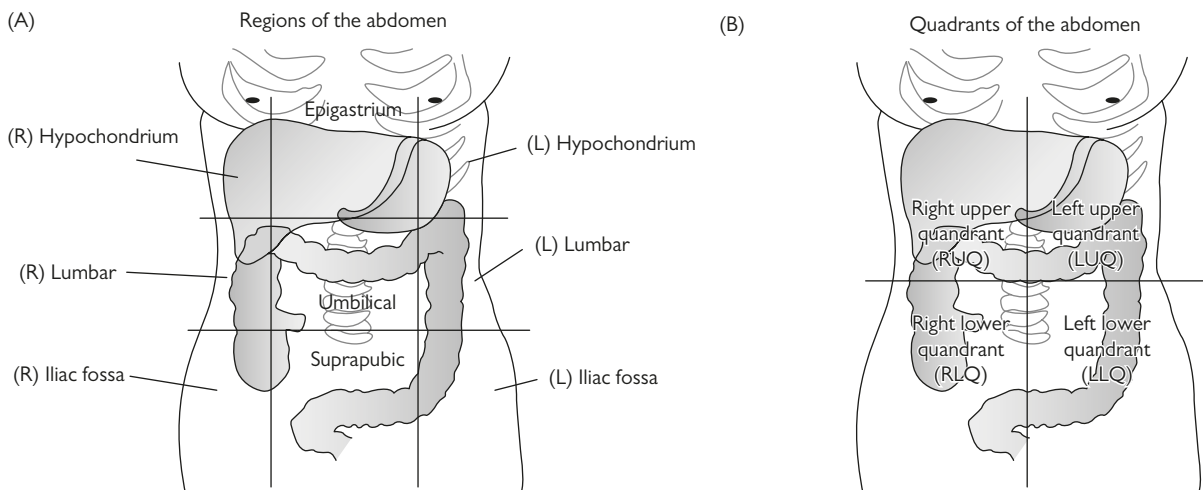

Figure 23.1 Regions and quadrants of the abdomen, and pain localization.

Adapted with permission from Mark Harrison, Revision Notes for the FRCEM Primary, Second Edition, Figure A.4.1, Oxford University Press, Oxford, UK, Copyright © 2017.

Introduction to therapy

Patients presenting with severe acute abdominal pain should be kept nil by mouth and treated with intravenous fluids, analgesics (usually opioids), and antibiotics until the diagnosis is clear, or symptoms resolve. The most serious causes of acute abdominal pain (perforation, peritonitis, obstruction, ruptured aortic aneurysm) will require urgent surgical intervention to remove the cause and repair associated damage. However, many other causes also require surgical care (e.g. appendicitis, ectopic pregnancy, torsion, strangulated herniae), and therefore early surgical referral is prudent. Pancreatitis and hepatitis may require intensive supportive care, and treatment, where possible, for the underlying cause. Dyspepsia and peptic ulcer disease respond to antacids and antisecretory therapy.

Prognosis

Most causes of acute abdominal pain resolve, either spontaneously or with appropriate therapy. Patients are often in severe pain, and terrified of a catastrophic outcome. Adequate analgesia and calm, competent, and urgent professional medical attention are critically important.

How to handle uncertainty in the diagnosis of this symptom

Some causes of acute abdominal pain can be catastrophic, and these should be diagnosed rapidly and treated, or excluded by appropriate testing. Other causes are either self-limiting or will reveal themselves as the illness evolves. For example, shingles may be unapparent initially, and then becomes clear when cutaneous vesicles appear in dermatomal pattern. Similarly, acute abdominal pain caused by biliary colic may occur before elevation in liver enzymes, which may be apparent the next day. Consider at all times that the primary pathology may lie outside the abdomen—especially checking for pneumonia and myocardial ischaemia.

24 Chronic abdominal pain

Satish Keshav and Alexandra Kent

Definition of the symptom

Separating chronic and acute abdominal pain is often difficult, and an arbitrary time limit of 4 weeks is often used. However, many chronic conditions (e.g. chronic pancreatitis) can cause relapsing symptoms, which may be acute during each episode.

Common causes

The common causes of abdominal pain are given in Table 24.1.

Context

The perception of abdominal pain varies between individuals and is influenced by their personality, cultural background, and psychosocial factors. Introspection, awareness of health issues, and stress increase the chance of perceiving abdominal pain as a medical complaint, and the chance of seeking medical attention. Pain receptors in the abdomen respond to chemical and mechanical stimuli. Stretch is the commonest mechanical stimulus to the viscera, although distension, torsion, and contraction are also sensed. Chemical receptors are stimulated by inflammation and infection, and this stimulation leads to the production of various substances, including serotonin, bradykinin, substance P, prostaglandins, and histamine. There are inter-individual differences in pain perception, with some people (e.g. patients with irritable bowel syndrome) being more sensitive to painful stimuli.

Chronic abdominal pain occurs in 9%–15% of all children, and is present on questioning in 75% of adolescents and 50% of adults who are otherwise healthy. It is often a non-specific symptom that alone has a poor sensitivity for organic disease. Usually, it is the associated symptoms, and/or abnormal blood tests, that direct the doctor to a diagnosis.

Approach to diagnosis

It is important to differentiate between organic disease (related to pathological abnormalities) and functional disease (no identifiable cause). Pain relieved by defaecation is a classic symptom of irritable bowel syndrome, and certain symptoms make an organic disease more likely: weight loss; fever; dehydration; electrolyte abnormalities; haemodynamic compromise; gastrointestinal blood loss; malnutrition; and anaemia. A change in bowel habit is useful, although a bowel habit varying between constipation and diarrhoea is more suggestive of functional disease. Patient age is influential, with functional disease more common in young adults. Although the most common diagnoses in older patients are benign (diverticular disease, constipation), the fear of cancer influences many presentations and is an important diagnosis to exclude. Differentiating the overall time course is also useful, separating conditions that cause intermittent/relapsing pain from those that cause constant pain. Furthermore, a long history of pain is unlikely to be related to a neoplastic process.

Specific clues to the diagnosis

Specific clues to the diagnosis are the following:

Medications: It is important to take a clear prescription history, as many medications can be associated with abdominal pain, or conditions associated with abdominal pain. For example, opioid-based medications are commonly associated with constipation; NSAIDs and aspirin are associated with peptic ulcer disease; and bisphosphonates are associated with oesophagitis and oesophageal ulceration. Other medications (e.g. metformin) can directly cause abdominal pain.

Alcohol intake: patients with excessive alcohol consumption are at risk of pancreatitis, peptic ulcer disease, and alcoholic hepatitis, all of which can be associated with abdominal pain. Peptic ulcer disease will often have a characteristic story more in keeping with dyspepsia (see 'Dyspepsia'). Chronic pancreatitis is classically associated with a central persistent abdominal pain, worsened by oral intake, and radiating through to the back. Patients with alcoholic hepatitis usually have a more acute history, jaundice, and associated signs of liver dysfunction (raised liver enzymes, thrombocytopenia, prolonged prothrombin time, etc.).

Site of pain: This can direct the physician to the underlying pathology:

- Right upper quadrant pain can be related to liver, pancreatic, and biliary tract disease.
- Left upper quadrant pain is less common and can be associated with disease of the spleen or colon. Epigastric pain is associated with gastric, pancreatic, or oesophageal disease.
- Right lower quadrant pain can relate to appendiceal, terminal ileal, or colonic disease.
- Left lower quadrant pain is more often associated with diverticular disease or other colonic diseases. Lower abdominal pain can also be caused by pelvic pathology, whereas renal disease usually causes loin pain.

Previous surgery: This can lead to surgical adhesions, placing patients at risk of subacute and acute bowel obstruction.

Background medical history: Patients with risk factors for, or the presence of, vascular disease are at an increased risk of mesenteric ischaemia. It can be associated with pain after eating ('mesenteric angina'), nausea, vomiting, and weight loss. Abdominal migraine more commonly occurs in patients who suffer from classic migraine, although this is not a prerequisite.

Common	Gastrointestinal disease	Dyspepsia Irritable bowel syndrome Cholelithiasis Inflammatory bowel disease (stricturing)
	Non-gastroenterological causes	Pelvic (gynaecological) disease, e.g. fibroids, ovarian cysts (common in primary care but rare in secondary care)
Uncommon	Gastrointestinal disease	Chronic pancreatitis Diverticular disease
	Non-gastroenterological causes	
Rare	Gastrointestinal disease	Lactose intolerance Abdominal migraine Eosinophilic gastroenteritis/colitis Mesenteric ischaemia Abdominal endometriosis
	Non-gastroenterological causes	Familial Mediterranean fever Acute intermittent porphyria Hereditary angioedema Painful rib syndrome

Dyspepsia: Pain related to acid is characteristically described as 'burning', usually in the epigastric region and radiating retrosternally. It is often worse when lying or bending over, and can be precipitated by meals, caffeine, or alcohol. Associated symptoms include acid reflux, water brash, nausea, or vomiting.

Inflammatory bowel disease: Inflammatory bowel disease is associated with diarrhoea, blood per rectum, abdominal mass, raised inflammatory markers, and anaemia.

Constipation: Constipation is associated with infrequent defaecation, incomplete evacuation, and hard stools.

Lactose intolerance: Lactose intolerance is associated with bloating and diarrhoea and is precipitated by dairy products.

Giardiasis: Giardiasis is associated with bloating and diarrhoea.

Pelvic disease: Pelvic disease is associated with pelvic pain, dyspareunia, dysmenorrhoea, menorrhagia, and abnormal vaginal bleeding. Pelvic inflammatory diseases can be associated with vaginal discharge and/or fever.

Hereditary angioedema: Hereditary angioedema is associated with intermittent swelling of the face or throat.

Muscular pain: This is pain that is precipitated by exercise and worsened by physical activity, with tender muscles.

Key diagnostic tests

Simple blood tests are a first-line investigation and can rapidly direct the doctor to the diagnosis, and influence further investigations. These should include a full blood count, haematinics (vitamin B₁₂, folate, ferritin/iron studies), urea, creatinine, electrolytes, liver chemistry, inflammatory markers (C-reactive protein/erythrocyte sedimentation rate), thyroid function, amylase, glucose, calcium, and coeliac serology.

Other diagnostic tests

Young people with chronic abdominal pain and a normal initial screen can often be diagnosed as having a functional disorder. This especially applies to patients who meet the Rome III criteria for irritable bowel syndrome. However, patients ≥ 50 years old almost always require further investigation to exclude a malignant process, since these occur in increasing frequency in these age groups. Associated symptoms will help direct investigations, as they will give clues as to the underlying cause. Additional investigations that should be considered include:

Colonoscopy: This is useful for patients with associated change in bowel habit. It allows direct visualization of the colon to identify abnormal lesions and diverticular disease, and provides the ability to obtain mucosal biopsies.

Gastroscopy: This can be used to visualize the upper gastrointestinal tract, to diagnose oesophageal, gastric, or duodenal inflammation or ulceration. It can also obtain biopsies to diagnose coeliac disease, eosinophilic infiltration, or the presence of *Helicobacter pylori* infection.

Ultrasound scan: This is good for visualizing the biliary tree, and diagnosing gallstones.

CT scan: This will provide clear views of all the intra-abdominal organs and can also be used to diagnose less common conditions, such as surgical adhesions. Often, a pelvic CT will be performed at the same time in order to view the pelvic organs. CT scans can be combined with angiography to visualize the mesenteric circulation and identify arterial narrowing and venous thromboses.

Laparoscopy: This is often reserved for patients with severe pain with signs or symptoms of organic disease. As a diagnostic technique, it is used far more commonly to diagnose gynaecological conditions causing chronic pain. Laparoscopy in abdominal problems is usually reserved for providing treatment, such as laparoscopic cholecystectomy, or laparoscopic fundoplication.

Lactose-hydrogen breath test: A lactose-hydrogen breath test can be performed to diagnose lactose intolerance. It is usually reserved for patients with a clear history of intolerance to dairy products.

Specific conditions: Specific conditions to look for are as follows:

Acute intermittent porphyria is a rare, autosomal dominant condition characterized by a deficiency of the enzyme porphobilinogen deaminase, which is involved in haem synthesis. A deficiency in haem synthesis results in the metabolite porphobilinogen

accumulating in the cytoplasm. Attacks are characterized by abdominal pain, muscle weakness, neuropathies (motor, sensory, autonomic), headaches, and psychiatric symptoms. Seizures can occur. It is diagnosed by elevated urinary porphobilinogen.

Familial Mediterranean fever is an inherited inflammatory disorder which can present with abdominal attacks of pain. Diagnosis is based on characteristic attacks of pain, and genetic testing is now available.

Hereditary angioedema is an autosomal dominant disorder of C1 inhibitor (C1-INH) deficiency. There are three types, with differing complement levels that can aid diagnosis:

Type 1: C1-INH low, C2 low, C4 low, C1q normal

Type 2: C1-INH normal or raised (but dysfunctional), C2 low, C4 low, C1q normal

Type 3: C1-INH normal, C4 normal

Introduction to therapy

Therapy in patients with chronic abdominal pain is varied, depending on the underlying diagnosis. A large number of patients will be diagnosed with functional pain related to irritable bowel syndrome or functional dyspepsia. Amitriptyline or imipramine is frequently effective for treating pain in the absence of an identified physical cause. In organic disease, treatment aimed at the underlying disease should lead to resolution of abdominal pain. Examples of the effect of therapeutic intervention include proton-pump inhibitors in dyspepsia, steroids in inflammatory bowel disease, and laparoscopic dissection of surgical adhesions. Specific treatment of disease is summarized below:

Diverticular disease: high-fibre diet and/or laxatives to avoid constipation; antibiotics for episodes of acute diverticulitis

Dyspepsia: antisecretory therapy (proton-pump inhibitors, H₂ antagonists), dietary adaptations, Nissen's fundoplication

Cholelithiasis: dietary adaptation (avoid fatty food), cholecystectomy

Chronic pancreatitis: analgesics, alcohol abstinence, treatment of exocrine insufficiency with enzyme supplements

Eosinophilic gastroenteritis: corticosteroids, food elimination diet

Mesenteric ischaemia: percutaneous angioplasty, endarterectomy; no effective medical therapy exists

Familial Mediterranean fever: colchicine

acute intermittent porphyria: glucose, analgesics, high-carbohydrate diet, supportive therapy

Hereditary angioedema: supportive therapy during attacks, androgenic agents (danazol, stanozolol), tranexamic acid, C1-INH infusions prior to interventional procedures

Prognosis

Compared to causes of acute abdominal pain, chronic abdominal pain has a lower mortality, but a greater morbidity related to pain, hospital admissions, and time off work. Many conditions are relapsing, associated with severe, and often unpredictable, attacks. Organic diseases, with specific efficacious treatments (gallstones, peptic ulcer disease) have an overall good prognosis, with resolution of pain with appropriate therapy. Functional diseases have the potential to cause far more morbidity, with far less effective treatment, although symptoms are rarely lifelong. It is common for functional symptoms to recur at times of stress and/or concomitant illness.

How to handle uncertainty in the diagnosis of this symptom

The main uncertainty associated with chronic abdominal pain lies in the decision between organic and functional disease. However, pain occurring in isolation is not common, and associated symptoms can aid diagnosis and investigation choice. Generally, a full blood screen and abdominal CT will exclude the majority of conditions. The unusual diagnoses, such as acute intermittent porphyria or familial Mediterranean fever, present with characteristic attacks and are unlikely to be the cause in a patient presenting with abdominal pain alone. If there are no associated symptoms, and blood and imaging tests are normal, then a functional disorder is the most likely diagnosis.

25 Dyspepsia

Satish Keshav and Alexandra Kent

Definition of the symptom

Dyspepsia is a term encompassing several symptoms of the upper gastrointestinal (GI) tract, including acid reflux, heartburn, nausea, vomiting, and abdominal pain or discomfort.

Common causes

The majority of patients presenting to their GP with dyspepsia will be suffering with gastro-oesophageal reflux disease (GORD) and will respond to a course of antisecretory therapy (proton-pump inhibitors (PPI) or H₂ antagonists). Of those who are referred onto secondary care and then subsequently undergo endoscopy, the cause is GORD (40%), functional or non-ulcer dyspepsia (40%), peptic ulcer disease (13%), or upper GI cancer (3%). Ten per cent of the population will have a hiatus hernia; this is a condition where a defect in the diaphragm allows part of the stomach to move into the chest. It can cause weakness in the lower oesophageal sphincter and be associated with GORD. However, many patients with a hiatus hernia do not suffer with dyspepsia. Functional dyspepsia is a condition characterized by dyspepsia symptoms, with no endoscopic evidence of acid damage, and normal oesophageal pH studies. It is thought to be due to oesophageal hypersensitivity and, as such, is usually poorly responsive to acid-related therapies.

Context

Up to 40% of the population suffer with dyspepsia; 5%–10% will consult their GP, and 1% will undergo endoscopic assessment. Over-the-counter medications cost patients £100 million annually, and prescribed drugs cost the NHS over £463 million annually. There is a steady rise in incidence with increasing age. *Helicobacter pylori* is present in 40% of the UK population, with many individuals acquiring the infection in childhood and remaining asymptomatic. It has been associated with peptic ulcer disease and distal gastric cancer.

Approach to diagnosis

A clear history should be taken, to identify the following alarm symptoms and factors contributing to symptoms:

Alarm symptoms: progressive weight loss, GI bleeding, iron deficiency anaemia, dysphagia, persistent vomiting, or an epigastric mass

Medications: NSAIDs, antiplatelet agents, bisphosphonates, nitrates, calcium channel antagonists, theophyllines, and steroids

Lifestyle: obesity, alcohol, coffee, chocolate, and fatty foods have all been associated with acid reflux

Psychological disorders: patients with functional dyspepsia are more likely to have psychological disorders

Specific clues to the diagnosis

Alarm symptoms have a poor positive predictive value for diagnosing upper GI cancer, but should still instigate an urgent referral. Patients with persistent symptoms despite PPI therapy will usually have functional dyspepsia, although this assumption should not be made in older patients.

Key diagnostic tests

H. pylori tests

H. pylori can be assessed by serology, faecal antigen test, or C-urea breath tests.

Endoscopy

Endoscopy should be reserved for those with alarm symptoms or suspicious radiological investigations. However, patients over 55 years with persistent symptoms, previous gastric ulcer or surgery, a family history of gastric cancer, a continuing need for NSAIDs, or pernicious anaemia should also be referred for endoscopic assessment.

There is no evidence for endoscopic screening for Barrett's oesophagus in patients with dyspepsia, as the absolute risk of adenocarcinoma is less than 1 in 1000. Furthermore, 40% of patients with Barrett's-associated adenocarcinoma are asymptomatic.

Other diagnostic tests

Oesophageal pH studies can identify between patients with pathological acid exposure and those with functional dyspepsia. This investigation involves placement of a pH probe 5 cm above the lower oesophageal sphincter. This can be achieved either by placement of a naso-oesophageal probe or a wireless capsule (less readily available). This procedure is usually reserved for patients with typical symptoms of GORD but who are failing to respond to a trial of PPI; those contemplating anti-reflux surgery; or patients with persistent GORD symptoms after anti-reflux surgery. Multichannel intra-luminal impedance is a newer oesophageal investigation which measures electrical resistance within the oesophagus, and can provide information regarding bolus transport within the oesophagus. When combined with a pH study, it can identify acid and non-acid reflux episodes.

Introduction to therapy

Lifestyle measures, such as weight loss, reduced alcohol intake, and smoking cessation, are integral to treatment. Raising the head of the bed may reduce nocturnal acid reflux. Dyspepsia is invariably a relapsing remitting condition. Medications used for dyspepsia include:

Antacids/alginate: These contain calcium carbonate, aluminium, or magnesium, and work by neutralizing gastric acid and inhibiting the proteolytic enzyme pepsin. They can relieve the symptoms of dyspepsia, although there is no evidence that they can heal peptic ulcers.

PPIs: These block the hydrogen-potassium pump in the gastric lining, and can relieve symptoms and promote ulcer healing.

H₂ antagonists: These block the histamine H₂ receptors in the gastric mucosa, reducing acid secretion, relieving symptoms, and promoting ulcer healing.

Misoprostol: This is a synthetic prostaglandin analogue, reducing acid secretion and promoting ulcer healing.

Initial treatment for dyspepsia should be test and treat for *H. pylori* and/or empirical PPI treatment for 1 month. PPI can be continued at the lowest dose necessary to control symptoms. Those unresponsive to PPI should be offered H₂ antagonists or prokinetic therapy. The only curative treatments are *H. pylori* eradication and anti-reflux surgery. The most common surgical procedure is a Nissen's fundoplication, which is usually performed laparoscopically. However, long-term outcomes from surgically and medically treated patients are not statistically different.

Functional dyspepsia can be harder to treat, and is usually poorly responsive to acid-blocking therapy. Psychological therapies have shown a modest, but short-lived response. Some patients respond to tricyclic antidepressants such as amitriptyline, although there is little evidence to support this treatment strategy.

Prognosis

Persistent acid exposure in the oesophageal can lead to the development of columnar-lined epithelium (Barrett's oesophagus). This is more common in patients with a history of reflux, and is seen in 1.4% of endoscopies. The main concern with Barrett's oesophagus is the association with adenocarcinoma, developing in 1% of patients. Consequently, patients diagnosed with Barrett's oesophagus should undergo endoscopic screening, based upon the degree of dysplasia seen in the columnar cells.

How to handle uncertainty in the diagnosis of this symptom

The vast majority of patients with dyspepsia have benign disease, especially given the low incidence rates of oesophageal and gastric cancer. Despite this, a large number of patients undergo potentially unnecessary upper GI endoscopy due to persistent symptoms. In young patients, it is worthwhile giving a 2-month course of high-dose PPI prior to initiating investigations, as this will significantly increase the healing rate of peptic ulcers.

26 Abdominal mass

Satish Keshav and Alexandra Kent

Definition of the symptom

Abdominal mass describes a visible or palpable swelling which is located in the abdomen and is abnormal. It may arise from one of the internal organs, such as an enlarged liver or spleen, or from musculo-skeletal structures such as a floating rib; alternatively, it may be a hernia containing mesenteric or visceral tissue.

Common causes

Abdominal mass is an uncommon presenting complaint, except where patients notice a hernia. Frequently, the herniation is intermittent or minor, and can be missed on examination. Organomegaly and neoplastic masses can be hard to detect until they are large, and the question of whether or not there really is a mass frequently has to be settled by imaging such as ultrasound or CT scanning. A list of potential diagnoses is shown in Table 26.1.

Context

The significance of an abdominal mass depends to a great extent on the context in which it is discovered—for example, did the patient notice a swelling and become consumed with a fear of cancer? Reassurance may be all that is required. Is cosmetic appearance critically important? If so, even a benign lesion may need to be assessed for potential correction. Was the discovery incidental? Or might it be related to a pathological process that has led to the examination? For example, in a patient with long-standing fatigue and mildly deranged liver tests, splenomegaly may indicate portal hypertension and cirrhosis, and may prompt a liver biopsy to establish the diagnosis.

Approach to diagnosis

There are several features of a palpable mass that can help develop a differential diagnosis:

- Where is the mass?
- What is the relationship of the mass to surrounding abdominal structures?
- Is the mass tethered to the skin or underlying structures, or is it freely mobile? (A fixed mass suggests a malignant or inflammatory process.)

Common	Hernia: femoral, inguinal, umbilical, epigastric Lipoma Faecal loading in constipation Pregnancy Aneurysmal dilation of the aorta Uterine leiomyoma Obstructed urinary bladder
Uncommon	Hepatomegaly Splenomegaly Enlarged kidney: e.g. hydronephrosis, polycystic kidney Intra-abdominal lymphoma Abscess: diverticular, appendix, hepatic, Crohn's disease Pancreatic pseudocyst Abdominal and pelvic tumours
Rare	Unusual tumours such as sarcomas Exostoses and healed fractures

- What is the consistency (hard, firm, soft)? (A hard liver mass is possibly indicative of cancer; a firm liver mass is possibly indicative of cirrhosis; a soft liver mass is possibly a lipoma.)
- Is the mass tender? (This is typical of inflammation.)
- Is the mass pulsating? Could this be an aneurysm?
- Has the mass developed slowly or quickly? (Tumours will develop more gradually, whereas infection or inflammation can develop quickly.)
- Is the mass present all the time, or is it intermittent? (Hollow organs can fill and empty.)
- Are there associated symptoms such as weight loss, change in bowel habit, jaundice, and so on?

Specific clues to the diagnosis

The site and nature of the abdominal mass can give huge clues as to the underlying cause:

- Abdominal aortic aneurysm:* a pulsating mass around the umbilicus
- Colon cancer:* a mass anywhere in the abdomen
- Crohn's disease:* a tender mass anywhere in the abdomen; associated raised inflammatory markers (C-reactive protein (CRP), erythrocyte sedimentation rate (ESR))
- Diverticular abscesses:* tender masses, classically located in the left lower quadrant
- Gallbladder cancer or cholangiocarcinoma:* a moderately tender, irregularly shaped right upper quadrant mass
- Gastric cancer:* causes a mass in the left upper abdomen in the stomach area (epigastric) if large
- Hepatic cancer:* hard irregular mass or hepatomegaly in the right upper quadrant
- Hepatomegaly:* a mass which is located in the right costal margin and epigastric area and moves down on inspiration
- Hydronephrosis:* a smooth, spongy-feeling ballotable mass in one or both flanks
- Ovarian cysts or cancer:* cause often smooth masses above the pelvis in the lower abdomen, arising from either side
- Pancreatic abscess or pseudocyst:* causes irregular masses in the upper abdomen in the epigastric area
- Renal cancer:* occasionally causes smooth, firm, non-tender, ballotable abdominal masses, in the flanks
- Splenomegaly:* palpated in the left upper quadrant, with the organ moving down on inspiration
- Uterine leiomyoma (fibroids):* can cause a round, lumpy mass above the pelvis in the lower abdomen
- Urinary retention:* a firm, often tender, mass in the suprapubic area; in extreme cases, it can extend as far up to the umbilicus
- Volvulus:* can cause a mass anywhere in the abdomen

Key diagnostic tests

If the history and examination do not identify the cause unequivocally, then ultrasound scanning and CT scanning are the key tests. Solid tumours may require percutaneous or laparoscopic biopsy.

Other diagnostic tests

Other imaging studies, such as magnetic resonance scanning, can provide valuable information, particularly for hepatobiliary and pancreatic masses. The presence of gastric or colonic masses may necessitate upper endoscopy or colonoscopy, respectively. Similarly, masses in the liver may necessitate endoscopic or laparoscopic investigation of

the gastrointestinal and genito-urinary tract to search for a primary source of metastasis or infection. Blood tests may give information about underlying organ function or disease states. For example, a raised white-cell count would be consistent with an abscess, and CRP and the ESR will be raised in infective and inflammatory processes. Tumour markers have poor sensitivity and specificity for diagnosing tumours, although, for instance, a highly elevated CA19-9 antigen or S100 antigen would favour the diagnosis of pancreatic and ovarian tumours, respectively. Carcinoembryonic antigen (CEA), for colorectal cancer, and alpha-fetoprotein (AFP), for hepatocellular cancer, are similarly useful to indicate the direction for further investigation.

Introduction to therapy

When organomegaly is due to systemic disease such as infection or tumour, the approach is clearly different to that taken when the mass itself is a problem. Making a clear and definite diagnosis is key to reassuring patients and allowing a reasonable dialogue about the risks and benefits of surgery, for example. The dialogue should include a discussion of the risk of failure from hernia repair, and the relative risk of strangulation and other complications of hernia. For some masses, watchful waiting is the appropriate strategy. This is true, for example, for small aortic aneurysms, lymphadenopathy of uncertain significance, and solid tumours when it is unclear if they are benign or malignant.

Prognosis

Given the long list of differential diagnoses, the majority of patients with an abdominal mass will have a benign cause, and prognosis. Those with underlying neoplasm have a worse prognosis, because palpable neoplastic masses are more likely to be more advanced.

How to handle uncertainty in the diagnosis of this symptom

Thorough investigation of a mass that might signify serious underlying pathology is critical. A reasonable approach when there remains doubt is to identify the most likely diagnoses which merit treatment and which, if untreated, could cause morbidity or mortality. Once these have been systematically explored and excluded, watchful waiting may be offered.

27 Constipation

Satish Keshav and Alexandra Kent

Definition of the symptom

Patients and doctors often define constipation differently. The normal frequency of defaecation is once every 3 days to three times per day, and constipation may be defined as abnormally infrequent defaecation. In addition, patients may describe hard stools, the need to strain at stool, a sense of blocked defaecation, the need to digitally or otherwise assist defaecation, or a sense of incomplete evacuation. A change in the normal pattern and frequency for the particular patient is pertinent.

Causes of constipation

There are numerous causes of constipation, and most can be encountered in both primary and secondary care. More abstruse diagnoses are more likely to be made after investigations in secondary care. Potential causes, grouped under headings, are shown in Table 27.1. Patients seen in secondary care will have causes that are similar to those of patients seen in primary care, but are usually referred when they become resistant to routine treatment or there is a need to exclude underlying pathology. Many cases are referred in order to alleviate patients' fears of an underlying cancer.

Common	Diet related	Low fibre intake Low fluid intake Low food intake Constipation is often due to changes in normal dietary habits
	Drug related	Opioids Iron supplements Anticholinergics Psychotropics
	Constitutive	Slow-transit constipation Old age
	Functional	Stress-related (usually transient) Irritable bowel syndrome (constipation predominant or mixed)
	Neurological	Parkinson's disease Stroke
	Endocrine disease	Hypothyroidism Hyperparathyroidism
Uncommon	Primary intestinal disease	Colorectal cancer Benign colonic stricture Ileus (post-operative, severe illness, electrolyte disturbance)
	Neurological	Spinal cord injury Multiple sclerosis
	Electrolyte disturbance	Hypercalcaemia Hypokalaemia Hypomagnesaemia
Rare	Primary intestinal disease	Volvulus Chronic idiopathic pseudo-obstruction (CIPO; Ogilvie's syndrome) Pelvic floor dysfunction Anorectal obstruction due to rectocele or intussusception

In patients with chronic constipation without an evident cause, irritable bowel syndrome (IBS) is the cause in 59%, pelvic floor dysfunction in 25%, slow transit in 13%, and a combination of pelvic floor dysfunction and slow transit in 3%.

Context

One UK survey found that 8.5% of women defined themselves as being constipated, and 8.2% had constipation meeting the Rome III criteria for IBS (see Chapter 205 for criteria). A larger survey (1892 adults) found that 39% of men and 52% of women reported straining at stool on over a quarter of occasions. Constipation affects twice as many women as men, with a higher prevalence in pregnant women. Prevalence is also greater in the elderly, affecting ~20% in the community.

Approach to diagnosis

A careful history is necessary to check diet, drugs, comorbidity, and symptoms that give clues as to a potential underlying cause for constipation. It is important to assess what each patient considers to be their normal bowel habit, and the effect of any change on their quality of life. Most patients feel that the effectiveness of laxatives declines with time. This is particularly true for stimulant laxatives such as senna.

Specific clues to the diagnosis

Specific clues to the diagnosis are as follows:

Colonic tumour: weight loss, rectal bleeding, tenesmus, iron deficiency anaemia, positive faecal occult blood

Volvulus: acute onset, abdominal pain

IBS: bloating, abdominal cramps, intermittent diarrhoea

Neurological causes: symptoms and signs of underlying disease

Drug-related causes: opiates, anticholinergics, antipsychotics, iron supplements

Hypothyroidism: weight gain, fatigue, cold intolerance, brittle hair, dry skin, myalgia, arthritis

Pelvic floor dysfunction: having undergone vaginal delivery, being multiparous, digital evacuation of stool, difficulty with evacuation

Key diagnostic tests

The key diagnostic test varies depending on the circumstances. Colonic transit studies help to confirm that evacuation is delayed and, in the acute setting, an abdominal X-ray may demonstrate faecal loading of the colon. Examination of the perineum, anus, and rectum to check for local disease, including excessive descent of the perineum associated with pelvic floor dysfunction, is too often omitted. Patients frequently present because they or their medical attendants are concerned about the possibility of colorectal cancer. This can be settled by optical or virtual (CT) colonoscopy. A study in patients undergoing colonoscopy to investigate constipation revealed cancers in 1.4%, and large or advanced adenomatous polyps in 4.3%.

Other diagnostic tests

Other diagnostic tests are:

Screening blood tests: These include thyroid function, biochemical profile, and fasting glucose.

Rectal manometry and special studies to delineate functioning of the pelvic floor: In these tests, a probe is passed into the rectum and

measures the strength of the anal sphincters during various retention and defaecation manoeuvres. A balloon is passed and blown up with increasing volumes of air while the patient's resulting sensations are assessed. This can give information about the rectum's sensitivity during defaecation, and the patient's response.

Introduction to therapy

Apart from the rare circumstance of being able to correct an underlying cause for constipation, therapy is aimed at optimizing diet, reducing factors that cause constipation, and offering laxatives, which are usually highly effective.

Diet may need to be assessed by a qualified dietician to ensure that the optimal amount of fluid and fibre is ingested. Too much insoluble fibre can worsen rather than ameliorate the symptom. Various laxatives are available. Patients often prefer what they see as gentle, natural remedies, such as cracked linseed and syrup of fig, which are good sources of soluble fibre. Osmotic laxatives such as polyethylene glycol and lactulose are highly effective, and do not wane in efficacy over time. Lactulose tends to aggravate bloating and flatulence. Stimulant laxatives such as glycerol suppositories, bisacodyl, and senna are also highly effective in the short term. Stool softeners such as docusate sodium are useful for patients complaining of hard, painful stool. Enemas such as phosphate and mineral oil may be helpful in the acute setting.

Obstructed defaecation due to dysfunction of the pelvic floor may require reconstructive surgery, although biofeedback therapy may also be effective in milder cases. In this therapy, patients are taught to retrain their muscles for defaecation, and trials have shown a response in up to 80% of patients compared to a response to laxatives in 21% of patients.

Prognosis

Constipation due to underlying organic disease often resolves with treatment for the underlying condition. The majority of patients will respond to dietary changes and laxatives. Constipation due to IBS or pelvic floor dysfunction can be more difficult to treat, and patients will often adapt their diet and laxative use to suit themselves. In extreme cases, patients may undergo a subtotal colectomy for relief of symptoms.

How to handle uncertainty in the diagnosis of this symptom

The main uncertainty is approaching a patient with constipation is in deciding how intensively symptoms should be investigated. Often, there is a long history, and investigations provide little that affects management. Fear of cancer is often present, and should be addressed. If the risk is low, for instance, in a young person with near normal and unchanged bowel habits, then appropriate reassurance, rather than inappropriate testing, should be offered. Generally, any person who is over 50 years of age and presenting with a change in bowel habit should undergo investigations to exclude an underlying colorectal cancer.

28 Acute diarrhoea

Satish Keshav and Alexandra Kent

Definition of the symptom

Acute diarrhoea is the abrupt onset of a change in bowel habit, with the passage of an unusually high volume of stool (greater than the normal of 200 ml per day), and/or increased bowel frequency of bowel opening (greater than the normal of up to three times per day).

The main causes of diarrhoea and infectious diarrhoea

Table 28.1 outlines the main causes of diarrhoea, and Table 28.2 outlines the main causes of infectious diarrhoea. In the UK, acute infectious diarrhoea is most commonly viral in aetiology; *Campylobacter jejuni* is the commonest bacterial pathogen.

Context

Infectious diarrhoea is the commonest cause of acute diarrhoea worldwide, responsible for 3 million deaths per year in children under 5 years in the developing world, mainly due to dehydration. In England, 20% of adults suffer an intestinal infection each year. The majority of infections will cause a benign, self-limiting illness. The overall incidence of infectious diarrhoea appears to be reducing, although under-reporting may bias numbers.

Diarrhoea can be caused by two different mechanisms:

1. impaired fluid, electrolyte, and/or nutrient absorption: this can be due to impaired epithelial transport, impaired water and sodium transport in the colon, incompletely absorbed nutrients (e.g. lactose intolerance), or increased transit time
2. increased intestinal secretion of fluid and nutrients: this is mainly caused by secretory enterotoxins

Often, these two processes coexist.

Approach to diagnosis

The most important factor in diagnosing the cause of diarrhoea is a thorough history, detailing contact history, travel, food/dietary history, medications, recent antibiotics, associated symptoms (fever, vomiting, weight loss), and risk factors, including extremes of age or immunosuppression. Physical examination is often unhelpful in ascertaining a cause, but is important to assess the state of hydration and general well-being.

Common	Infectious diarrhoea Drug-induced, e.g. laxatives, antacids Diverticulitis Antibiotic-associated diarrhoea Toxicogenic <i>Clostridium difficile</i> infection
Uncommon	Inflammatory bowel disease
Rare	First presentation of coeliac disease Pancreatic insufficiency Endocrinopathy, including carcinoid syndrome Acute abdomen, e.g. appendicitis, intussusception Chemotherapy/radiation-induced enteritis Ingestion of toxins, e.g. copper, tin, daffodils, mistletoe

Bacteria	Viruses	Parasites
Diarrhoeagenic <i>Escherichia coli</i> <i>Campylobacter jejuni</i> <i>Vibrio cholerae</i> O1 <i>Vibrio cholerae</i> O139* <i>Shigella</i> spp. <i>Vibrio parahaemolyticus</i> <i>Bacteroides fragilis</i> <i>Campylobacter coli</i> <i>Campylobacter upsaliensis</i> Non-typhoidal <i>Salmonellae</i> <i>Clostridium difficile</i> <i>Yersinia enterocolitica</i> <i>Yersinia pseudotuberculosis</i>	Rotavirus Norovirus (calicivirus) Adenovirus (Serotype 40/41) Astrovirus Cytomegalovirus*	Protozoans ● <i>Cryptosporidium parvum</i> ● <i>Giardia intestinalis</i> ● <i>Microsporidia</i> * ● <i>Entamoeba histolytica</i> ● <i>Isospora belli</i> * ● <i>Cyclospora cayetanensis</i> ● <i>Dientamoeba fragilis</i> ● <i>Blastocystis hominis</i> Helminths ● <i>Strongyloides stercoralis</i> ● <i>Angiostrongylus costaricensis</i> ● <i>Schistosoma mansoni</i> ● <i>Schistosoma japonicum</i>

* These agents are no longer reported in the Indian subcontinent.

Data from Farthing M, Salam MA, Lindberg G, Dite P, Khalif I, Salazar-Lindo E, et al. Acute diarrhea in adults and children: a global perspective. *J Clin Gastroenterol* 2013; 47: 12–20.

Specific clues to the diagnosis

Infectious diarrhoea will often be accompanied by systemic symptoms such as fever, nausea, vomiting, and abdominal pain. The following factors can help narrow down the identity of the infectious agent:

Travel: Enterotoxigenic *Escherichia coli* is the leading cause of traveller's diarrhoea, although *Rotavirus* spp., *Shigella* spp., *Salmonella* spp., and *Campylobacter* spp. are prevalent worldwide and should be considered in any returning traveller. The highest risk area is Africa, followed by Central and South America and Eastern Europe. North America and Europe have had documented major outbreaks of giardiasis and cryptosporidiosis, following contamination of water supplies.

Food contamination: Ingestion of undercooked or contaminated food is a common etiological factor. Contaminated meat often contains *Clostridium perfringens*, *Campylobacter* sp., *Salmonella* sp., or enterohaemorrhagic *E. coli* (EHEC), whereas dairy products are associated with *Campylobacter* and *Salmonella*, and eggs are associated with *Salmonella*. Seafood often contains *Vibrio* spp., astroviruses, or *Plesiomonas shigelloides*.

Animal exposure: Cats and dogs are associated with carriage of *Campylobacter* spp.

Water exposure: Swimming in seawater, freshwater, or swimming pools is also a risk factor for intestinal infection, and *Giardia* spp., *Cryptosporidium* spp., and *Entamoeba* spp. are resistant to water chlorination.

Institutions: Some organisms, including rotaviruses, *Campylobacter* spp., *Shigella* spp., *Giardia* spp., astroviruses, caliciviruses, and *Cryptosporidium* spp., will spread quickly in institutions.

Further factors which can aid diagnosis

Infectious diarrhoea will often present with a very acute onset, compared to inflammatory bowel disease or diverticular disease, which

usually have a longer onset of symptoms, and are thus discussed in Chapter 29. Further factors which can aid diagnosis are:

Associated symptoms: Diverticulitis is often accompanied by abdominal pain (which is often left-sided) and fever.

Nutritional depletion: Patients with inflammatory bowel disease may present complaining of acute diarrhoea, but other factors, such as anaemia, weight loss, and hypoalbuminaemia, may indicate a more chronic disease.

Key diagnostic tests

Infection is the commonest cause of acute diarrhoea, and so stool microscopy and culture should be the first-line investigation. Enteroinvasive bacteria will cause leucocytes to be shed into the stool. Different culture mediums are required to isolate bacteria and, subsequently, the microbiologist should be provided with any helpful medical history, such as contact or exposure. A diagnosis of *C. difficile* requires detection of Toxin A via an enzyme-linked immunosorbent assay.

Other diagnostic tests

Rotavirus and adenovirus antigens can be detected by enzyme immunoassay, although the false-negative rate for rotaviruses approaches 50%. The stool anion gap can be calculated in order to differentiate between osmotic and secretory diarrhoea, with levels >100 mOsm/kg being consistent with osmotic diarrhoea. The false-positive rate of stool microscopy and culture means that at least three stool samples should be examined. An abdominal X-ray should be performed in patients who are unwell, to exclude perforation, to assess the extent of colitis, and for toxic dilatation. In patients with persistent symptoms and negative stool examinations, a lower gastrointestinal (GI) endoscopy examination can be performed to obtain mucosal biopsies, although these are more useful when performed in the first 72 hours of infection.

Introduction to therapy

Fluid replacement

Fluid and electrolyte replacement is the cornerstone of therapy. Glucose-based oral rehydration solutions are extremely effective, taking advantage of the active carrier-mediated sodium–glucose co-transport. The ideal solution should have a low osmolarity (210–250 mmol/l) and a sodium content of 50–60 mmol/l. This means that the majority of commercially available drinks are far less suitable as rehydration agents. In more extreme cases, intravenous fluids can be given and will usually reverse any metabolic acidosis associated with the illness.

Antibiotics

The use of antibiotics in GI infections is controversial. In infections that are improving with conservative therapy, antibiotics will often

be avoided. Antibiotic therapy should be considered for patients with immunosuppression, malignancy, or cardiac disease; with valvular, vascular, or orthopaedic prostheses; or at the extremes of age. Antibiotics are indicated in shigellosis, *V. cholerae* infections, pseudomembranous enterocolitis, and parasitic infection. However, they should be considered in cases of persistent yersinia infections and early in the course of campylobacter, aeromonas, and plesiomonas infections. Antibiotic therapy, in general, reduces the severity and length of symptoms.

Probiotics

The evidence for the use of probiotics is limited. They have been shown to shorten the length of rotavirus illnesses and bacterial illnesses in children by 1 day.

Antidiarrhoeal therapy

The use of anti-motility agents (usually loperamide) is contentious, associated with fears of increasing the risk of toxic dilatation and increasing the faecal carriage of enteropathogens. Studies have usually used loperamide in combination with antibiotic therapy with some success, and few doctors would be prepared to treat infective diarrhoea with loperamide alone. New antisecretory agents are in development.

Prognosis

The majority of patient will recover from acute diarrhoeal illnesses with no long-term complications. However, it is well recognized that GI infections can precipitate irritable bowel syndrome. *Yersinia enterocolitica* and *C. jejuni* have been associated with Reiter's syndrome, which may present with painful swollen joints. *C. jejuni* infection is the commonest cause of Guillain-Barré syndrome. Haemolytic uraemic syndrome is an important although uncommon complication of shigellosis and EHEC infection.

How to handle uncertainty in the diagnosis of this symptom

Infectious diarrhoea will often have signs or symptoms of underlying infection (fever, leucocytosis, raised inflammatory markers), and a combination of stool samples and mucosal biopsies will often pinpoint a pathogen. In patients with worsening symptoms, empirical antibiotics can be given after liaison with the local microbiologist. However, the majority of patients will improve with conservative therapy.

29 Chronic diarrhoea

Satish Keshav and Alexandra Kent

Definition of the symptom

Diarrhoea is defined as the passage of more than three stools per day or a stool weight >400 g/day, and duration ≥4 weeks is regarded as chronic.

Differential diagnosis

The list of possible causes of chronic diarrhoea is long, and likely to be incomplete as many rare conditions may present unusually with diarrhoea as part of the symptom complex (Table 29.1). The key to the diagnostic process is to consider the context in which the presentation occurs, and the most likely causes. Colorectal cancer rarely presents only with diarrhoea, although this is frequently the diagnosis which is most feared and the one which might prompt attendance in primary and secondary care. Most patients will be referred to secondary care for investigations, but their ongoing care will be provided by the GP.

Context

Four to five per cent of the Western population suffers from diarrhoea, with irritable bowel syndrome (IBS) being the commonest cause in 20–40 year-old patients. It is the commonest reason for referral to secondary care gastroenterology clinics. In the absence of

rectal bleeding, loss of weight, or abnormal blood tests, it is unlikely to be due to a serious illness.

Approach to diagnosis

The patient's age helps in deciding the direction of investigation. Patients who are ≥50 years old should undergo colonic imaging to check for colorectal cancer. Although colorectal cancer is unlikely to present with diarrhoea only, this is an anxiety for patients and referrers and, with the likely introduction of colorectal cancer screening in asymptomatic adults over the age of 50 years, it seems prudent to screen those who have symptoms.

The history will give clues to the likely diagnosis. It is important to compare current symptoms to what the patient considers to be their usual bowel habit. Specific triggers should be sought; commencing new medications, recent surgery, travel, food poisoning or infection, and stress should all be checked. The help of a dietician examining the patient's food diary can be invaluable in identifying excessive or inadequate fibre intake, excessive caffeine, and potential dietary triggers such as lactose or gluten.

Examination should include the perineum, anus, and rectum, checking for evidence of inflammatory bowel disease; constipation and faecal impaction with paradoxical diarrhoea; and corroborative evidence of diarrhoea with excoriation of the perianal skin. Is the patient malnourished or dehydrated? Is there evidence of hyperthyroidism?

Specific clues to the diagnosis

Specific clues to the diagnosis are as follows:

Weight loss/rectal bleeding: These are alarm symptoms irrespective of the patient's age, necessitating urgent investigations due to their association with inflammatory bowel disease and colorectal cancer.

Previous surgery: Bowel resection can lead to diarrhoea due to reduced water absorption (colonic resection), bile salt or fat malabsorption (terminal ileal resection), decreased transit time, or small bowel bacterial overgrowth. Ten per cent of patients develop diarrhoea post cholecystectomy.

Systemic disease: Multiple diseases can be associated with diarrhoea, through various mechanisms. Such diseases include diabetes, thyrotoxicosis, vasculitis, scleroderma, hypoparathyroidism, Addison's disease, and amyloidosis.

Pancreatic disease: Diarrhoea in a patient with a history of excess alcohol consumption or pancreatitis may be due to pancreatic exocrine insufficiency, and resultant fat malabsorption.

Recent travel: Giardiasis is more common following travel to the USA or Eastern Europe, whereas amoebiasis is endemic to western and southern Africa, South Asia, South America, and Mexico.

Family history: There is a strong familial association recognized in colorectal cancer, inflammatory bowel disease, and coeliac disease.

Medication history: Four per cent of cases are drug related, and symptoms may develop some weeks or months after commencing new medications.

Key diagnostic tests

The key test in this diagnosis rests entirely on the context. IBS accounts for the majority of presentations, and it is helpful to be able to make this clinical diagnosis confidently and positively without recourse to excessive testing that can serve to heighten anxiety and reaffirm the patient's suspicion that 'they still can't find what is wrong'. In other contexts, it is critically important to check for inflammatory bowel disease or colorectal cancer, and here either colonic

Common	Irritable bowel syndrome Post-infectious irritable bowel syndrome Diet related: excessive fruit, non-digestible carbohydrate sweeteners, excessive caffeine intake Iatrogenic drug related: e.g. proton-pump inhibitors, metformin, antibiotics Coeliac disease Microscopic colitis Diverticular disease Giardiasis
Uncommon	Inflammatory bowel disease Lactose intolerance Pancreatic insufficiency Small bowel bacterial overgrowth Chronic infection, e.g. cryptosporidiosis, microsporidiosis, parasitic worm infestation (especially in immunocompromised) Autonomic neuropathy (e.g. diabetes mellitus, alcohol, uraemia, amyloid) Colonic or ileal resection Bile acid malabsorption Post-cholecystectomy diarrhoea Endocrine disease (e.g. hyperthyroidism, Addison's disease, hypoparathyroidism)
Rare	Factitious diarrhoea and laxative abuse Colorectal cancer (rarely presents with diarrhoea) Villous adenoma of the colon Ischaemic colitis Hormone-secreting tumours (e.g. carcinoid, VIPoma, gastrinoma) Villous adenoma of the colon Factitious diarrhoea and laxative abuse Fabry's disease

imaging or colonoscopy and biopsy are the key tests. Coeliac disease and thyrotoxicosis frequently present with diarrhoea. In both cases, the key test can be performed on a blood sample, with no need for colonoscopy, although many physicians consider it necessary to confirm the diagnosis of coeliac disease with duodenal biopsy.

Other diagnostic tests

Other diagnostic tests are as follows:

Faecal fat levels: Steatorrhoea can be confirmed from a 3-day stool collection or on spot stool samples, although further tests are required to determine the underlying cause.

Faecal elastase levels: Pancreatic insufficiency can be diagnosed by the finding of reduced faecal elastase levels.

SeHCAT nuclear medicine scan: Bile salt malabsorption can be diagnosed with this test, which checks for reduced retention of an exogenously administered labelled bile acid.

Glucose or lactulose hydrogen breath tests: These test for small bowel bacterial overgrowth.

Gut hormone levels: This test requires a fasting blood sample and tests for levels of gastrin, vasoactive intestinal peptide, pancreatic polypeptide, glucagon, and neurotensin. For accurate gastrin levels, H₂ antagonists should be stopped 24 hours prior to the test, and proton-pump inhibitors stopped 6 days prior to the test.

Barium follow-through/MRI small bowel: This can identify small bowel diverticula, entero-enteric fistulae, or terminal ileal disease.

Enteroscopy: This is not often required; it is usually reserved for identifying small bowel lesions seen on radiological examination.

Urinary 5-hydroxyindoleacetic acid: This is raised in patients with carcinoid syndrome.

Lactose hydrogen breath test: This can be used to diagnose lactose intolerance.

Introduction to therapy

Therapy is dictated by the underlying diagnosis, and dealt with in the appropriate section. Symptomatic relief of diarrhoea can be readily achieved using loperamide, diphenoxylate, or codeine phosphate. Codeine is best avoided because of its sedating and potentially addictive properties. Loperamide is well tolerated and can be used in the long term if needed. Table 29.2 gives a summary of treatment strategies for each condition. Advice from a dietician can be extremely helpful for patients requiring dietary modification in IBS, and for those with coeliac disease and therefore needing to follow a strict gluten-free diet.

Prognosis

Organic causes of diarrhoea usually respond to therapy, while IBS can be harder to treat. Patients often learn to cope with their symptoms,

Table 29.2 Treatment of diarrhoeal conditions

Condition	Treatment options
Inflammatory bowel disease	5-ASA, steroids, immunosuppression, anti-TNF α therapy
Coeliac disease	Gluten-free diet
Irritable bowel syndrome	Dietary modification, optimized fibre intake, antidiarrhoeals
Diverticular disease	High fibre diet, colonic resection
Giardia, amoebiasis	Antibiotics
Microscopic colitis	Budesonide, bismuth, 5-ASA
Post-cholecystectomy syndrome	Cholestyramine, loperamide
Bile acid malabsorption	Cholestyramine
Pancreatic insufficiency	Pancreatic enzyme supplements
Bacterial overgrowth	Antibiotics
Vasculitis	Steroids, immunosuppression
Hormone-secreting tumours	Resection, octreotide, chemotherapy

Abbreviations: 5-ASA, 5-aminosalicylic acid; TNF α , tumour necrosis factor alpha.

using loperamide and other antidiarrhoeals to maintain social and professional lives.

How to handle uncertainty in the diagnosis of this symptom

Care should be taken not to over-investigate patients with IBS. However, patients with continuing weight loss, anaemia, or persistently raised inflammatory markers may require intensive investigation, and referral to specialist and tertiary care. Changes from microscopic colitis and inflammatory bowel disease can be patchy, and systemic inflammatory conditions can remit spontaneously temporarily, so that repeated investigation may be necessary when the first tests are normal. In difficult cases, in-hospital assessment of diarrhoea may be necessary to quantify stool volume and to determine if diarrhoea is dependent on oral intake or not. Secretory diarrhoea due to endocrinopathy and secretory tumours of the bowel continues even when the patient does not eat or drink, while diarrhoea due to malabsorption or inflammation tends to be improved when oral intake ceases.

30 Rectal bleeding

Satish Keshav and Alexandra Kent

Definition of the symptom

Rectal bleeding (haematochezia) refers to the passage of bright red blood per rectum.

Differential diagnosis

The differential diagnosis of rectal bleeding, ordered by probability, is shown in Table 30.1.

Context

Rectal bleeding is a common symptom, affecting all age groups, with the highest incidence in the sixth and seventh decades and associated with a higher mortality and morbidity with increasing age. Epidemiological studies have shown rectal bleeding to occur in nearly 1% of hospital admissions. Bleeding stops spontaneously in 80% of cases, although rebleeding occurs in 25%. The majority of patients will present to their general practitioner and will be referred to colorectal or gastroenterology outpatient clinics. Massive lower gastrointestinal (GI) bleeding is a medical emergency.

Approach to diagnosis

The initial approach to patient care should be assessment of their haemodynamic stability, including vital signs. The most important diagnosis to be excluded is colorectal cancer, especially in older (>50 years) patients. Associated GI symptoms may narrow the differential diagnosis (weight loss, abdominal pain), although many causes of bleeding may be otherwise asymptomatic (angiodysplasia, polyps). A concise history and examination should significantly narrow the differential diagnosis.

Specific clues to the diagnosis

Clues to the diagnosis of rectal bleeding are given in Table 30.2.

Key diagnostic tests

Endoscopic evaluation by flexible sigmoidoscopy or colonoscopy is the key test and allows biopsies to be taken from abnormal lesions. Bleeding lesions can be treated endoscopically by sclerotherapy or cauterization; in these instances, biopsies are usually deferred until active bleeding has settled. Brisk lower GI bleeding usually precludes effective endoscopy and treatment, and CT scanning with or without angiography may be necessary in the acute situation. In elderly patients in whom rectal bleeding is not causing haemodynamic

Common	Infrequent	Rare
Haemorrhoids (affects 4% of the population)	Inflammatory bowel disease	Radiation proctitis
Anal fissure	Fistula-in-ano	Ischaemic colitis
Diverticular disease	Arteriovenous malformations/angiodysplasia	Solitary rectal ulcer
Neoplasia (distal colorectal cancer, polyps)	Massive upper gastrointestinal bleed	

Note: In ~10% of cases, the cause of bleeding is not found.

Table 30.2 Clues to the diagnosis of rectal bleeding

Diagnosis	Comorbidities and background	Symptoms and signs
Diverticular disease	Diverticulitis	Left iliac fossa pain, constipation
Inflammatory bowel disease	Family history	Diarrhoea, abdominal pain, fatigue, weight loss, extra-intestinal manifestations
Neoplasia	Family history, smoker	Weight loss, constipation, change in bowel habit
Arteriovenous malformations/angiodysplasia	Aortic stenosis	Asymptomatic
Ischaemic colitis	Ischaemic heart disease, peripheral vascular disease, diabetes, hypertension, hyperlipidaemia	Severe abdominal pain, bloody diarrhoea
Radiation proctitis	Previous pelvic radiotherapy	–
Solitary rectal ulcer		Constipation, straining, mucus per rectum
Haemorrhoids	Constipation	Pruritus ani, mucus, palpable lump
Anal fissure	Constipation	Pain on defaecation
Fistula-in-ano	Previous anorectal abscess, inflammatory bowel disease	Visible fistula, perianal discharge, pain, swelling
Upper gastrointestinal bleed	Recent NSAID/aspirin use, excess alcohol	Haematemesis, dyspepsia

compromise, a CT scan may be preferable, to identify possible causes (e.g. diverticular disease) or exclude serious pathologies (e.g. malignancy).

Other diagnostic tests

Brisk bleeding may obscure endoscopic views. Diagnostic tests can usually be deferred until bleeding has settled and patients have received pre-endoscopic bowel purgatives. In cases where bleeding is torrential with associated haemodynamic compromise, mesenteric angiography may identify the bleeding site, and allow embolization of the responsible vessel.

Each patient should be assessed individually; many patients presenting with lower GI bleeding are elderly and/or frail, and endoscopy may be difficult. In such cases, radiological imaging (abdominal CT, barium enema) may exclude diagnoses such as neoplasia or diverticular disease, with more invasive tests avoided unless bleeding persists.

Introduction to therapy

The stability of the patient and rate of bleeding dictate the initial approach to patient care, with restoration of intravascular volume

being the most important objective. Patients require surgery more often when bleeding is due to a lower GI source than when it is due to an upper GI source, and patients requiring ≥ 4 units of blood in the first 24 hours have a 50% chance of requiring surgery.

Specific therapeutic options are as follows:

Haemorrhoids: stool softeners, high-fibre diet, band ligation, local injection

Solitary rectal ulcer: endoscopic treatment of active bleeding ulcer using endoscopic adrenaline injection or cauterization

Diverticular disease: The majority of cases will stop bleeding spontaneously; some centres advocate endoscopic adrenaline injection, although endoscopic therapy does incur a higher risk of colonic perforation. Persistent bleeding usually leads to surgical resection.

Arteriovenous malformation: usually endoscopically cauterized using argon plasma coagulation

Radiation proctitis: Bleeding points can be treated endoscopically using argon plasma coagulation. Other rectal therapies, including steroids, 5-aminosalicylic acid (5-ASA), or sucralfate, are less effective.

Inflammatory bowel disease and colorectal cancer: see Chapters 203 and 204, respectively.

Prognosis

Rectal bleeding is a common symptom and as such has a poor positive predictive value for diagnoses such as colorectal cancer. The majority of patients will have a benign diagnosis.

How to handle uncertainty in the diagnosis of this symptom

Since rectal bleeding is associated with colorectal cancer, all patients age ≥ 50 years, or < 50 years and without an obvious cause for bleeding, should have a test to exclude colon cancer. In patients with normal investigations and stable haemoglobin, rectal bleeding is usually due to local anorectal causes, which may not require further treatment.

31 Jaundice

Satish Keshav and Alexandra Kent

Definition of the symptom

Jaundice, also known as icterus, is the yellowish discolouration seen in skin, mucous membranes, and sclerae when the plasma bilirubin concentration is $>40 \mu\text{mol/l}$.

Differential diagnosis

The differential diagnosis of jaundice, ordered by probability, is shown in Table 31.1.

Context

As erythrocytes are destroyed, haemoglobin is broken down, releasing haem, which is further broken down to produce bilirubin. This bilirubin, referred to as 'free', 'indirect', or 'unconjugated', binds to albumin and is transported to the liver, where it is conjugated with glucuronic acid and becomes water soluble. It is then excreted in the bile into the small intestine. In the colon, it is metabolized by bacteria to urobilinogen and then stercobilinogen, and is subsequently oxidized to stercobilin. Stercobilin gives stool its brown colour. A small amount of urobilinogen is absorbed from the intestine and excreted in the urine, giving urine its yellow colour. Eighty per cent of bilirubin comes from haemoglobin, and the remainder comes from breakdown of other iron-containing proteins, such as myoglobin and cytochromes.

Jaundice may arise from increased production of bilirubin, for instance, in haemolysis; from reduced conjugation of bilirubin in the liver, as in Gilbert's syndrome; or from reduced excretion of bilirubin via bile, as in intra-hepatic cholestasis. Jaundice also occurs when the flow of bile is obstructed, for instance, by gallstones. In these cases, hepatic function might not be impaired profoundly, although, again, the disease process causing biliary obstruction, such as malignancy, may be advanced by the time jaundice is apparent.

Approach to diagnosis

The initial approach is to determine if the jaundice is pre-hepatic, intra-hepatic, or post-hepatic.

Pre-hepatic jaundice

Causes of pre-hepatic jaundice include conditions such as sickle cell anaemia, spherocytosis, glucose-6-phosphate dehydrogenase deficiency, and haemolytic uraemic syndrome, which associated with an increased rate of haemolysis and thus lead to an increased production of unconjugated bilirubin. Serum bilirubin will be unconjugated and, since unconjugated bilirubin is not water soluble, there will be no bilirubin in the urine.

Table 31.1 Causes of jaundice

Common	Infrequent	Rare
Gilbert's syndrome	Hepatic metastases from cancer	Inherited disorders of bilirubin metabolism
Drug-induced jaundice	Pancreatic cancer	Cholangiocarcinoma
Viral hepatitis	Haemolysis	Pancreatic cysts/pseudocysts
Alcoholic hepatitis/alcoholic liver disease		
Cirrhosis of the liver		
Cholelithiasis		

Hepatic jaundice

Conditions leading to a reduction in the capacity of the liver to metabolize and excrete bilirubin cause hepatic jaundice. All causes of acute hepatitis can cause hepatic jaundice in which bilirubin is usually conjugated. Inherited conditions that affect bilirubin metabolism include Gilbert's syndrome, and Types I and II Crigler-Najjar syndrome, in which reduced levels, or a total lack, of glucuronosyltransferase causes unconjugated hyperbilirubinaemia, and Dubin-Johnson and Rotor syndromes, which are caused by defective bilirubin excretion, with conjugated hyperbilirubinaemia.

Post-hepatic jaundice

Post-hepatic jaundice is also known as obstructive jaundice, as it is caused by a blockage within the biliary system, resulting in failure of biliary drainage. The blockage prevents bile from being excreted into the gastrointestinal tract, and the stool subsequently becomes pale. Urine darkens due to the excess bilirubin being excreted into the urine. Causes of post-hepatic jaundice include gallstones, pancreatic tumours, pancreatic cysts, cholangiocarcinomas, and, in neonates, biliary atresia.

Hepatic impairment

It is important to determine the extent of hepatic impairment associated with jaundice by measuring serum transaminases, prothrombin time, and albumin, and by checking clinically for evidence of hepatic dysfunction. This can vary from virtually none, for example, in Gilbert's syndrome or massive haemolysis, to fulminant liver failure in other instances. Management is very much guided by the degree by the degree of hepatic impairment.

Specific clues to the diagnosis

As described in 'Context', changes in urine and stool colour can be used to predict whether hyperbilirubinaemia is pre- or post-conjugation: unconjugated bilirubin is not water soluble and therefore the bilirubin will pass into the GI tract, and the urine will not change colour; in contrast, conjugated bilirubin is water soluble, and the excess bilirubin passes into the urine as it cannot drain out of the liver, so stool becomes paler, and urine darker. The following factors also give clues as to the underlying diagnosis:

Pain: Impacted gallstones causing biliary obstruction will be associated with biliary colic and classically right upper quadrant abdominal pain.

Alcohol intake: This suggests liver injury and raises the possibility of more chronic liver damage and cirrhosis.

Weight loss: Pancreatic tumours classically present as painless obstructive jaundice, and may well have associated symptoms such as weight loss and cachexia.

Viral symptoms: The viral illnesses which most commonly cause acute jaundice are hepatitis A and infectious mononucleosis (glandular fever). Hepatitis A often presents with fever, fatigue, diarrhoea, anorexia, nausea, and abdominal pain. Glandular fever presents with fatigue, sore throat, fever, arthralgia, and lymphadenopathy. Many other viruses can cause jaundice, including the hepatitis B virus, the hepatitis E virus, cytomegalovirus, and so on.

Medications: The commonest causes of drug-induced hepatitis are co-amoxiclav, flucloxacillin, chlorpromazine, and drugs used for antituberculosis therapy. Any recent changes to medications should be noted, as liver derangement is a common side effect.

Key diagnostic tests

With respect to liver chemistry, classically, the alkaline phosphatase and gamma-glutamyl transferase levels are elevated in post-hepatic (obstructive) causes of jaundice, whereas the transaminases are elevated in hepatic causes. Acute cholelithiasis and cholangitis can, however, be associated with markedly raised transaminases.

The most important test to perform is an ultrasound scan of the biliary tract, to determine if there is biliary obstruction. Ultrasonography can diagnose biliary obstruction, gallstones, pancreatic masses, biliary tree dilatation, and liver echogenicity.

Prothrombin time and albumin concentration provide a measure of hepatic synthetic function, which is particularly important in acute jaundice where there is concern about liver failure.

Other diagnostic tests

The following blood tests may give further information regarding the cause of jaundice:

Unconjugated and conjugated bilirubin: This test can ascertain whether the rise in bilirubin occurs before or after conjugation in the liver.

Tests for haemolysis: Haemolysis can be confirmed from a blood film, a reticulocyte count, haptoglobin levels, the lactate dehydrogenase test, and/or the Coombs test.

Viral serology: Hepatitis A IgM is positive in acute hepatitis A (IgG is not diagnostic). Infectious mononucleosis is diagnosed by the presence of Epstein–Barr virus IgM, or the heterophile antibody test (the monospot test). Infectious mononucleosis may also be associated with thrombocytopenia, raised transaminases, and a raised erythrocyte sedimentation rate.

If an ultrasound is inconclusive, magnetic resonance cholangiopancreatography (MRCP) can provide clear views of the biliary tree, and is safer than endoscopic retrograde cholangiopancreatography (ERCP). However, ERCP may be required to allow removal of obstructing stones, or relief of a stricture by stenting, and to aid diagnosis by obtaining biopsies or biliary brushings.

Introduction to therapy

Treatment of jaundice is dependent on the underlying cause. ERCP involves passing an endoscope into the duodenum and intubating the sphincter of Oddi; the test is used to identify the site and cause of obstruction, and potentially to relieve it by removal, stenting, and, or sphincterotomy. Treatment of pancreatic cancer and

cholangiocarcinoma will be decided by a multidisciplinary team, including oncologists and gastroenterologists.

Non-obstructive jaundice requires treatment aimed at the underlying disease. Viral illnesses are usually self-limiting. Treatment of drug-induced jaundice depends on the causative medication. The majority of drug-induced jaundice require removal of the offending agent and close monitoring for signs of liver failure. Alcoholic liver disease and alcoholic hepatitis require supportive treatment with laxatives, nutrition, and an investigation into underlying precipitant of decompensation (e.g. toxins, infection, constipation, GI bleed).

Prognosis

The prognosis is as follows:

- The overall prognosis of a patient with jaundice depends on the underlying disease process.
- Patients with obstructive jaundice from gallstones usually respond well to ERCP treatment, with further episodes being prevented by a cholecystectomy.
- The presence of ascending cholangitis worsens the prognosis, but the early institution of antibiotics can resolve sepsis.
- The elderly, and patients with cardiovascular disease, always have a poorer prognosis from cases of obstructive jaundice.
- Pancreatic and cholangiocarcinoma have an overall poor prognosis.
- Viral causes of jaundice usually recover with conservative treatment.
- Drug-induced jaundice, if caught late, can be fatal due to the associated liver failure.

How to handle uncertainty in the diagnosis of this symptom

The most important diagnosis to exclude is obstructive jaundice, as patients can rapidly deteriorate due to associated ascending cholangitis. In the setting of fever and obstructive jaundice, it is safer to advocate early antibiotics if ascending cholangitis is a possible diagnosis. A combination of blood tests and radiological investigations usually provides a clear diagnosis, and the commonest cause in patients with no additional symptoms or signs is Gilbert's syndrome.

32 Ascites

Ehoud Shmueli

Definition of the symptom

Ascites is the accumulation of fluid within the peritoneal cavity.

Differential diagnosis

The differential diagnosis of a swollen abdomen includes obesity, large bowel obstruction, and huge liver, ovarian, or mesenteric cysts. Differentiation from ascites is by physical examination and imaging. Most patients with ascites usually have a known diagnosis of cirrhosis, malignancy, or heart failure.

Context

For patients newly presenting with ascites, the diagnostic problem is usually to differentiate between cirrhosis and malignancy. For patients with established liver disease, ascites represents a deterioration of their liver function, the development of a hepatocellular carcinoma, or another complication. Worsening of preexisting ascites may be due to spontaneous bacterial peritonitis. In malignancy, ascites denotes the development of peritoneal deposits or massive liver metastases.

Approach to diagnosis

The diagnosis may be obvious from the context, but can be confirmed with imaging and a diagnostic paracentesis. The serum–ascites albumin gradient (SAAG; [ascitic fluid albumin] – [serum albumin]) reflects portal pressure, and is the key diagnostic test. A SAAG >11 g/l indicates portal hypertension, and therefore probably cirrhosis. A SAAG <11 g/l excludes portal hypertension, and therefore the ascites is not caused by cirrhosis. The SAAG can be determined almost immediately and will guide further investigation.

The causes of ascites according to the SAAG

The causes of ascites are shown in Tables 32.1 and 32.2.

Key diagnostic tests

Diagnostic paracentesis

In obvious ascites, this should not wait for the ultrasound scan. Severe thrombocytopenia and impaired clotting are only relative contraindications. Bleeding is a rare complication of paracentesis. Patients with an international normalized ratio greater than 2.0 can receive fresh frozen plasma prior to the procedure, although it is not clear that this is absolutely necessary. Patients with a platelet count lower than $20 \times 10^3/\mu\text{l}$ should receive an infusion of platelets before the procedure.

Ascitic fluid should routinely be analysed as shown in Tables 32.3, 32.4, and 32.5

Imaging

Abdominal ultrasound is usually the first imaging to confirm the diagnosis, image the liver, and determine patency of the portal vein. CT scanning of chest–abdomen–pelvis should follow a finding of a low SAAG.

Laparoscopy

If, in a low-SAAG ascites, CT scanning and cytology fail to provide a diagnosis, a diagnostic laparoscopy will be the next step. Typical findings are tuberculous or malignant peritoneal deposits.

Table 32.1 High serum–ascites albumin gradient (11 g/l or greater, denoting portal hypertension)

Cause	Comment
Cirrhosis (about 80% of patients)	Stigmata of chronic liver disease Clear yellow fluid Albumin concentration usually <10 g/l Protein concentration is <25 g/l
Alcoholic hepatitis	Recent alcohol intake of 10 units or more per day Jaundice Hepatomegaly—often tender Moderately raised alanine aminotransferase Neutrophilia
Spontaneous bacterial peritonitis	Should be considered in any patient with advanced cirrhosis who deteriorates from any cause The fluid may or may not look cloudy The neutrophil count in ascitic fluid is >250/mm ³ The protein concentration is <10 g/l
Budd–Chiari syndrome	Acute liver failure and ascites in the context of myeloproliferative disease, hypercoagulable states, or hepatocellular carcinoma Diagnosis is by imaging
Portal vein thrombosis	Can complicate cirrhosis In the absence of liver disease, consider pancreatic pathology, myeloproliferative disorders, hypercoagulable states, and abdominal sepsis or surgery
Cardiac failure	Including severe tricuspid regurgitation, and constrictive peritonitis Total ascites protein concentration is usually >25 g/l, which helps differentiate it from cirrhosis
Massive liver metastases	Usually obvious on abdominal ultrasound

Other diagnostic tests

Tests for levels of CA19-9, carcinoembryonic antigen, and alpha-fetoprotein may be useful if the primary malignancy is not obvious. A CA-125 test should not be requested, as it is always high in ascites, regardless of the cause. In high-SAAG ascites, serology for the hepatitis B and C viruses, an autoantibody screen, and iron studies should be requested.

Introduction to therapy

Ascites with portal hypertension

Patients with alcoholic cirrhosis are often also fond of salt. They can improve dramatically with abstinence from alcohol, and with salt restriction. The latter involves three instructions to patients:

- avoid adding salt in cooking or before eating
- avoid obviously salty foods, such as crisps, salted nuts, and some cheeses
- avoid or take care with pre-prepared or 'fast foods'

Failure to comply with salt restriction is a frequent cause of 'diuretic failure'

Most patients require diuretic therapy starting with 100 mg spironolactone and 40 mg furosemide per day. The doses can be

Table 32.2 Low serum–ascites albumin gradient (<11 g/l denoting normal portal pressure)

Cause	Comment
Peritoneal deposits	From ovary, breast, colon, lung, pancreas, or liver, and occasionally mesothelioma CT may be normal Overall cytology is positive in 50%–100%, but usually negative in mesothelioma The neutrophil count in ascitic fluid may be >250/mm ³ , but there is a predominance of lymphocytes in the total white-cell count Spontaneous bacterial peritonitis is rare in malignant ascites, but secondary bacterial peritonitis from perforation should be considered in the context of fever and pain
Peritoneal tuberculosis	Abdominal pain and ascites developing over several months About one-third of patients may have signs of old TB on a chest X-ray The majority of patients have an ascitic white-cell count of 150–4000 mm ³ , with a lymphocytic predominance Diagnosis usually requires laparoscopy and biopsy of the white peritoneal deposits
Nephrotic syndrome	Peripheral oedema usually dominates the picture Proteinuria greater than 3.0–3.5 g in 24 hours, or spot urine protein:creatinine ratio of >300–350 mg/mmol
Pancreatitis	Protein concentration is usually >30 g/l, and there is a high amylase concentration often >1000 IU/l
Meigs syndrome	Benign solid ovarian tumour associated with ascites and pleural effusion that disappear after tumour removal
Chylous ascites	Disruption of the lymphatic system Ascitic triglycerides should be >2.26 mmol/l, or twice serum levels

titrated upwards to a maximum of 400 mg spironolactone and 160 mg furosemide per day. Amiloride 10–40 mg can be substituted for spironolactone if gynaecomastia is a problem but it is less effective.

There is no limit to the daily weight loss of patients who have significant oedema. Once the oedema has resolved, 0.5 kg is probably a reasonable daily maximum.

NSAIDs, beta blockers, angiotensin-converting-enzyme inhibitors, and angiotensin receptor II blockers can all impair the effectiveness of diuretic treatment in ascites by reducing renal perfusion and function. Hyponatraemia (<120 mmol/l), a rising creatinine, or encephalopathy are indications for stopping diuretic therapy and using large-volume paracentesis.

At large volume, paracentesis human albumin solution (HAS) is usually infused to prevent hypovolaemia, although the necessity for this remains controversial. Approximately 8 g of albumin are infused per litre of ascites drained (100 ml of 20% HAS contains 20 g of albumin).

Transjugular intra-hepatic portosystemic shunt (TIPS) is used to decompress the portal circulation in patients who require frequent large-volume paracentesis. Hepatic encephalopathy, portal vein

Table 32.3 Appearance

Clear or straw-coloured	Uncomplicated ascites; deeply jaundiced patients will have a darker coloured ascites
Cloudy	Infection
Milky	Chylous ascites
Bloody	Traumatic tap causes a heterogeneously bloody specimen Malignancy causes a homogeneously bloody specimen

Table 32.4 Biochemistry

SAAG*	SAAG reflects portal pressure >11 g/l = portal hypertension <11 g/l = no portal hypertension
Protein	<10 g/l is a risk for spontaneous bacterial peritonitis >10 g/l with more than 250/mm ³ neutrophils should prompt suspicion of bowel perforation >25 g/l and an SAAG of >11 g/l suggests heart failure
Glucose (not required routinely)	A low glucose occurs with malignancy An undetectable glucose may occur with bowel perforation
Ascitic fluid:serum LDH ratio (not required routinely)	<0.4 in uncomplicated cirrhotic ascites Approaches 1.0 in spontaneous bacterial peritonitis May be greater than 1.0 in perforation or malignancy
Amylase (not required routinely)	High, often >1000 IU/ml in pancreatic ascites

Abbreviations: SAAG, serum–ascites albumin gradient; LDH, lactate dehydrogenase.
*SAAG = [ascitic fluid albumin] – [serum albumin].

thrombosis, and heart failure are contraindications to TIPS. Hepatic encephalopathy occurs in up to 30% of patients who receive a TIPS; hence, it is used mostly as a last resort and usually in younger patients with less severe liver dysfunction and who are thus less likely to become encephalopathic.

Ascites from peritoneal carcinomatosis

This is treated with repeated large-volume paracentesis. Unlike the case for patients with ascites due to portal hypertension, in patients with peritoneal carcinomatosis, large volumes of fluid can be removed without fear of haemodynamic problems, and HAS infusion is not required. Diuretics do not work unless there is also portal hypertension from hepatic metastases.

Prognosis

This depends on the cause but, in general, malignancy-associated ascites carries a prognosis of 1–4 months. Patients who develop ascites as a complication of cirrhosis have a 50% 2-year mortality. However, patients with alcoholic cirrhosis who stop drinking can do surprisingly well.

How to handle uncertainty in the diagnosis

The diagnosis of newly presenting ascites is often unclear. The stigmata of liver disease can be subtle, an alcoholic history may be hidden, malignancy may not be apparent on CT, and the admitting

Table 32.5 Microbiology and pathology

Cell count	>500 WBCs or >250 neutrophils/mm ³ suggests infection. A predominance of lymphocytes suggests TB or malignancy
Gram stain	Rarely positive
Culture (not required routinely)	A repeat sample of 20 ml ascitic fluid in blood culture bottles (10 ml/bottle) before antibiotics are stated gives the best chance of obtaining a culture
Cytology (not required routinely)	If malignancy is suspected, send 50 ml

Abbreviations: WBC, white blood cell.

clinician may have forgotten to request an ascitic albumin concentration. A high Ca-125 can lead clinicians in the wrong direction. The SAAG is the key test. A high-SAAG ascites will usually indicate cirrhosis. A low-SAAG ascites most commonly indicates a malignancy.

About 5% of patients may have a combination of causes for the ascites, such as cirrhosis plus malignancy or tuberculosis, and it is important to be open to that possibility.

Pericleous M, Sarnowski A, Moore A, Fijten R, and Zaman M. The clinical management of abdominal ascites, spontaneous bacterial peritonitis and hepatorenal syndrome: a review of current guidelines and recommendations. *Eur J Gastroenterol Hepatol* 2016; 28: e10–18.

33 Chylous ascites

Ehoud Shmueli

Definition of the symptom

Chylous ascites is ascites that has a cloudy or milky appearance due to a high level of triglycerides (>2.26 mmol/l).

The causes of chylous ascites

The causes of chylous ascites are given in Table 33.1.

Cause	Comment
Cirrhosis	Due to rupture of serosal lymphatics spontaneously or due to hepatocellular carcinoma; SAAG > 11 mg/l
Neoplastic: lymphoma, and any malignancy disrupting the lymphatics	The diagnosis may be obvious from the history; SAAG < 11 mg/l
Complex surgery or trauma: involving the retroperitoneum, e.g. abdominal aortic aneurism repair or retroperitoneal node dissection	Lymphatic disruption during surgery or following trauma causes chylous ascites in the first post-operative week; chylous ascites occurring weeks/months after surgery is due to adhesions or other extrinsic lymphatic compression
Congenital: yellow nail syndrome; primary lymphatic hypoplasia, or hyperplasia; intestinal lymphangiectasia	The most common cause in children
Infection: Tuberculosis, filariasis	The most common cause in developing countries
Inflammatory causes: Radiotherapy, pancreatitis, retroperitoneal fibrosis	Causing fibrosis of the lymphatics
Right heart failure, constrictive pericarditis	Impaired drainage of lymph; SAAG > 11 mg/l
Nephrotic syndrome	Unknown pathogenesis
HIV associated	Kaposi's sarcoma, mycobacterium avium intracellulare

Abbreviations: SAAG, serum–ascites albumin gradient.

Context

Chylous ascites is very rare and is due to disruption of the lymphatic system. The cause may be clear from the history; in developed countries, the differential rests between cirrhosis and malignancy, especially lymphoma. In developing countries, tuberculosis or filariasis is more likely.

Key diagnostic tests

Check triglycerides (should be >2.26 mmol/l, or twice serum levels) and exclude infection. Lymphocytes should predominate; neutrophils indicate infection. Request culture, cytology, and albumin concentration. The serum–ascites albumin gradient (SAAG) is calculated as follows: SAAG = [ascitic fluid albumin] – [serum albumin]. A SAAG >11 g/l indicates portal hypertension. A SAAG <11 g/l indicates that there is no portal hypertension. Low-SAAG chylous ascites should be investigated by CT scanning for tumour and, if necessary, laparoscopy for tumour, tubercle deposits, or lymphatic leaks. Lymphangiography and lymphoscintigraphy can detect abnormal retroperitoneal nodes, leakage from dilated lymphatics, fistulization, and patency of the thoracic duct.

Treatment

Treatment is directed to the cause. Cirrhosis is treated in the usual way. In malignancy, repeated large-volume paracentesis may be necessary. A high-protein low-fat diet with orlistat (a lipase inhibitor) reduces chyle flow by restricting long-chain triglyceride availability to the intestinal lymph ducts. If malnourished, add medium-chain triglycerides that are absorbed and transported directly to the liver via the portal vein, avoiding the lymphatics. Avoid medium-chain triglycerides in severe cirrhosis, as they precipitate hepatic encephalopathy. Somatostatin or analogues with a low-fat diet or total parenteral nutrition close lymphatic leaks following surgery and relieve symptoms in malignancy.

34 Swelling in the neck

John Newell-Price, Alia Munir, and Miguel Debono

Definition of the symptom

Swelling in the neck is defined as the presence of a swelling in or around the neck; this swelling can involve any structure within this anatomical region. A number of conditions may present with a swelling or lump in the neck. A detailed history and examination, defining the site of the swelling is paramount in reaching a diagnosis.

The differential diagnosis

Table 34.1 and Box 34.1 outline the differential diagnosis, ordered by probability.

Context

The commonest cause of neck swelling is enlarged lymph nodes secondary to infection, of which non-specific infection is most common (followed by infectious mononucleosis, TB, syphilis, toxoplasmosis, and cat scratch fever). But the second most common cause is secondary metastatic deposits, then lymphoproliferative diseases, and sarcoid. Even when only one lymph node is palpable, the adjacent nodes are invariably diseased.

Approach to diagnosis

History

To determine **generalized** aetiology, ask about malaise, weight loss, fever, rigours, infectious disease, and travel history to indicate an infective cause.

To determine **local** causes, ask about pain in the mouth, sore throats, ulcers, nasal discharge, blockage of the airway, problems swallowing, changes in voice, difficulty breathing, and skin lesions.

In non-specific **inflammatory lymphadenopathy**, recurrent bouts of tonsillitis are common. The majority of patients are young; age <10 years, pyrexia, anorexia, and a painful lump are common. Typically, lymph nodes may be tender and hot, and firm but not fixed.

With **tuberculous lymphadenitis and abscess**, upper cervical lymph nodes are commonly affected. Children, young adults, the elderly, immigrants, and those who are immunosuppressed are commonly affected. A neck lump appears with or without pain; if abscess formation occurs, the lump may become painful. It may discharge. There may be signs of TB in the lungs, other lymph nodes, and urinary tract. Typically, nodes are not hot and may be firm and matted together. An abscess may feel fluctuant. Consider associated HIV infection.

Table 34.1 Lateral neck swellings

	Anterior triangle	Posterior triangle
Lymph nodes	Lymph nodes Cold abscess	Lymph nodes Cold abscess
Salivary glands	Submandibular swelling Parotid swelling	
Cystic structure	Branchial cyst	Cystic hygroma
Vascular structures	Carotid body tumour Carotid body aneurysm	Subclavian artery aneurysm
Other	Sternomastoid tumour	Tumour of clavicle

Box 34.1 Midline neck swellings

Common

- thyroid swellings
- thyroglossal cyst

Uncommon

- lymph nodes
- sublingual dermoid cyst
- plunging ranula
- pharyngeal pouch
- subhyoid bursa
- carcinoma of the larynx/trachea/oesophagus

Carcinomatous lymphadenopathy is seen most often in patients over the age of 50 (the exception being papillary carcinoma of the thyroid, which occurs in younger adults). Upper deep cervical nodes drain lesions above the hyoid bone. Middle and lower deep cervical lymph nodes drain the thyroid and larynx, and supraclavicular lymphadenopathy indicates thoracic or abdominal disease. Lymph nodes may be non-tender and hard, and may be fixed.

Lymphoma presents with a painless lump or lumps, with systemic symptoms, typically, malaise, weight loss, pallor, itching, and periodic fevers (Pel–Ebstein). There may also be bone pain. Typically, lymph nodes are described as rubbery.

If **thyroid goitre** is suspected, take a history to determine thyroid status, ask about a change in appearance, intolerance to hot or cold temperatures, tremor, palpitations, change in appetite or bowel habit, dyspnoea, chest pain, irritability, and, in females, a change in the menstrual cycle. Also ask about any eye symptoms, in particular, staring or protruding eyes and difficulty closing eyelids (exophthalmos), and double vision (ophthalmoplegia). Swelling of the conjunctive (chemosis) may be present, as may pain secondary to corneal ulceration. An enlarged thyroid in Graves' disease is typically diffusely enlarged and moves on swallowing.

Other, rarer, neck masses include carotid body tumours, cystic hygromas, pharyngeal pouch, sternomastoid tumour, and cervical rib.

Examination

The neck is divided into the anterior triangle (bounded by the anterior border of the sternocleidomastoid, the lower edge of the jaw, and the midline) and the posterior triangle (bounded by the posterior border of the sternocleidomastoid, the anterior edge of trapezius, and the clavicle). The differential diagnoses for swellings in these regions are listed in Table 34.1.

Specific clues to the diagnosis

Specific clues to the diagnosis are:

- history and age of the patient
- 75% of lateral neck masses in patients aged >40 are caused by malignant tumours
- in the absence of overt signs of infection, a lateral neck mass is metastatic squamous cell carcinoma or lymphoma until proven otherwise

Key diagnostic tests

Depending on clinical suspicion, the key diagnostic tests are:

- full blood count
- urea and electrolytes
- liver function tests
- bone chemistry
- thyroid function tests
- inflammatory markers
- Ziehl–Neelsen stain (also known as the acid-fast stain)
- TB PCR
- HIV test
- fine-needle aspiration, with or without neck ultrasound; in experienced hands, this technique is accurate, inexpensive, and can be performed in the clinic for histological diagnosis

Other diagnostic tests

Other diagnostic tests are:

- chest X-ray
- CT neck; thorax and abdomen, if indicated

Introduction to therapy

Therapy will depend on the underlying diagnosis. Liaison with other specialists may be recommended as follows:

Tuberculosis: Refer to infectious disease team to start a 6-month course of chemotherapy and offer HIV test.

Malignancy: Tissue diagnosis will be required, as will liaison with surgeons and oncologists for consideration of surgery, chemotherapy, and radiotherapy.

Lymphoma: Refer to medical oncologists/haematologists for consideration of chemotherapy.

Thyroid disease: Refer to endocrinologists for management of hyper- or hypothyroidism. Thyroid malignancies require thyroidectomy and referral to oncology for joint management. Radioiodine therapy may be required. Chronic suppression of TSH is standard practice.

Prognosis

The prognosis will depend upon the underlying diagnosis:

Tuberculosis: Tuberculosis, if untreated, kills two-thirds of affected people; however, with treatment, the mortality rate is <5%.

Head and neck cancer: Early head and neck cancers have high cure rates; however, 50% present with advanced disease, and probability of cure is inversely proportional to the size of the tumour and to the extent of regional node involvement.

Lymphoma: Indolent non-Hodgkin's lymphoma has a good prognosis, with a median survival of 10 years; however, if it is advanced, it is not curable. High-grade lymphomas are more aggressive but more chemo-responsive, with a median survival of 2 years. Overall cure rates for Hodgkin's lymphoma are around 75%–80%. For young people at an early stage of the disease, cure rates approach 100%.

Thyroid malignancy: Thyroid conditions are mostly benign. Of the thyroid malignancies, papillary thyroid carcinoma and follicular thyroid carcinoma carry a 97% cure rate; medullary thyroid carcinoma is usually more aggressive and has a worse prognosis but is rarer; anaplastic thyroid carcinoma is aggressive, and the prognosis is poor, with a mean survival of 6 months from diagnosis.

How to handle uncertainty in the diagnosis of this symptom

Retake the history and re-examine the patient. Arrange an ultrasound or a CT if these have not already been done. Refer to an ENT surgeon.

35 Splenomegaly and other disorders of the spleen

Chris Bunch

The spleen

The spleen is a predominantly lymphoid organ, normally about the size of a clenched fist (11 cm in length; 150–200 g) located beneath the diaphragm in the left upper abdomen. It has a dual role as a filter for the circulation, and a primary lymphoid organ in its own right. About three-quarters of its volume is a matrix of capillaries and sinuses (the red pulp), through which blood is able to percolate slowly and come into contact with fixed macrophages, which are able to remove senescent or damaged red cells, or other particulate matter such as bacteria. An important function is maintenance of red-cell integrity: the spleen is able to remove red-cell inclusions or damaged portions of membrane. The slow circulation through the spleen leads to a 'pooling' effect, with up to one-third of circulating platelets and 5% of red cells present in the spleen at any one time. The degree of pooling increases with splenomegaly.

The lymphoid tissue is organized into scattered follicles (the white pulp), which have a particularly important role in initiating primary humoral immune responses and antibody (IgM) synthesis.

In the fetus, both the liver and the spleen are major sites of haemopoiesis, but this reduces rapidly and the bone marrow becomes predominant after birth. However, in certain infiltrative bone marrow disorders, such as myelofibrosis, chronic myeloid leukaemia, and polycythaemia vera, extramedullary haemopoiesis can return to these organs.

Splenomegaly

The spleen commonly enlarges when either its filtration function is increased—as in haemolysis—or it is stimulated by infection or inflammation. It may also be involved in myeloproliferative and lymphoproliferative neoplasias. Common causes are listed in Box 35.1.

Hypersplenism

Increased splenic pooling and phagocytic activity may accompany any cause of splenomegaly, leading to a variable degree of anaemia, thrombocytopenia, or neutropenia out of proportion to any expected from the underlying cause of splenomegaly. Splenectomy may be of benefit if symptoms of the cytopenias are a problem.

The combination of splenomegaly, neutropenia, and longstanding seropositive rheumatoid arthritis is known as **Felty's syndrome**. Patients are particularly prone to infection because of the neutropenia.

Splenectomy

The spleen is probably most often removed surgically because of trauma, but may be removed electively in a number of haematological conditions (Box 35.2). Awareness of the risks of overwhelming pneumococcal sepsis (see 'Overwhelming post-splenectomy infection') has led to a more cautious approach to splenectomy in most situations.

Hyposplenism

Loss of splenic function due to its removal, congenital absence, damage from conditions such as sickle cell disease, or atrophy in coeliac disease (Box 35.3) produces characteristic changes in the blood, reflecting mainly the loss of the spleen's function in maintaining red-cell integrity. The red cells show Howell–Jolly bodies, acanthocytes,

Box 35.1 Causes of splenomegaly

Infections, esp.:

- chronic bacterial infections
- glandular fever
- rubella
- brucellosis
- subacute bacterial endocarditis
- malaria
- kala azar

Inflammatory disorders

- rheumatoid arthritis
- systemic lupus erythematosus
- sarcoidosis

Malignancy

- lymphomas
- leukaemias
- myeloproliferative disorders, e.g. polycythaemia vera, chronic granulocytic leukaemia
- **not** carcinomas, as a rule

Increased 'work' (phagocytic activity)

- haemolytic anaemias

Congestion

- portal hypertension

Storage disorders

- Gaucher's disease

and target cells; there may also be a mild monocytosis, lymphocytosis, and thrombocytosis.

There are no entirely reliable tests for diagnosing or excluding functional hyposplenism. Most but not all patients will have the aforementioned blood film changes; in addition, phase contrast microscopy of red cells may reveal pits in the membrane which would normally lead to removal of the cell by a functional spleen. Cross-sectional or ultrasound imaging will usually reveal absence of the spleen or a significant reduction in its size.

Overwhelming post-splenectomy infection

Overwhelming post-splenectomy infection (OPSI), that is, overwhelming sepsis with pneumococci (or, less commonly, haemophilus or meningococci) is a rare but devastating late complication of splenectomy, and also occurs in those who have lost splenic function for other reasons, such as sickle cell disease. This risk is low

Box 35.2 Common indications for splenectomy

- trauma
- hereditary spherocytosis
- chronic idiopathic thrombocytopenia
- hypersplenism
- for diagnosis of splenomegaly, when cause cannot otherwise be determined

Box 35.3 Causes of functional hyposplenism

- splenectomy
- splenic irradiation
- therapeutic splenic embolization
- coeliac disease
- sickle cell disorders
- chronic graft-vs-host disease

(less than 1%), but is considerably higher in children, reflecting perhaps relatively immature immunity. It may be lower in those who have had splenectomy for trauma, although such patients are not normally followed up as assiduously. There is some evidence that the traumatized spleen may seed sufficient splenic tissue into the abdominal cavity for some splenic function to be retained.

In its early stages, post-splenectomy infection is indistinguishable from any other febrile illness of acute onset, but its subsequent course may fulminate within 24–48 hours, so early recognition is essential. For this reason, various approaches to prophylaxis have been recommended:

Immunization: All individuals with absent or dysfunctional spleens should be fully immunised according to the national schedule (see below). Immunization should preferably be undertaken before splenectomy, as the spleen may be important for a satisfactory response, but if this is not possible it should still be offered after the operation

Prophylactic antibiotics: Adults (>16) at high risk of pneumococcal infection should be prescribed life-long prophylactic antibacterials. High-risk patients include the following:

- greater than 50 years of age;
- history of previous invasive pneumococcal disease;
- * splenectomy for underlying haematological malignancy, particularly in the context of ongoing immunosuppression.

Penicillin is usually recommended (250 mg, once or twice daily) but erythromycin is a satisfactory alternative.

Life-long antimicrobial prophylaxis for all hyposplenic patients is no longer recommended.

Contingent antibiotics: All hyposplenic patients not on prophylaxis should have a ready supply of antibiotic (amoxicillin or erythromycin) to take at the very first sign of any febrile illness. Most such situations will not be serious, but it is not worth taking the risk of waiting to see. This approach requires close co-operation of the general practitioner in maintaining a fresh supply of antibiotics.

Patient education is important, and patients should be encouraged to wear an alert bracelet or carry a card with relevant details (see Further Reading). It is important also that they understand the need for prompt treatment of any febrile illness.

Other infections in hyposplenic patients

Patients with functional hyposplenism are also at increased risk of infection from tick-borne organisms (e.g. babesiosis, Lyme disease), rickettsial diseases and malaria. Appropriate advice should be given to those contemplating travel to endemic areas for such conditions.

36 Lymphadenopathy

Chris Bunch

Lymph nodes

Lymph nodes are small, bean-shaped structures generally a few millimetres in size, distributed widely throughout the body and assuming a major role in the immune system. There are several hundred lymph nodes, networked by lymphatic channels and the blood stream and organized into anatomical groups, for example, cervical, submandibular, hilar, mediastinal, axillary, para-aortic, inguinal, and so on. They are composed principally of lymphocytes and macrophages.

Box 36.1 Causes of lymphadenopathy

Inflammatory

Suppurating

- pyogenic infection

Non-suppurating

- infection
- rheumatoid arthritis
- systemic lupus erythematosus
- dermatopathic (draining skin affected by e.g. psoriasis or eczema)

Granulomatous

- tuberculosis
- histoplasmosis
- toxoplasmosis
- sarcoidosis
- syphilis

Malignant

- secondary carcinoma, melanoma, or sarcoma
- lymphoma
- leukaemia

Congenital

- lymphangiomas
- cystic hygroma

Lymph draining from the tissues percolates through lymph nodes, coming into contact with lymphocytes and macrophages, which will respond to the presence of foreign antigen by proliferation and production of antibody and sensitized cells.

Lymphadenopathy

Peripheral lymph nodes are not normally palpable except in thin individuals. Enlargement of lymph nodes is called lymphadenopathy, important causes of which are shown in Box 36.1. It is important to distinguish between reactive lymphadenopathy, which is usually an appropriate response to infection or inflammation, and malignant or neoplastic lymphadenopathy. This is often possible on clinical grounds, but biopsy may be required if lymphadenopathy is persistent or progressive over several weeks and is not associated with other evidence of infection. Surgical excision biopsy gives the most reliable information, and histological examination can be supplemented by immunological or molecular analysis as required. Fine-needle-aspiration cytology is simpler and more rapid, but does not yet have the accuracy of surgical biopsy.

Clinical assessment of lymphadenopathy should include full examination of all superficial lymph node groups: cervical (anterior and posterior), occipital, submandibular, supraclavicular, axillary, epitrochlear, inguinal, and femoral. Note should be taken of their size, texture (soft, hard), mobility, and attachment as well as the number of enlarged glands in each group. Abnormally large iliac or abdominal nodes may also be palpable in thin individuals.

Radiologically, lymphadenopathy is best assessed by CT scanning. PET scanning can indicate metabolic activity in enlarged lymph nodes and can be helpful in monitoring effects of treatment in malignant lymph nodes.

37 Anaemia

Chris Bunch

Definition

Anaemia denotes a reduction in the circulating haemoglobin (Hb) level or red-cell count below that which is normal for the individual's age and sex.

There are, however, wide individual and population differences in the levels of Hb and the red-cell count, so absolute criteria for diagnosing anaemia are difficult to define. A more functional definition is a state in which the circulating red-cell mass is insufficient to meet the oxygen requirements of the tissues, although this is also subject to wide variation, and is influenced by other factors such as the presence of cardiovascular or lung disease.

Anaemia may be graded as severe (less than 60 g/L), moderate (60–90 g/L), or mild (between 90 g/L and the lower limit of normal).

Context

Anaemia is common and may be a primary problem or a feature of a wide variety of other conditions (Box 37.1). Its presence in these should be unsurprising, and further investigation is only warranted if there are unusual features or it does not improve with treatment of the underlying condition.

Box 37.1 Principal causes of anaemia (with examples)

Primary anaemia

- blood loss
- deficiency anaemias:
 - iron deficiency
 - B₁₂ deficiency
 - folate deficiency
- defective haemoglobin production:
 - thalassaemias
 - lead poisoning
- haemolytic anaemia, congenital:
 - haemoglobinopathies (haemoglobin S, haemoglobin C)
 - red-cell enzyme defects (glucose-6-phosphate dehydrogenase, pyruvate kinase)
 - red-cell membrane defects (spherocytosis, elliptocytosis)
- haemolytic anaemia, acquired:
 - autoimmune haemolytic anaemia
 - paroxysmal nocturnal haemoglobinuria
 - poisoning

Secondary anaemia

- anaemia of chronic disease:
 - infection
 - inflammatory disorders
 - malignancy
- marrow failure:
 - leukaemia
 - myelodysplasia
 - myeloproliferative disorders
- renal failure
- liver disease
- endocrine disorders:
 - hypothyroidism
 - hyperthyroidism
 - adrenal insufficiency

In primary care, a general practitioner can expect to encounter one new case of anaemia every month; most of these will be mild or moderate anaemias due to blood loss/iron deficiency, or the anaemia of chronic disease.

Approach to the diagnosis

Anaemia is neither a symptom nor a disease. The function of Hb is to transport oxygen to the tissues. Actual tissue oxygen delivery is also influenced by several other factors, for example, blood flow (itself influenced by cardiac output and vascular resistance) and the oxygen affinity of Hb, which can be varied adaptively to a significant degree.

The clinical consequences of anaemia are thus variable and depend upon the degree to which the body has compensated for a falling Hb level: it may be entirely asymptomatic or may cause varying degrees of tiredness and fatigue. Moderate-to-severe anaemia is likely to exacerbate symptoms and signs of any coexisting cardiac or respiratory disease, such as angina, dyspnoea, and heart failure.

There are no specific clinical signs of anaemia: some pallor of the mucous membranes is usual in moderate-to-severe anaemia. Jaundice accompanies significant haemolysis (with haemoglobinuria, if haemolysis is intravascular) and a 'lemon-yellow' tinge is characteristic of megaloblastic anaemias. Glossitis and cracking of the corners of the mouth (angular cheilosis) may occur in deficiency anaemias, and nail changes (koilonychia) are characteristic of severe iron deficiency.

Anaemia is usually classified in terms of the average red-cell size (mean corpuscular volume (MCV)) as **normocytic** (MCV 80–100 fl), **microcytic** (MCV less than 80 fl), or **macrocytic** (MCV greater than 100 fl).

Microcytic anaemias

Small red cells indicate inadequate haemoglobinization of the red cell, and are the hallmark of iron-deficient erythropoiesis and the thalassaemias. Lesser degrees of microcytosis are also seen in the anaemia of chronic disease (infections, inflammation, malignancy), and sideroblastic anaemias.

Macrocytic anaemias

Minor degrees of macrocytosis are common in alcohol excess and pregnancy, and are usually of no consequence unless associated with anaemia, when causes include liver disease, haemolytic anaemia (reflecting a high proportion of reticulocytes, which are larger than normal red cells), hypothyroidism, myeloma, and myelodysplasia. Significant macrocytosis (MCV > 110 fl) is characteristic of megaloblastic erythropoiesis (B₁₂ or folate deficiency). An MCV greater than 120 fl is usually an artefact due to red-cell clumping in vitro, which can occur in autoimmune haemolytic anaemias.

Normocytic anaemias

As the MCV is an average of the red-cell size distribution, there is considerable overlap between micro- and macrocytic anaemias, and anaemias with a normal MCV. Causes include blood loss, renal failure, anaemia of chronic disease, haemolytic anaemia, bone marrow failure, myelodysplasia, and haematological malignancies.

Specific clues to the diagnosis

A full blood count will be a routine investigation in a wide range of clinical situations, and will reveal anaemia if it is present. In individuals with unexplained tiredness, fatigue, or pallor, the result will often be reassuring.

Key diagnostic tests

The key diagnostic test for anaemia is the full blood count (see Chapter 278), and the important parameters are the Hb level, red-cell count, and MCV. Other red-cell parameters—packed cell volume, or haematocrit; mean cell Hb levels, and mean cell Hb concentration—are calculated from these but are of relatively little use clinically.

The reference range for Hb varies slightly between laboratories but, for adults in developed countries, Hb levels between 120 and 160 g/L would generally be considered normal in females, and between 140 and 180 g/L for males. The difference in Hb levels between adult males and females reflects higher levels of androgens (which stimulate erythropoiesis) in males.

Other diagnostic tests

Specific tests for specific anaemias are described in the relevant chapters.

Introduction to therapy

The principles of treatment in anaemia are to correct any deficiencies if present, treat any underlying conditions, and, as a last resort, to consider red-cell transfusion, but only if the anaemia is moderate or severe, symptomatic, and unlikely to respond to the first two approaches. In selected situations, for example, renal disease and cancer, administration of recombinant erythropoietin may be useful.

Prognosis

The prognosis in anaemia is dependent on the cause and the prognosis of any underlying condition. Simple deficiency anaemias are usually easily corrected. On the other hand, congenital anaemias such

as sickle cell disease and thalassaemias are essentially incurable, and homozygous forms are life shortening. More details are available in the relevant chapters.

How to handle uncertainty in the diagnosis of anaemia

The diagnosis of anaemia is based on the Hb concentration, which is normally accurate and reproducible. However, there are situations where this may give an inaccurate or misleading picture. In addition, the Hb concentration may vary in an individual by as much as 10 g/L from day to day.

Blood for the full blood count should be taken with care: prolonged tourniquet pressure may give rise to slight haemoconcentration and an artefactual rise in the Hb level, while taking blood from an arm that also has a running intravenous infusion in place commonly leads to haemodilution and an abnormally low Hb level. Samples may deteriorate if delayed in transit to the laboratory.

The clinical context is important: for example, Hb levels are commonly slightly reduced in the elderly for no easily discernible reason. It is unwise to label such patients as anaemic on the basis of a single Hb estimation.

38 Bruising and bleeding

Nicola Curry and Raza Alikhan

Definition of the symptom

The amount of blood that leaks from a blood vessel into the subcutaneous tissue will determine the size and description of a lesion. Minute amounts of blood producing pin-point red lesions <2 mm in size are described as petechiae, larger lesions (2 mm–1 cm) are purpura, and bruises (ecchymoses) tend to be >1 cm.

Differential diagnosis in primary care and secondary care

Box 38.1 gives examples of the causes of bruising and bleeding that are likely to present in primary and secondary care, as well as causes relating specifically to neonates and children.

Context

Bruising is extremely common and a normal response to injury. Perception of what is a normal level of bruising is subjective and it can be difficult to differentiate a patient with 'normal' bruising from a patient who has bruising due to a mild bleeding disorder.

However, spontaneous bruising or bruises that seem incongruent to the degree of injury experienced must be taken seriously. Therefore, it is important that you assess your patient globally before providing reassurance that their symptoms are not worrying.

Approach to the diagnosis, and specific clues to the diagnosis

It can be helpful to categorize patients with bruising/bleeding into two clinical groups: those who have no other symptoms, in whom the cause is likely to be either a normal response to injury, or an isolated platelet disorder or clotting factor deficiency; and those who have additional symptoms, in whom haematological disease (e.g. thrombocytopenia due to bone marrow infiltration) or systemic disease (e.g. connective tissue disorder) is more likely.

The history is the most important part of the assessment of a patient who presents with bruising or bleeding. The main considerations to make are:

- the accompanying symptoms
- the timescale of the symptoms
- the site of bruising or bleeding
- the severity of the problem

Accompanying symptoms

Try to get a feel for whether the patient has an isolated bleeding problem, or whether their symptoms are a manifestation of a wider problem. Ask about accompanying fatigue (anaemia), increased infection (leucopenia), lymphadenopathy, joint pains, and so on. Be guided by the history.

Timescale of the symptoms

It is important to determine whether the problem has been a lifelong one or whether it started recently, to differentiate between inherited or acquired disease. If the history suggests an inherited disease, ask whether there is a family history of bleeding. Inherited bleeding disorders can be X-linked (haemophilia), autosomal dominant (some forms of von Willebrand's disease), or autosomal recessive (some factor deficiencies

Box 38.1 Causes of bruising and bleeding likely to present in primary and secondary care, and causes relating specifically to neonates and children

Primary care

- 'easy bruising'
 - no underlying diagnosis
 - elderly
 - steroid therapy
- drugs
 - antiplatelet agents
 - anticoagulants
- systemic disease
 - liver disease, including alcoholic liver disease
 - uraemia
 - thyroid disease
 - Cushing's disease
 - autoimmune disease
- thrombocytopenia
 - in particular, immune thrombocytopenia purpura
- von Willebrand's disease
- haemophilia A
- haemophilia B

Secondary care

- drugs
 - antiplatelet agents
 - anticoagulants
 - heparin
- systemic disease
 - liver disease
 - uraemia
- sepsis/disseminated intravascular coagulopathy
- thrombocytopenia
 - platelet destruction
 - immune thrombocytopenia purpura
 - disseminated intravascular coagulopathy
 - thrombotic thrombocytopenia purpura
 - haemolytic uraemic syndrome
 - reduced production of platelets
 - marrow failure
 - marrow infiltration
- von Willebrand's disease
- haemophilia A
- haemophilia B
- vasculitis
- collagen disorders

Causes relating specifically to neonates and children

Neonates

- sepsis/disseminated intravascular coagulopathy
- congenital infection (TORCH):
 - toxoplasmosis
 - other (syphilis)
 - rubella
 - cytomegalovirus
 - herpes simplex virus
- vitamin K deficiency
- immune thrombocytopenia purpura

Box 38.1 (Continued)

- neonatal alloimmune thrombocytopenia
- haemophilia

Childhood

- immune thrombocytopenia purpura
- leukaemia
- inherited bleeding disorders
- non-accidental injury

and various platelet diseases). It may therefore, in some circumstances, be important to ask whether the patient's parents are related other than by marriage. If the problem started recently, ask whether the symptoms relate temporally to any new medications, or new activities.

Site of bruising or bleeding

Epistaxis

Bleeding from the nose is one of the most common symptoms of platelet disorders and von Willebrand's disease. It is also a common symptom of hereditary haemorrhagic telangiectasia. However, a large number of the population also suffer from nosebleeds. If the bleeding is confined to a single nostril, it is more likely due to a localized abnormality rather than a coagulopathy. Epistaxis during childhood is also common and tends to disappear after puberty. The need to seek medical advice, nasal packing, cautery, or transfusions must be sought from the history.

Gums

Spontaneous bleeding from the gums is another common symptom of a platelet disorder or von Willebrand's disease. Bleeding from the gums after tooth brushing may be normal or abnormal, depending on the presence or absence of gingival disease and the type of toothbrush employed.

Skin

Is the bleeding response excessive or in keeping with the degree of trauma to the skin? Spontaneous bruising is likely to be pathological. It is sometimes difficult to elicit a history of trauma from a patient; therefore, the location of a bruise can help in deciding if bruising is traumatic. In general, bruises following trauma arise at bony surfaces and on the arms and legs. Bruising arising on the back or trunk are likely to be spontaneous or due to minimal trauma.

Tooth extraction

This is often the first and only significant haemostatic challenge a person faces. The need for packing, suturing, or transfusions may be significant and indicate the presence of an underlying bleeding disorder.

Haematemesis

It is important to look for an anatomical cause. Defects in haemostasis may arise in patients with liver disease or oesophageal varices, or who are on aspirin.

Haemoptysis

As with haematemesis, it is important to look for an anatomical cause.

Menorrhagia

Menorrhagia is defined as the loss of more than 80 ml of blood per cycle. It is often difficult to assess the severity of blood loss from the history or by the number of sanitary towels used. Pictorial menstrual charts have been found to be useful in quantifying blood loss. If no gynaecological cause is present, it is important to look for platelet disorders and, specifically, von Willebrand's disease.

Pregnancy

It is important to take a detailed history of bleeding both during pregnancy and in the post-partum period. The need for transfusions,

dilatation and curettage, iron therapy, and/or hysterectomy needs to be documented.

Haemarthroses

Spontaneous joint bleeds are a feature of haemophilia (see Chapter 284).

Umbilical stump bleeding

Delayed bleeding from the umbilical stump is a feature suggestive of Factor XIII deficiency, but may also occur in haemophilia.

Severity of the problem

As a general rule, the more severe the symptom, the more severe is the bleeding disorder. The following points suggest further investigation is required:

- recurrent bleeding (i.e. more than three times at one site of the body)
- more than two sites of the body affected at one time
- unusual bleeding following a routine operation/childbirth, particularly if a blood transfusion is required
- iron deficiency anaemia secondary to blood loss
- bleeding lasting more than 30 minutes and requiring intervention (such as nasal packing)

Key diagnostic tests

The following tests should be performed as a screen for patients with increased bruising and bleeding symptoms:

- full blood count and film
- coagulation profile (prothrombin time, activated partial thromboplastin time, fibrinogen)

Any abnormality that arises in these tests can then guide you to your next investigation.

If the history suggests a systemic cause for the bleeding, consider checking:

- urea and electrolytes
- liver function tests
- thyroid function tests
- an autoantibody screen

Other diagnostic tests

If you have a patient with a suspected bleeding disorder, it is often best to refer them to a haematologist. The specialized testing is often only available in haemophilia centres (see Chapter 273). These tests include:

- coagulation factor assays (Factor VIII, Factor IX, and Factor XI)
- von Willebrand's disease screen (FVIII:C, vWF:Ag, vWF:RiCof)
- platelet analysis:
 - platelet aggregometry and nucleotide testing
 - electron microscopy
 - flow cytometry
- DNA analysis

Introduction to therapy

Treatment for patients with symptoms of bruising will depend on the underlying diagnosis. Many patients will require simple reassurance that their bruising is not clinically concerning and that no active intervention is required.

For those patients that are bruising because of a systemic disorder, symptoms can be ameliorated by treating the underlying disease.

When drugs such as aspirin or warfarin are the cause of the symptoms, the risks and benefits of continuing or stopping the drug must be weighed up.

Whatever the cause of the bleeding, simple instructions can be given to reduce risks of further bleeding:

- avoidance of intramuscular injections
- avoidance of antiplatelet/anti-inflammatory/anticoagulant drugs, if possible
- avoidance of contact sports in severe bleeding disorders
- informing any physician/dentist, prior to an invasive procedure, of the bleeding history and, if possible, seeking advice from a haematologist

Patients with inherited bleeding disorders, and those with significant acquired bleeding disorders, should be treated by a haemophilia centre so that, at times of significant haemostatic challenge (such as childbirth or surgery), they are managed appropriately and safely.

Prognosis

It is impossible to provide specifics regarding prognosis, as this will entirely depend on the underlying cause of the bleeding and the severity of the disease.

How to handle uncertainty in the diagnosis of this symptom

Bruising is a very difficult symptom to diagnose with accuracy. Therefore, uncertainty is common.

The simple rule to follow is, don't ignore bruising/bleeding if:

- a patient has systemic symptoms
- it is spontaneous or recurrent
- it has required active intervention to halt it
- it has led to the need for iron replacement or blood transfusion

These types of symptoms require urgent attention. Less convincing evidence of disease can be investigated at a more leisurely pace and, indeed, underlying pathology may not be found.

39 Transient loss of consciousness

Jonathan Timperley and Sandeep Hothi

Definition of the symptom

Transient loss of consciousness (TLoC) is characterized by a rapid, transient, and complete loss of consciousness of short duration with spontaneous, complete recovery. Syncope is a specific type of TLoC caused by transient, global, cerebral hypoperfusion.

Differential diagnosis

TLoC may be traumatic or non-traumatic. Causes of non-traumatic TLoC include syncope, epilepsy, psychogenic causes, and other, rarer causes. Causes of syncope are shown in Box 39.1.

Context

TLoC is common and affects up to half the population at some point in their lives. It accounts for approximately 3% of A & E attendances and 1% hospital admissions; with etiologies ranging from benign conditions and clinical courses on the one hand, and up to 33% mortality on the other when there is underlying cardiac structural disease. The incidence of TLoC rises with age, particularly beyond the age of 70 years. The diagnostic process can be difficult, investigations can be costly, and even potentially serious conditions may be difficult to diagnose early.

Approach to diagnosis

The first aim is to confirm a diagnosis of TLoC (see 'Definition of the symptom'), and then to determine if there are features predictive

Box 39.1 Causes of syncope

Reflex (neurally mediated)

- vasovagal
 - emotional stress
 - orthostatic
- situational
 - micturition
 - coughing, sneezing
 - post-exercise
- carotid sinus hypersensitivity

Orthostatic hypotension

- drug induced
- hypovolaemia
- primary autonomic failure
- secondary autonomic failure

Cardiovascular

- arrhythmia
 - bradyarrhythmias (sinus node dysfunction; atrioventricular block)
 - supraventricular and ventricular tachyarrhythmias
- structural heart disease
 - stenotic valve disease
 - cardiomyopathies
- acute major pulmonary embolism
- severe pulmonary hypertension

Data from Task Force for the Diagnosis and Management of Syncope of the European Society of Cardiology (ESC), volume 30, p. 2631, Copyright © 2009 Eur Heart Journal

Box 39.2 History taking after syncope

Questions regarding circumstances prior to the attack:

- position (supine, sitting, or standing)
- activity (rest, change in posture, during or after exercise, during or immediately after urination, defaecation, cough, or swallowing)
- predisposing factors (e.g. crowded, warm, prolonged standing, postprandial) and precipitating factors (fear, pain, neck movements)

Questions about the onset of the attack:

- nausea, vomiting, abdominal discomfort, feeling cold, sweating, aura, neck or shoulder pain, blurred vision, dizziness
- palpitations

Questions about the attack (eyewitness):

- way of falling, skin colour, duration of loss of consciousness, breathing pattern, movements, duration of movements, onset of movements in relation to fall, tongue biting

Questions about the end of the attack:

- nausea, sweating, feeling cold, confusion, muscle aches, skin colour, injury, chest pain, palpitations, urinary or faecal incontinence

Questions about the background:

- family history of sudden death, cardiomyopathy, or fainting
- previous cardiac disease
- neurological history
- metabolic disorders
- medication and other drugs, including alcohol
- if recurrent syncope, information about recurrences including time from first event and frequency of events

Data from Task Force for the Diagnosis and Management of Syncope of the European Society of Cardiology (ESC), volume 30, p. 2631, Copyright © 2009 Eur Heart Journal

of a high risk of cardiovascular events or death. The presence of the following features makes syncope highly likely: complete loss of consciousness; rapid loss of consciousness; spontaneous and full recovery; and loss of postural tone. If any of these features are absent, a non-syncopal cause of TLoC should be considered.

The account of a witness, if available, is of importance. This, together with the patient's account, will be required to build a description of events from before the episode through to the recovery. Thus, the features in the Box 39.2 should be elicited.

Specific clues to the diagnosis

History

The duration of TLoC due to syncope is typically in the region of 20 seconds, and rarely up to a few minutes. A previous history of episodes of TLoC and their descriptions may help confirm the diagnosis as well as establishing the frequency and impact upon the patient's life.

Myoclonic jerks can occur after the onset of syncope, but only last for seconds; in contrast, during epilepsy, they occur simultaneously with the onset of loss of consciousness and usually last minutes.

Neurally mediated syncope is suggested by the absence of cardiac disease; multiple episodes; and onset after prolonged standing or after exertion, head rotation, or specific situational triggers.

Orthostatic hypotension is suggested by TLoC after standing; the recent start of drugs causing hypotension; TLoC in hot, crowded places; autonomic neuropathy; Parkinson's disease; and TLoC associated with standing after the cessation of exercise. Cardiac syncope is suggested by structural cardiac disease, exertional symptoms, palpitations, or an abnormal ECG.

Features suggesting epilepsy include prodrome, tongue biting, unilateral head rotation during the event, prolonged jerking of the limbs, and postictal confusion. Tongue biting (especially of the lateral tongue) is very rare in syncope. Its presence strongly suggests the diagnosis of epilepsy.

The previous medical history may reveal conditions predisposing to TLoC, such as known heart disease, Parkinson's disease, and epilepsy. The drug history may identify a cause, for instance, anti-hypertensives, diuretics, antiarrhythmic drugs, QT-prolonging drugs, or alcohol. The family history may reveal a familial predisposition to a specific cause for TLoC, such as inherited cardiac or neurological diseases. A family history of sudden death or syncope is therefore important, whether the diagnosis is certain or not.

Physical examination

Measurement of vital signs may identify abnormalities of heart rate and/or blood pressure. A postural blood pressure should be checked: a decrease in systolic pressure of 20 mm Hg or more, or 10 mm Hg diastolic, within 3 minutes of standing, is significant and represents orthostatic hypotension.

Cardiovascular examination may reveal an irregular pulse, a diminished pulse volume in severe aortic stenosis, a bradycardia, or a tachycardia. On auscultation there may be a mid-systolic murmur with aortic stenosis or hypertrophic cardiomyopathy; there may be a malar flush and diastolic murmur with mitral stenosis.

Neurological examination should, by definition, demonstrate no permanent de novo neurological abnormalities causing TLoC. There may, however, be neurological deficits secondary to neurological injury sustained during injury caused by the loss of consciousness. There may also be features of Parkinson's disease or autonomic neuropathy and its causes (multiple system atrophy, diabetes mellitus, Lewy body dementia, amyloidosis, renal failure, spinal cord lesions).

Key diagnostic tests

Key diagnostic tests are:

ECG: conduction abnormalities, ventricular pre-excitation, ventricular or atrial arrhythmias, long or short QT intervals, ST- or T-wave changes, pathological Q waves, Brugada syndrome

Blood tests: full blood count, to exclude anaemia, and blood glucose, to exclude hypoglycaemia

Other diagnostic tests

Other diagnostic tests are:

TSH level: Where tachyarrhythmias or bradyarrhythmias are identified, the TSH level should be checked to exclude hyperthyroidism and hypothyroidism (bradycardia).

Urea and electrolytes: These must also be checked; hypokalaemia is associated with tachyarrhythmias and acquired long-QT syndrome; hyperkalaemia may also cause ventricular arrhythmias.

Echocardiography: This test may reveal aortic or mitral stenosis, aortic dissection, or left ventricular systolic dysfunction.

Carotid sinus massage: Carotid sinus massage (CSM) is performed by applying pressure to the carotid sinus (the point of bifurcation of the common carotid artery) while recording the heart rate and blood pressure to identify symptomatic bradycardia or hypotension. Carotid sinus hypersensitivity (CSH) is diagnosed when CSM causes a pause of 3 or more seconds or a reduction in systolic blood pressure of 50 mm Hg or more. This must be performed with resuscitation facilities to hand in case of asystole. CSH in the presence of a history of syncope is highly suggestive of carotid

sinus hypersensitivity as the cause of TLoC. Complications include a small risk of stroke. CSM should be avoided in patients with a history of TIA, recent stroke (3 months), or carotid bruits.

ECG monitoring: Cardiac monitoring (in hospital) is appropriate in patients considered high risk for cardiac arrhythmia as the cause of TLoC in the immediate phase after presentation. Other forms of monitoring include Holter monitoring (up to 48 hours recording), external event recorder (applied by the patient when palpitations occur), or implantable event recorder (over 3 years monitoring). The selection of these forms of monitoring is based on the frequency of episodes of TLoC.

Short Synacthen test: This test is done when adrenal insufficiency is suspected to cause orthostatic hypotension.

Orthostatic challenging: A change in posture from supine to upright results in venous pooling and reduced venous return. In the normal situation, compensatory mechanisms act to minimize consequent hypotension and syncope. Abnormalities may be cardioinhibitory response (reflex bradycardia), vasodepressor response (reflex hypotension), or both, in such patients. Two forms of test exist to identify significant hypotension and syncope caused by a change in posture. The first involves a change from supine to standing, where the blood pressure is measured in the supine position and then on standing (commonly known as postural blood pressure, described in 'Physical examination'). The second method is known as tilt-table testing. In this test, the patient has blood pressure and heart rate monitoring while being put into a head-up tilt, to assess for neurally mediated syncope. It is thus useful in assessing for neurally mediated orthostatic hypotension. False positives may be seen in other forms of neurally mediated syncope as well as sinus node dysfunction.

EEG: This is useful in suspected epilepsy rather than as a test for the investigation of syncope.

CT head: This is performed to exclude injury secondary to TLoC when there is suspected head injury, and to exclude structural brain abnormality where a new diagnosis of epilepsy is considered.

CT pulmonary angiogram: This is done where pulmonary embolism is suspected.

Transoesophageal echocardiography/CT/MR aorta: These are done to exclude aortic dissection.

Exercise testing: This is done to assess syncope during or post exertion.

Cardiac catheterization: This is done to exclude myocardial ischaemia or ischaemia-induced arrhythmias.

Introduction to therapy

Patients must be advised not to drive while awaiting specialist review; the relevant driving guidelines must be consulted. Depending on the patient's occupation, modification of working patterns may be needed, such as working at height or operating machinery. Lifestyle advice should be given, including avoidance of triggers, and modification of behaviours that might be dangerous.

Neurally mediated syncope and orthostatic hypotension

In terms of lifestyle advice, education and reassurance should be given that the condition is quite benign. Advice of the identification and avoidance of triggers is also important. Cessation of exacerbating factors, such as specific drugs, should be advised. Education in recognizing prodromal symptoms will enable the patient to perform manoeuvres to prevent progression to TLoC (e.g. physical counterpulsation manoeuvres that cause a rise in blood pressure). Tilt training may reduce TLoC caused by reflex orthostatic hypotension. An adequate intravascular volume should be aimed for by sufficient fluid intake (2–3 l/day) and ~10 g salt per day, in the absence of hypertension.

Compression stockings can help reduce gravitational venous pooling. Physical counterpressure may be useful if patients have prodromal symptoms that can be used as warnings. Midodrine (an alpha agonist) may be of help in chronic autonomic failure, and the mineralocorticoid fludrocortisone may also be helpful. Especially if the patient is unable to adequately increase their fluid and salt intake. In

severe cases of TLoC due to reflex syncope with a cardioinhibitory response revealed on tilt testing, permanent pacing may be indicated.

Carotid sinus syndrome

In carotid sinus syndrome, when TLoC is caused by a predominant cardioinhibitory response, permanent cardiac pacing is the treatment of choice.

Cardiac arrhythmia

Permanent pacing is indicated in sinus node dysfunction causing bradycardia as well as atrioventricular block with symptoms. Syncope caused by atrioventricular reentrant tachycardia, atrioventricular nodal reentrant tachycardia, or atrial flutter is ideally treated by ablation. Antiarrhythmic therapy is used while awaiting ablation or following failed ablation.

For ventricular tachycardia (VT) or ventricular fibrillation (VF), any proarrhythmic drugs must be stopped. An implantable cardioverter defibrillator (ICD) is indicated in VT with a reduced ejection fraction, or VT/VF without reversible causes. Ablation may be considered in a structurally normal heart. Revascularization should be considered in ischaemic arrhythmias.

Structural heart disease

Where TLoC is secondary to underlying structural heart disease, treatment is aimed at the specific abnormality as well as an aim to reduce the risk of future events. Treatment thus varies but includes, for instance, surgery for severe aortic stenosis, revascularization, and secondary prevention for myocardial ischaemia and anticoagulation for pulmonary embolism. An ICD may be indicated where the risk for arrhythmia remains high despite optimum management (see 'Further reading').

Epilepsy

Treatment should be directed by an expert and includes antiepileptic drugs and driving advice.

Prognosis

Situational and vasovagal syncope usually follow a benign course. The EGSYS 2 (Guidelines in Syncope 2) study demonstrated that, in patients presenting to the emergency department with TLoC, a higher mortality was observed in those with an abnormal ECG and/or heart disease, seen in 82% of those who died.

In general, features suggestive of a serious condition need rapid assessment, include an abnormal ECG, signs of heart failure, exertional TLoC, cardiac murmur, family history of sudden cardiac death or cardiac disease, and unexplained or new breathlessness.

How to handle uncertainty in the diagnosis of this symptom

Where the diagnosis remains unclear despite appropriate investigations, psychogenic pseudosyncope and psychogenic non-epileptic seizures should be considered. These are particularly likely if TLoC events are variable in their nature, prolonged, or accompanied by other unexplained physical features. In addition, an implantable loop recorder will determine if a cardiac arrhythmia is the underlying causes in cases of recurrent, unexplained TLoC.

40 Coma

David Sprigings

Definition

Coma is a pathological state of unconsciousness from which a patient cannot be roused to wakefulness by stimuli. The comatose patient has closed eyes and no speech, and lacks both wakefulness and awareness, the two clinical dimensions of consciousness. The level of consciousness can be graded using the Glasgow Coma Scale (GCS), based on eye-opening, verbal, and motor responses to stimuli (Table 40.1). Coma is defined as a score of 8 or below on the GCS.

Differential diagnosis

Coma reflects dysfunction of the brainstem reticular system and its thalamic projections (the neuronal basis of wakefulness), or diffuse injury of both cerebral hemispheres. A unilateral lesion of a cerebral hemisphere (e.g. haemorrhagic stroke) will not cause coma unless there is secondary compression of the contralateral hemisphere or brainstem. Coma may be due to systemic or primary intracranial disease. Often both mechanisms and both etiologies are involved (e.g. alcohol intoxication complicated by head injury; opioid poisoning complicated by respiratory arrest with resultant hypoxic-ischaemic brain injury). Excluding head trauma, the commonest causes of coma are poisoning, stroke, and metabolic disorders. Box 40.1 summarizes the causes of coma (defined in this study as a GCS score of 10 or below for >30 minutes) in a series of 938 medical patients presenting to two urban emergency departments in Sweden; the data are probably representative of the case in the UK as well. Over half the cases of poisoning involved alcohol, either alone or in combination with sedative drugs. Poisoning was the cause of coma in 80% of patients under 40, but only 11% of those over 60.

Context

Over 70 causes of coma are recognized, ranging from the common disorders in Box 40.1 to rarities such as cerebral fat embolism following long-bone fracture or hyperammonaemic coma complicating ornithine transcarbamylase deficiency (an X-linked urea cycle disorder). However, the age of the patient, the comorbidities present, the setting in which coma occurs, and the examination findings generally limit the differential diagnosis to a handful

Table 40.1 Grading of level of consciousness using the Glasgow Coma Scale*

Points	Eye opening (E)	Best verbal response (V)	Best motor response (M)
6	–	–	Obeys commands
5	–	Orientated	Localizes pain
4	Spontaneous	Confused	Withdraws to pain
3	To speech	Words	Flexes to pain
2	To pressure	Sounds	Extends to pain
1	None	None	None

* The score is expressed both as its components (e.g. E2, V1, M4) and sum (e.g. Glasgow Coma Scale (GCS) 7). By definition, a patient in coma will have a score of E < 3, V < 3, and M < 5. In a patient with an endotracheal tube in place, preventing assessment of verbal response, the modifier 'T' is attached to the score (e.g. E2, M4; GCS 6T). The accuracy and reliability of the measurement of the GCS score are influenced by technique and experience.

of diseases. The common causes of coma by context are given in Table 40.2.

Approach to diagnosis

Coma is a medical emergency, because a comatose patient is at high risk of permanent brain injury or death, caused either by the

Table 40.2 Causes of coma by context

Patient group	Causes to consider*
Emergency department patient under 40	Poisoning with alcohol and/or other psychoactive substances Postictal state Hypoglycaemia Traumatic brain injury Carbon monoxide poisoning
Emergency department patient over 40	Stroke Subdural haematoma Hypoxic-ischaemic brain injury following cardiac arrest Postictal state Hypoglycaemia Respiratory failure Traumatic brain injury Poisoning with alcohol and/or other psychoactive substances Carbon monoxide poisoning
Medical inpatient	Respiratory failure Stroke Subdural haematoma (e.g. following fall in hospital) Liver failure Septic encephalopathy
Surgical inpatient	Respiratory failure Opioid intoxication Septic encephalopathy
Patient with cancer	Raised intracranial pressure due to brain or meningeal metastases Opioid intoxication Hypercalcaemia Hyponatraemia

*This is not an exhaustive list, but highlights those causes which are commonly seen in the given context.

underlying disorder or the secondary effects of coma. Stabilization of the airway, breathing, and circulation, and exclusion of hypoglycaemia, are the first priorities before diagnosis is explored further. In coma, the reflexes which protect the airway (pharyngeal (gag) and tracheal (cough) reflex, mediated via cranial nerves IX and X) are impaired or lost, and endotracheal intubation to protect the airway should be discussed with an anaesthetist. It is particularly important that the patient's airway is protected during neuroimaging, when supine positioning of the patient and relative isolation during scanning increase the risk of airway compromise. Blood glucose should be checked by stick test at the bedside, and hypoglycaemia corrected. Seizures should be treated. If Wernicke's encephalopathy is suspected (e.g. coma with eye signs in the setting of chronic alcohol abuse and malnutrition, recurrent vomiting or after gastrointestinal surgery), give thiamine intravenously (before the administration of glucose). When opioid poisoning or the use of benzodiazepine in hospital (e.g. for procedural sedation) is suspected as the cause of coma, the appropriate antidote (naloxone/flumazenil) should be given.

Having dealt with these priorities, the cause of coma must be determined, as the quicker this is treated, the better is the outcome. Clinical assessment together with neuroimaging will usually identify the likely cause or causes. As a general rule, the absence of meningeal signs or focal neurological abnormalities indicates a systemic cause of coma (usually toxic or metabolic). However, some intracranial diseases (e.g. hypoxic-ischaemic brain injury, bilateral subdural haematomas) may not give rise to meningeal or focal signs. Conversely, focal signs do not necessarily indicate a primary intracranial cause of coma: they may be the consequence of secondary pathology (e.g. cerebral herniation with brainstem compression complicating cerebral oedema due to fulminant hepatic failure), may reflect previous unrelated disease (e.g. stroke) or may be seen in certain metabolic disorders (e.g. hyperglycaemic or hyperammonaemic states).

The history

The history is the richest source of information relevant to the diagnosis and needs to be gathered from all available sources, including ambulance personnel, family and friends, GP and hospital records, and the patient's belongings. The patient's age and comorbidities, and the setting and time course of loss of consciousness provide the most important clues. Current medications, history of previous or recent alcohol/substance abuse, and travel history (to determine whether infectious diseases acquired abroad (e.g. malaria) should be included in the differential diagnosis) must be established. Additional questions may of course be relevant in particular circumstances.

The examination

The examination of the comatose patient has general and neurological aspects. Findings on neurological examination contribute to diagnosing the mechanism and cause of coma, determine immediate management, and serve as a reference point against which neurological progress can be measured.

The general examination

The general examination begins with assessment of airway, breathing, and circulation, and measurement of body temperature. Severe hypertension suggests raised intracranial pressure (or, rarely, hypertensive encephalopathy) as the cause of coma. A rapid comprehensive examination should then be done, including checking for signs of head injury (e.g. scalp laceration or bruising; bleeding from an external auditory meatus or from the nose) and possible complications of coma (e.g. pressure injury of skin or muscle; corneal abrasions; inhalation pneumonia). If there are signs of head injury, additional cervical spine injury should be suspected until proven otherwise: the neck must be immobilized in a collar and X-rayed before testing for neck stiffness and the oculocephalic response.

The neurological examination

The neurological examination should include documentation of the level of consciousness using the GCS, examination of the eyes and fundi, testing for neck stiffness, and examination of the limbs.

Examination of the eyes

The position of the eyes; the size and symmetry of the pupils; the response of the pupils to bright light; the corneal reflex; and the oculocephalic response should be observed (Table 40.3).

The fundi

The fundi should be examined for spontaneous venous pulsation (which, if present, excludes raised intracranial pressure), papilloedema, and retinal haemorrhages. Subhyaloid and vitreous haemorrhage may be seen in aneurysmal subarachnoid haemorrhage.

Testing for neck stiffness

Neck stiffness is an important sign of meningeal irritation, and may be seen in bacterial meningitis, meningoencephalitis, subarachnoid haemorrhage, cerebral or cerebellar haemorrhage with extension into the subarachnoid space, and cerebral malaria. In any of these conditions, neck stiffness may be lost with increasing depth of coma.

The limbs

Limb tone, response to painful stimuli, tendon reflexes, and plantar responses should be examined. Consistent asymmetry between right- and left-sided findings usually indicates a structural cause for coma, although symmetrical findings do not exclude this. Limb tone is generally normal or reduced in toxic/metabolic coma (an exception is neuroleptic malignant syndrome, which is characterized by bilateral limb rigidity). An extensor plantar response usually indicates a structural lesion in the motor pathway (cerebral cortex, subcortex, brainstem, or spinal cord). However, bilateral extensor plantar responses

Table 40.3 Diagnostic significance of eye signs in the comatose patients

Sign	Significance
Conjugate deviation of the eyes	Seen with cerebral hemisphere lesions (eyes and head deviated away from the hemiplegic side) and pontine lesions (towards the hemiplegic side); also a feature of focal epilepsy
Dysconjugate deviation of the eyes	Indicates brainstem dysfunction (either primary brainstem lesion or secondary compression) or III/VI nerve lesion
Roving eye movements	Seen in toxic/metabolic coma (may be absent in deep coma); indicate an intact brainstem
Pupillary size and response to light	Small unreactive pupils are seen in opioid poisoning and pontine lesions, and fixed mid-point pupils in midbrain lesions; fixed dilated pupils are seen with central herniation and severe hypoxic-ischaemic brain injury; asymmetric pupillary size and response to light indicate brainstem dysfunction or III nerve lesion (compression of III nerve by uncus herniation results in ptosis, pupillary dilatation, reduction, and eventual loss of light reflex and deviation of the eye laterally and downwards)
Corneal reflex	A normal response bilaterally (eyelid closure and upward deviation of the eyes) indicates normal function of the midbrain and pons; the corneal reflex may be lost in deep coma due to a toxic/metabolic cause; loss of the corneal reflex is associated with loss of the cough reflex
Response to rotation of the head	Normal reflex eye movements (both eyes rotate counter to movement of the head) indicate normal brainstem function; abnormal eye movements may be seen in brainstem lesions and Wernicke's encephalopathy

may be seen transiently after tonic–clonic seizures. Hemiplegia with a contralateral III palsy may be seen with a unilateral cerebral hemisphere mass lesion complicated by uncal herniation and brainstem compression.

Other signs

Other signs are as follows:

- Multifocal myoclonus (brief, random, asynchronous jerks in limb, trunk, or facial muscles) suggests a toxic/metabolic cause.
- Myoclonic twitches of facial muscles and fingers may be seen in non-convulsive status epilepticus.
- Focal or general seizures may complicate many systemic and primary intracranial diseases causing coma.

Specific clues to the diagnosis

The cause of coma may be obvious (e.g. documented ingestion of alcohol and psychoactive medication in a young patient; coma following prolonged cardiorespiratory arrest). However, in many cases, the cause or causes of coma are less clear. The neurological signs allow patients to be placed in one of three subsets (Box 40.2) which constrain the differential diagnosis and establish priorities in management and therapy (e.g. urgency of neuroimaging; need for empirical antimicrobial therapy).

Key diagnostic tests

Key diagnostic tests are:

Blood glucose: This should be checked immediately at the bedside, and confirmed by laboratory testing.

CT: This should be done urgently in all patients, unless there is a clear toxic cause of coma in a younger patient, with no features pointing

to additional disease. CT is very sensitive for intracranial haemorrhage (sensitivity for subarachnoid haemorrhage, 95%; for other intracranial haemorrhage, >95%) and will identify mass lesions, hydrocephalus, marked cerebral oedema, and large cerebral hemisphere ischaemic strokes. Non-contrast CT may be normal in patients with meningitis or meningoencephalitis; early ischaemic stroke, especially of the brainstem or cerebellum; diffuse axonal injury from trauma; hypoxic-ischaemic brain injury; and white matter disorders (e.g. central pontine myelinolysis).

Examination of the cerebrospinal fluid: This test (assuming no contraindication to lumbar puncture) should be done in patients with a normal CT scan and in whom coma remains unexplained, to rule out intracranial infection.

Other key tests: Other key tests are measurement of arterial blood gases and pH; full blood count; a coagulation screen; and a biochemical profile. A toxicology screen and measurement of plasma paracetamol and salicylate levels should be done if poisoning is possible.

Other diagnostic tests

Other diagnostic tests are:

MRI: This should be done if CT and other tests do not establish the cause of coma, or a cause to which CT is insensitive is suspected.

EEG: This is indicated if the clinical findings suggest non-convulsive status epilepticus or if the cause of coma remains unclear after neuroimaging and other tests.

Other tests: Other tests such as blood culture, measurement of adrenal and thyroid function, measurement of plasma osmolality (raised in poisoning with ethanol, ethylene glycol, isopropyl alcohol, or methanol), measurement of plasma ammonia (raised in hepatic encephalopathy, valproate poisoning, and ornithine transcarboxylase deficiency), and measurement of red-cell transketolase level (reduced in Wernicke's encephalopathy due to thiamine deficiency) may be helpful in specific circumstances.

Box 40.2 Clues to the diagnosis of coma from the neurological findings (less common or rare causes are placed in parentheses)

No meningeal or focal signs

- toxic/metabolic disorders
- hypoxic-ischaemic brain injury
- postictal state
- septic encephalopathy
- (cerebral venous sinus thrombosis)
- (bilateral subdural haematomas)
- (cerebral vasculitis)
- (cerebral fat embolism)

Meningeal but no focal signs

- subarachnoid haemorrhage
- bacterial meningitis
- meningoencephalitis
- (cerebral malaria)

Focal signs

Cerebral hemisphere signs

- trauma
- cerebral infarction
- mass lesion (haematoma, neoplasm, abscess)
- (cerebral venous sinus thrombosis)
- (acute demyelinating encephalomyelitis)

Brainstem signs

- trauma
- brainstem infarction or haemorrhage
- cerebellar infarction or haemorrhage
- posterior fossa mass lesion causing hydrocephalus
- Wernicke's encephalopathy
- (brainstem encephalitis)
- (central pontine myelinolysis)
- (basilar artery thrombosis)

Introduction to therapy

Patients with coma should be nursed in a high-dependency or intensive care unit. As well as specific treatment directed at the underlying cause, supportive care of the comatose patient, including stabilization of the airway, breathing, and circulation, correction of hypoglycaemia or hyperglycaemia, treatment of seizures if present, correction of fever or hypothermia, and anticipation and prevention of the complications of coma (e.g. use of pressure mattress and positioning/turning to prevent pressure injury of skin and muscle) should be performed. Induced hypothermia can improve the neurological prognosis for coma after cardiac arrest. Thiamine and other B vitamins should be given intravenously (before the administration of glucose) if Wernicke's encephalopathy is possible (e.g. in the setting of chronic alcohol abuse, hyperemesis, or refeeding syndrome). If bacterial meningitis or viral meningoencephalitis is possible (because of fever and meningism), empirical antimicrobial therapy (with cefotaxime (plus ampicillin in patients over 55 or at increased risk of *Listeria* infection) and aciclovir) should be started immediately, after taking blood for culture. An urgent neurosurgical opinion should be sought if CT shows a structural cause for coma.

Prognosis

Patients in coma may make a complete recovery (e.g. after poisoning with psychoactive drugs), survive with varying degrees of brain injury (including the vegetative state), or die from brain death or systemic disease. The prognosis largely depends on the cause of coma, and is poor when due to major structural brain disease. For a given cause, the depth of coma and the status of brainstem reflexes influence prognosis (better with normal brainstem function).

In patients with coma after cardiac arrest, the neurological findings in the first 24 hours do not allow a firm prognosis to be made. However, if pupillary or corneal reflexes are absent at 24 hours, or motor responses are absent at 72 hours, the prognosis is very poor.

How to handle uncertainty in the diagnosis

Coma versus psychogenic unresponsiveness

Psychogenic unresponsiveness should be considered if there is a resistance to passive eye opening, the avoidance of stimuli, a response to stimuli discordant with the assessed level of consciousness, and a history of non-epileptic seizures or other functional disorders. The diagnosis should not be made simply because the existing investigations are normal. Appropriate consideration should always be given to the possibility of additional organic pathology, which should be assessed and investigated according to the principles discussed in this chapter.

Coma versus brain death

Brain death may follow coma because of the primary and secondary effects of the underlying disease or diseases. In brain death,

brainstem reflexes and respiratory function (response to arterial carbon dioxide level >8.0 kPa) are absent. There are no motor reflexes. In the UK, brainstem death can be confirmed on the basis of clinical examination by two experienced doctors. When performed, EEG shows electrocerebral silence, and evoked potentials are absent. A PET scan or a functional MRI shows absent cortical metabolism.

41 Delirium (acute confusional state)

David Sprigings

Definition

Delirium (from the Latin *delirare*, to deviate from the furrow when ploughing, and hence to be crazy or rave) is a functional brain disorder characterized by disturbances of consciousness, attention, and cognition which develop over a period of hours to days, and often fluctuate during the day. Delirium can reflect a primary neurological disorder, substance intoxication or withdrawal, an adverse effect of drugs (especially those with an anticholinergic effect), or a systemic disorder such as sepsis. The term 'acute confusional state' is often used synonymously with delirium, although delirium is preferred (as confusion is not specific to delirium, and its definition is imprecise). Delirium may be associated with a range of associated clinical features including increased or decreased psychomotor activity (hyperactive and hypoactive variants), hallucinations and delusions, and efferent sympathetic hyperactivity. Delirium with pronounced psychomotor and sympathetic hyperactivity is more often seen in younger patients with alcohol or substance intoxication/withdrawal (delirium tremens), but no cause is specific to a clinical subtype.

Delirium is distinguished from dementia (with which it may coexist, as dementia is a major risk factor for delirium) by its speed of onset (over hours or days), and its reversibility with correction of the underlying cause. In some patients, however, delirium may be followed by long-term cognitive impairment, suggesting that the pathophysiology of delirium overlaps with that of dementia.

Differential diagnosis

Several neuropsychiatric disorders may give rise to abnormal consciousness, language, memory, or behaviour, and thus enter the differential diagnosis of delirium (Table 41.1).

Context

Delirium is present on hospital admission in around 15% of older patients (age over 65), and develops after admission in a further 20%, making it the commonest complication of hospitalization in this age group. In patients of all ages, delirium may reflect a primary neurological disorder, or substance intoxication/withdrawal. In older patients, it can be caused by a wide range of systemic disorders (most commonly infection) or medications, especially those with an anticholinergic effect. Delirium predisposes to injury, falls, dehydration, malnutrition, incontinence, and pressure ulceration, and thus

Box 41.1 Major risk factors and precipitants of delirium

Major risk factors

- dementia
- age over 65
- current hip fracture
- severe illness

Common precipitants

- infection
- medications, especially with those with an anticholinergic or psychoactive effect
- electrolyte disorders
- alcohol intoxication or withdrawal
- major surgery
- urinary retention or faecal impaction
- sleep deprivation

Data from NICE, Delirium: prevention, diagnosis and management, 2010 nice.org.uk/guidance/cg103

significantly increases morbidity and mortality. Given these adverse consequences, prevention of delirium is of high importance; studies suggest that 30%–40% of cases are preventable, and multicomponent intervention (see 'Introduction to therapy') has been shown to reduce the incidence in vulnerable patients.

Delirium can be conceived as the interaction between risk factors which predispose to delirium (brain vulnerability), and precipitants which trigger it. Common risk factors and precipitants are shown in Box 41.1; the interval between onset of precipitant and delirium is typically >24 hours. A postulated model of the neuronal pathophysiology underlying delirium is illustrated in Figure 41.1. In highly vulnerable patients, such as those with dementia, a relatively minor precipitant such as a urinary tract infection may cause delirium. Often, several precipitants act in concert. Causes of delirium to consider in particular patient groups are summarized in Table 41.2.

Major surgery is a common precipitant of delirium in older patients, with rates of up to 50% after cardiac surgery and surgery for hip fracture. Delirium typically appears 2–7 days post-operatively, when plasma levels of inflammatory and catabolic mediators reach their peak, consistent with these having a causal role.

Table 41.1 Differential diagnosis of delirium

Diagnosis	Comment
Dementia	Delirium and dementia often coexist, as dementia is a major risk factor for delirium; dementia is characterized by the gradual onset of impairment of memory, impairment of the execution of activities of daily living, and impairment of social behaviour; there is no clouding of consciousness
Acute functional psychosis (manic or schizophrenic)	In acute functional psychosis, hallucinations, if present, are typically auditory, whereas in delirium they are typically visual or tactile; assume a diagnosis of delirium rather than acute functional psychosis if the patient is older than 40 with no previous psychiatric history, there is a history of alcohol or substance abuse, there are major medical comorbidities, there is disorientation, clouding of consciousness, or decreased alertness, or if physiological observations are abnormal
Non-convulsive status epilepticus	In non-convulsive status epilepticus, there are often mild clonic movements of the eyelids, face, or hands, or simple automatisms; the EEG is abnormal
Transient global amnesia	In transient global amnesia, there is an abrupt onset of anterograde amnesia without clouding of consciousness or loss of personal identity; cognitive impairment is limited to amnesia, and there are no focal neurological or epileptic signs; symptoms resolve within 24 hours
Fluent (receptive) dysphasia	Speech is fluent but with meaningless words, unnecessary phrases, and nonsensical grammar; there is no clouding of consciousness

Figure 41.1 Neuronal pathophysiology underlying delirium: A postulated model based on clinical and research observations. (A) In the normal situation, peripherally produced pro-inflammatory cytokines, such as tumour necrosis factor alpha (TNFα) can enter the brain and activate microglia that produce inflammatory mediators affecting neuronal functioning, thus causing delirium. However, cholinergic inhibition controls microglial activation and thereby limits the severity and duration of delirium. (B) In old age, incipient neurodegenerative disease, or anticholinergic drug treatment, microglia might already be primed, which leads to overactivation on new stimuli. If cholinergic inhibition also fails, because of either preexisting neurodegeneration or use of drugs with anticholinergic effects, neuroinflammation could spin out of control, leading to severe prolonged delirium that can become associated with dementia. The green arrows indicate four ways in which control could be re-established over activated microglia: (1) direct inhibition of microglial activation by anti-inflammatory treatment (e.g. minocycline); (2) inhibition of the effects of cytokines (e.g. anti-TNFα); and augmentation of inhibitory cholinergic control by (3) nicotine-receptor ligands (e.g. anabesine) or (4) other cholinomimetic drugs (e.g. cholinesterase inhibitors).

Reprinted from *The Lancet*, Volume 375, Gool WA, van de Beek D, Eikelenboom P., Systemic infection and delirium: when cytokines and acetylcholine collide, pp.73-75, Copyright 2010, with permission from Elsevier.

Approach to diagnosis

There are two aspects to the diagnosis of delirium: recognition of the syndrome, and identification of its cause or causes. Any patient with an abnormal mental state may have a disease which is an immediate threat to life (e.g. respiratory failure), and therefore exploration of the diagnosis should be preceded by a rapid assessment of the patient to

ensure that the airway, breathing, and circulation are not compromised. Blood glucose should be measured and hypoglycaemia excluded.

Recognition of delirium requires examination of the mental state and establishing the antecedent history by talking to family members, carers, or hospital staff. Mental state examination should include tests of attention, orientation, and memory and can be done in a few minutes with the 10-item abbreviated mental status examination, or equivalent (Box 41.2). The Confusion Assessment Method (CAM) instrument is an alternative and simpler method of confirming a diagnosis of delirium, with a sensitivity and specificity of >90% when compared to a diagnosis based on the criteria of the *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition, Text Revision* (a recognized standard) (see Inouye et al., 1990). Using CAM, the diagnosis of delirium requires an acute onset and fluctuating course, with evidence of reduced attention together with disordered thinking or an altered level of consciousness.

Given the broad range of disorders which may underlie delirium, identification of the cause requires a comprehensive assessment of the patient. Of particular importance in the history are the presence

Table 41.2 Causes of delirium by context	
Patient group	Causes to consider*
Older patient in the emergency department	Acute infection Adverse effect of medication Electrolyte disorder Stroke Subdural haematoma
Younger patient in the emergency department	Alcohol intoxication Poisoning with cocaine, amphetamine, or other psychoactive drugs Primary neurological disorder (e.g. encephalitis)
Older patient with delirium after surgery	Acute infection Adverse effect of medication Urinary retention Faecal impaction
Patient from psychiatric hospital	Neuroleptic malignant syndrome Primary neurological disorder (e.g. encephalitis)
Patient with alcohol dependence	Alcohol intoxication or withdrawal Wernicke's encephalopathy Liver failure Acute infection (e.g. pneumonia, spontaneous bacterial peritonitis)
Patient with cancer	Adverse effect of medication (e.g. opioid toxicity) Brain or meningeal metastases Electrolyte disorder (e.g. hyponatraemia, hypercalcaemia) Paraneoplastic effect

* This is not an exhaustive list, but highlights those causes which are commonly seen in the given context.

Box 41.2 Examination of the mental state in suspected delirium (abbreviated mental status examination)

- Age
- Time (to nearest hour)
- Address for recall at end of test—this should be repeated by the patient to ensure it has been heard correctly: 42 West Street.
- Year
- Name of hospital
- Recognition of 2 people (e.g. doctor, nurse)
- Date of birth (day and month sufficient)
- Year of 2nd World War
- Name of present monarch
- Count backwards 20–1

Each correct answer scores one mark. The healthy elderly score 8–10.

of other systemic or neuropsychiatric symptoms; comorbidities which may be systemic (e.g. chronic obstructive pulmonary disease, diabetes, chronic liver disease), neurological (e.g. dementia, parkinsonism), or psychiatric; a complete list of current and recent medications; and enquiry about alcohol or substance abuse. In addition to assessment of the mental state and conscious level, the examination should include assessment of the airway, breathing, and circulation; measurement of body temperature; abdominal findings; and testing for neck stiffness, lateralized weakness, tendon reflexes, and plantar responses. Blood glucose should be checked at the bedside by stick test.

Specific clues to the diagnosis

Delirium is under-diagnosed in hospital, particularly in patients with the hypoactive variant. Patients with major risk factors for delirium (Table 41.2) should be screened on admission by mental state examination. Delirium should also be suspected in patients with:

- abnormal cognitive function (confusion, impaired concentration, slow responses to questions—the patient described as a ‘poor historian’)
- abnormal mood (‘depression’ developing in hospital)
- abnormal perception (visual or auditory hallucinations)
- abnormal behaviour (hyperactivity or hypoactivity (restlessness, agitation, or reluctance to mobilize); unwillingness to eat or drink; abnormal sleep–wake cycle)
- abnormal social behaviour (withdrawal from social contact; unwillingness to cooperate with care—the patient described as ‘uncooperative’ or ‘difficult’)

Key diagnostic tests

Delirium is a diagnosis based on clinical findings. There is no laboratory test for delirium, although investigation is usually needed to establish the cause or exclude other diagnoses (Table 41.1). As a

general rule, all patients with delirium should have a full blood count, a biochemical profile, a C-reactive protein test, and urinalysis.

Other diagnostic tests

Other diagnostic tests are:

Neuroimaging (by CT or MRI): This is indicated if delirium followed a fall or head injury; if there are new focal neurological signs; if there is papilloedema or other evidence of raised intracranial pressure; if the patient has cancer or HIV–AIDS; if the patient’s behaviour prevents adequate neurological examination; or if no systemic cause for the delirium is apparent.

Examination of the cerebrospinal fluid: This should be done (assuming no contraindication to lumbar puncture) if meningitis or encephalitis is suspected; if the patient is febrile and no systemic focus of infection is found; or if the cause of delirium remains unclear.

Electroencephalography: This is indicated if non-convulsive status epilepticus or encephalitis is suspected, or no cause for delirium is apparent. It may be useful in distinguishing delirium from psychosis.

Introduction to therapy

The major elements in the therapy of delirium are:

- identification and treatment of the underlying cause
- comprehensive supportive care (summarized in Table 41.3), with avoidance of physical restraint, and anticipation and prevention of complications of delirium
- avoidance of unnecessary medications, especially those with anticholinergic effect

Short-term (1 week or less) therapy with haloperidol (in a dose of <3 mg daily) or olanzapine (the latter is contraindicated in patients with dementia) can be used if patients are distressed or are likely to injure themselves or others.

Table 41.3 Interventions to prevent delirium

Clinical factor	Preventive intervention
Cognitive impairment or disorientation	<ul style="list-style-type: none"> • Provide appropriate lighting and clear signage. A clock (consider providing a 24-hour clock in critical care) and a calendar should also be easily visible to the person at risk. • Reorientate the person by explaining where they are, who they are, and what your role is. • Introduce cognitively stimulating activities (for example, reminiscence). • Facilitate regular visits from family and friends.
Dehydration or constipation	<ul style="list-style-type: none"> • Encourage the person to drink. Consider offering subcutaneous or intravenous fluids if necessary. • Seek advice if necessary when managing fluid balance in people with comorbidities (for example, heart failure or chronic kidney disease).
Hypoxia	<ul style="list-style-type: none"> • Assess for hypoxia and optimise oxygen saturation if necessary.
Immobility or limited mobility	<ul style="list-style-type: none"> • Encourage the person to: <ul style="list-style-type: none"> – mobilise soon after surgery – walk (provide walking aids if needed – these should be accessible at all times). • Encourage all people, including those unable to walk, to carry out active range-of-motion exercises.
Infection	<ul style="list-style-type: none"> • Look for and treat infection. • Avoid unnecessary catheterisation. • Implement infection control procedures in line with ‘Infection control’ (NICE clinical guideline 2).
Multiple medications	<ul style="list-style-type: none"> • Carry out a medication review for people taking multiple drugs, taking into account both the type and number of medications.
Pain	<ul style="list-style-type: none"> • Assess for pain. Look for non-verbal signs of pain, particularly in people with communication difficulties. • Start and review appropriate pain management in any person in whom pain is identified or suspected.
Poor nutrition	<ul style="list-style-type: none"> • Follow the advice given on nutrition in ‘Nutrition support in adults’ (NICE clinical guideline 32). • If the person has dentures, ensure they fit properly.
Sensory impairment	<ul style="list-style-type: none"> • Resolve any reversible cause of the impairment (such as impacted ear wax). • Ensure working hearing and visual aids are available to and used by people who need them.
Sleep disturbance	<ul style="list-style-type: none"> • Avoid nursing or medical procedures during sleeping hours, if possible. • Schedule medication rounds to avoid disturbing sleep. • Reduce noise to a minimum during sleep periods⁴.

⁴ See ‘Parkinson’s disease’ (NICE clinical guideline 35) for information about sleep hygiene.

From National Institute for Health and Clinical Excellence (2010) CG 103 Delirium: diagnosis, prevention and management. London: NICE. Available from <http://guidance.nice.org.uk/CG103> Reproduced with permission.

Prognosis

As compared to matched controls, patients with delirium have increased hospital morbidity and mortality rates, longer lengths of stay, higher readmission rates, and poorer cognitive and functional status during the year after hospital admission.

How to handle uncertainty in the diagnosis

The differential diagnosis of delirium is given in Table 41.1, where those clinical features discriminating delirium from other neuropsychiatric disorders are highlighted. Bear in mind that delirium can complicate any of these disorders (e.g. a patient treated

for an acute functional psychosis may develop delirium due to neuroleptic malignant syndrome). If in doubt, assume a diagnosis of delirium, and look for an underlying acute illness, pending a detailed collateral history from family members, carers, or hospital staff.

42 Seizures

Dirk Bäumer

Definition

Seizures are transient neurological events caused by abnormal excessive or synchronous neuronal activity in the brain. This can arise from a localized brain region, causing focal seizures, or simultaneously from both hemispheres, leading to generalized seizures. Epilepsy is the tendency to develop recurrent seizures and is usually diagnosed after two or more unprovoked seizures.

Clinical types of primary generalized seizures include tonic–clonic convulsions, absence seizures (manifesting as a brief impairment of consciousness with no or minimal motor manifestations), and myoclonic jerks. The onset of primary generalized epilepsies occurs in childhood, adolescence, or young adulthood, and may be associated with photosensitivity.

Focal (or partial) seizures present with paroxysmal motor, sensory, autonomic, or psychic manifestations, corresponding to the following sites of origin:

Motor cortex: contralateral clonic or tonic movements, commonly of hand or face due to large area of representation; sometimes spread of seizure activity (Jacksonian march)

Sensory cortex: tingling or numbness, again commonly affecting hand or face

Visual cortex: flashing lights, geometrical figures

Temporal lobes: rising epigastric sensation, fear, depersonalization, smell, strange feeling in the head

If full awareness is maintained, the seizures are simple partial seizures. Complex partial seizures are focal seizures with impairment of consciousness. They often start as a simple partial seizure (which is then called an aura) before awareness becomes impaired, and manifest as motor arrest or motionless staring, followed by automatisms such as lip smacking, chewing or hand movements, or more complex behaviour. Complex partial seizures frequently arise from the temporal lobes, but can arise from other parts of the brain. Simple and complex partial seizures can secondarily generalize into tonic–clonic seizures. Status epilepticus is defined as seizures of any type lasting for >30 minutes or recurring repeatedly without recovery of consciousness.

Differential diagnosis

Paroxysmal neurological symptoms occur in a large number of conditions, and the differential diagnosis depends on the type of presentation (see Table 42.1).

Context

Seizures will affect between 5% and 10% of the population at some time in their life. This can be in the form of isolated or acute symptomatic seizures during an acute medical or neurological illness, or as part of an epilepsy syndrome. Epilepsy has a point prevalence of 5–10/1000 persons. Some people with epilepsy also have non-epileptic, psychologically mediated attacks (dissociative seizures), although most people with non-epileptic attacks do not have epilepsy.

Common presentations in the acute medical take include:

- seizures or other paroxysmal events in a patient with known epilepsy
- first seizure
- seizure in the context of an acute medical or neurological illness

Table 42.1 Differential diagnosis of seizures and other paroxysmal events

Loss of consciousness	<p>Syncope</p> <ul style="list-style-type: none"> • reflex • orthostatic hypotension • cardiac arrhythmia • obstruction to the circulation <p>Metabolic disturbance (e.g. hypoglycaemia)</p> <p>Intoxication</p> <p>Daytime sleep attacks</p> <p>Non-epileptic/psychogenic</p>
Paroxysmal motor disorder	<p>TIA</p> <ul style="list-style-type: none"> • basal ganglia ischaemia • shaking TIAs <p>Movement disorders</p> <ul style="list-style-type: none"> • tics • myoclonus • chorea • tremor <p>Tonic spasms (e.g. in MS)</p> <p>Sleep disorders</p> <ul style="list-style-type: none"> • hypnagogic jerks • periodic limb movements • REM parasomnia
Paroxysmal sensory disorder	<p>TIA</p> <p>Migraine with aura</p>
Paroxysmal behaviour disturbance	<p>Psychiatric disease</p> <ul style="list-style-type: none"> • panic attacks • hysterical fugue • episodic dyscontrol • acute psychotic episode <p>Acute encephalopathy (metabolic/toxic)</p> <p>Transient global amnesia</p> <p>Basilar migraine</p> <p>Sleep disorders</p>
Drop attacks without loss of consciousness	<p>Spinal cord disease</p> <p>Cataplexy</p> <p>Third ventricular colloid cyst</p> <p>Idiopathic drop attacks</p>

Approach to diagnosis

Step 1: Establish whether or not the paroxysmal event was a seizure.

For past events, this distinction lies solely in the history taken from the patient and, whenever possible, from an eyewitness. If no witness is with the patient, a telephone call to a person who saw what happened is more useful than any diagnostic test.

Step 2: Further define the type of seizure by analysis of the seizure semiology and use of the EEG (see 'Key diagnostic tests').

Is there more than one seizure type? Aim to define a syndrome.

Step 3: Establish the underlying aetiology. Demographic features can point to a likely cause, but investigations are needed to establish the cause of seizures (see 'Key diagnostic tests').

Specific clues to the presence of seizures

Ask the patient and witnesses what happened before, during, and after the event, bearing in mind that no single feature in the history is completely specific for the presence of a seizure. A common difficulty is to distinguish between epileptic seizures, syncope (loss of consciousness due to a global reduction in cerebral blood flow), and non-epileptic events (Table 42.2).

Table 42.2 Differential diagnosis of seizures, syncope, and non-epileptic attacks

Timing	Feature	Seizure	Syncope	Non-epileptic attack
Before	Precipitating factors	Uncommon Sleep deprivation, alcohol Specific trigger in reflex epilepsies (rare)	Pain, emotion, standing, Valsalva Exercise or none (cardiac)	Stressful circumstance
	Prodrome	Non-specific warning in some Aura (part of seizure)	Tiredness, sweating, nausea, visual disturbance (brief hallucinations and tunnel vision), muffled hearing	None or symptoms of anxiety
During	Onset	Sudden	Often gradual	Gradual
	Duration	1–3 minutes	1–30 seconds	Minutes to hours
	Facial appearance	Blue/cyanosed Frothing at mouth	Pale	Normal
	Eyes	Open, or clonic eyelid movements	Open, turned up	Closed, resists eye opening
	Movement	Synchronous rhythmic limb movements	None, can have brief convulsion (less than 15 seconds), myoclonus, and tonic flexion or extension	Asynchronous, waxing and waning, pelvic thrusts
	Tongue biting	Common, lateral tongue biting	Rare	Occasionally, tip of tongue
	Incontinence	Common	Uncommon	Uncommon
After	Recovery	Slow Headache, myalgia, fatigue	Rapid	Variable
	Injury	Common	Uncommon	Uncommon
	Confusion	Prolonged	Brief	None (maybe emotional)

Specific clues to the nature of seizures

Specific clues to the nature of seizures are as follows:

- Is this an acute symptomatic seizure? Ask about preceding febrile illness and look for meningism and rash (meningitis, encephalitis?), trauma (head injury), and signs of alcohol or substance intoxication or withdrawal.
- If patients present with generalized tonic–clonic seizures, search for additional seizure types suggestive of a generalized epilepsy syndrome. For example, a young adult with absences and myoclonus in addition to generalized tonic–clonic seizures might have juvenile myoclonic epilepsy. There might be a family history.
- Are seizures preceded by other symptoms (motor, sensory, autonomic, psychic) that could represent focal seizures? For example, a rising sensation from abdomen to chest before a convulsion would indicate medial temporal lobe focal seizures.
- Does the physical examination show features of a syndrome known to be associated with epilepsy, for example, a neurocutaneous syndrome, or focal signs such as weakness or reflex asymmetry, which point towards an underlying structural lesion?
- The age of onset will narrow the differential diagnosis (Table 42.3).

Table 42.3 Differential diagnosis of seizures according to age

Age	Aetiology
Neonates and infants	Birth injury/hypoxia Metabolic disorder Infantile spasms
Childhood	Febrile convulsions Metabolic disorder Developmental disorder Primary generalized epilepsy
Adolescence and early adulthood	Primary generalized epilepsy Trauma Drugs/alcohol Neoplasm
Middle age	Trauma Neoplasm Metabolic disorders (renal/liver failure, electrolyte abnormalities)
Late life	Stroke Degenerative disease Neoplasm

Key diagnostic tests

Key diagnostic tests are as follows:

- Blood tests:** In the acute setting, rule out hypoglycaemia, electrolyte abnormalities (Na^+ , Ca^{2+} , Mg^{2+}), and infection (full blood count, C-reactive protein). Check renal and liver function to look for precipitant factors and guide therapy. The creatine kinase is often raised. Perform a toxicology screen.
- ECG:** Rhythm disturbance can mimic seizures. In particular, look at the PR interval (heart block) and QTc time.
- Neuroimaging:** MRI of the brain is the imaging modality of choice to detect epileptogenic lesions and should be performed in any patient with suspected epilepsy unless contraindicated. A CT brain is not sufficiently sensitive, but can be helpful in emergency presentations to rule out gross underlying pathology.
- EEG:** An EEG may be helpful to make an accurate diagnosis of the epilepsy type and to distinguish between focal and generalized epilepsies. Epileptiform discharges (sharp waves, spikes, spike-and-wave forms, polyspikes) are present in ~55% of interictal EEGs in patients with epilepsy, so a negative EEG does not rule out epilepsy. The sensitivity is higher in the sleep EEG. Normal people may have non-specific abnormalities (10%) and rarely epileptiform changes (<1%).

Other diagnostic tests

Other diagnostic tests are as follows:

- Serum prolactin levels:** Serum prolactin levels rise after generalized tonic–clonic and complex partial seizures of non-frontal origin and can be helpful if obtained within 20 minutes, but are not of sufficient sensitivity or specificity to be generally recommended.
- EEG video telemetry:** The prolonged, simultaneous recording of EEG and video is useful when there is diagnostic uncertainty about the nature of paroxysmal attacks, and in the workup for epilepsy surgery, to unequivocally establish the site of onset in focal epilepsies.

Introduction to therapy

Therapy is as follows:

- Emergency treatment:** Convulsions not subsiding after 5–10 minutes should be treated as potential status epilepticus, using locally agreed guidelines.

General advice: Give general advice about avoiding potentially dangerous situations such as swimming or bathing, lifestyle measures such as avoiding triggers like sleep deprivation and excessive alcohol intake, and the need to cease driving.

Antiepileptic treatment: Generally, antiepileptic treatment is deferred after the first seizure, unless imaging and/or EEG show features suggest a high risk of recurrence. Antiepileptic drugs are chosen according to seizure and epilepsy type as well as comorbidities:

- Sodium valproate is a reasonable first choice for primary generalized epilepsies, and carbamazepine for focal seizures, but treatment needs to be tailored to the patient.
- All anticonvulsant drugs increase the risk of fetal anomalies. Sodium valproate in particular increases the risk of neural tube defects. Therefore, it is not recommended as first-line treatment in women of childbearing age (consider lamotrigine or levetiracetam).
- All women on anticonvulsant drugs and contemplating pregnancy should also be prescribed high-dose folic acid 5 mg daily for several months before conception. Some agents interfere with the oral contraceptive pill (in particular, enzyme inducers such as carbamazepine) and, in women of childbearing age, this may influence the choice of either the contraception method or the anticonvulsant drug.

Prognosis

The risk of recurrence after a single seizure is about 50%, and about 70% after a second one. It is higher when congenital or acquired brain abnormalities are present, and lower when the seizure had an

acute precipitant. Approximately 70% of epilepsy patients become seizure-free with medication. Epilepsy is associated with excess mortality, related to the underlying cause, to the seizures themselves (causing accidents or leading to status epilepticus), and to suicide. Sudden unexpected death in epilepsy (SUDEP) is rare but important.

How to handle uncertainty in the diagnosis of seizures

This is common after one isolated event, and it is better to leave the diagnosis open than to attach a diagnostic label. If paroxysmal events recur and uncertainty remains, revisit the history, try to get an eyewitness and ask for a (mobile-phone) video recording of the event. A repeat sleep EEG can be helpful. In some cases, uncertainty about the diagnosis remains even after prolonged ambulatory and video telemetry monitoring.

43 Difficulty speaking (including dysphasia and dysarthria)

Dirk Bäumer and Melanie Lord

Definitions

Difficulty speaking can arise from a problem with speech content, or the production of speech due to defective articulation or alteration of the voice (see Box 43.1)

Differential diagnosis

Differential diagnosis of dysphasia syndromes

Subdividing dysphasias may help in neuroanatomical diagnosis. Language is a function of the left hemisphere in the majority of people (even when they are left-handed). The main language areas border the Sylvian fissure: a receptive area is located in the inferior parietal and posterior superior temporal lobe and includes Wernicke's area. Lesions here cause problems in understanding written and spoken language, but also faulty (paraphasic) but fluent language output. An expressive region subserving motor aspects of speech is located in the posterior inferior frontal lobe (Broca's area) and adjacent insula. Lesions here cause non-fluent, agrammatic speech with relatively intact comprehension. These two main regions (receptive and expressive) are linked via the arcuate fasciculus. Several distinct aphasia syndromes are recognized with damage to either core language centre or their connections, but rarely occur in the pure form (Table 43.1). In addition, because neuronal networks underlying language

have interconnected and overlapping functions, there is often incomplete correlation of symptoms with lesion site.

Lesions in the periphery of the peri-Sylvian area can cause dysphasia syndromes with markedly intact repetition that otherwise look like Broca's or Wernicke's dysphasia. These are called transcortical motor and transcortical sensory aphasias.

Differential diagnosis of dysarthria

In analogy to limb weakness, dysarthria can result from pathology of the muscle, neuromuscular junction, lower motor neuron, and upper motor neuron, as well as the extrapyramidal and cerebellar control of articulation. Mixed pathology, for example, of the lower and upper motor neurons or of the upper motor neuron and cerebellum, is common.

Context

Dysphasia commonly occurs in anterior circulation stroke. Occlusion of the superior branch of the middle cerebral artery causes Broca's aphasia; occlusion of the inferior branch is likely to cause aphasia of the Wernicke type. Posterior circulation stroke can occasionally cause dysphasia by involvement of the dominant posterior thalamus (mixed transcortical aphasia).

Intra-cerebral haemorrhage, primary or metastatic tumours, brain abscess, or encephalitis can equally cause dysphasia, depending on their localization. Anomic aphasia in particular can be an early sign of Alzheimer's disease and is the main feature of the language-variant forms of frontotemporal dementia.

Dysarthria also occurs in cerebrovascular disease. Because the bulbar muscles on each side are innervated by both motor cortices, unilateral stroke of the cerebral hemispheres usually causes only mild or transient dysarthria. Bilateral involvement of the corticobulbar tract as in widespread cerebrovascular disease or multiple sclerosis causes spastic ('pseudobulbar') dysarthria.

The dysarthria of amyotrophic lateral sclerosis (motor neuron disease) can be spastic or a combination of upper and lower motor neuron bulbar dysfunction. Lower motor neuron and neuromuscular dysarthria (flaccid or 'bulbar' dysarthria) commonly occur in motor neuron disease (progressive bulbar palsy) and myasthenia gravis. Other causes include primary muscle disease (oculopharyngeal muscular dystrophy, myotonic dystrophy, inclusion body myositis, polymyositis) and spinobulbar muscular atrophy (Kennedy syndrome). Guillain-Barré syndrome and botulism are causes of acute bulbar weakness. Diphtheria and bulbar poliomyositis are now rare.

Multiple lower cranial nerve palsies can give rise to dysarthria and dysphonia. They can result from infectious or malignant meningitis, compression by tumours (including nasopharyngeal carcinoma, neurofibromas, meningiomas, and lymphomas), structural abnormalities of the craniocervical junction such as platybasia or the Chiari malformation, or inflammatory conditions such as vasculitis or sarcoidosis.

Ataxic dysarthria occurs in multiple sclerosis, stroke, after anoxic encephalopathy, and in a large number of degenerative disorders affecting the cerebellum. Hypokinetic dysarthria occurs in Parkinson's disease, whereas hyperkinetic dysarthria is common in dystonia and Huntington's disease. Stuttering is usually a developmental problem giving rise to spasms in the articulatory muscles, but can occasionally occur in patients recovering from aphasic disorders, or as an early sign of left-hemisphere lesions such as gliomas.

Box 43.1 Definitions

Dysphasia is impairment of production and/or comprehension of spoken or written language.

Dyslexia is difficulty reading.

Dysgraphia means difficulty writing.

Dysarthria is defective articulation with otherwise normal language function.

Dysphonia is an alteration of the voice due to a laryngeal problem.

The prefix 'a-' (as in 'aphasia') means complete loss of the respective function but, in practice, is often used interchangeably with 'dys-'.

Paraphasia relates to the use of malformed or inappropriate words which can be **semantic** (using the wrong word, e.g. 'fork' for 'spoon') or **phonemic** (using a wrong sound within a word, e.g. 'shoon' for 'spoon').

Neologisms are non-existent word forms. Together with paraphasias, they are characteristic of jargon **aphasia**.

Mutism is the complete failure of speech output, caused by a severe language disorder, anarthria, or psychiatric disturbance.

Dysphagia means difficulty swallowing, which often accompanies dysarthria and dysphonia.

Stuttering and **stammering** are used synonymously to characterize dysfluent speech with sound repetitions (e.g. 'b-b-b-book'), blocks, and prolongations, the latter being mainly of initial sounds.

Table 43.1 Main types of dysphasia

Type of dysphasia	Speech	Comprehension	Naming	Repetition	Lesion
Broca	Non-fluent Labourled Phonemic paraphasia	Relatively intact Problems at sentence level	Poor	Impaired	Anterior to Sylvian fissure
Wernicke	Fluent Devoid of meaning Jargon Neologisms, semantic paraphasias	Very impaired	Poor	Impaired	Posterior to Sylvian fissure
Global	Non-fluent, mute	Very impaired	Poor	Impaired	Extensive peri-Sylvian
Conduction	Fluent	Relatively intact	Poor	Severely impaired	Broca–Wernicke connections
Anomic	Fluent Word-finding difficulties	Relatively intact	Poor	Spared	Left hemisphere, non-localizing

Approach to diagnosis

The first step in assessing the patient with difficulty speaking is to decide whether the problem is one of articulation or of speech content. Systematically assess spontaneous speech, comprehension, naming, and repetition using the following steps; at this stage, try to decide if a major aphasia or dysarthria type is present (Tables 43.1 and 43.2):

Step 1: Major communication difficulties with altered speech content will become apparent quickly while taking the history and engaging the patient in conversation. Assess spontaneous speech for alterations of articulation (is it slurred or indistinct?) and decide whether it is fluent or non-fluent. Does the patient use long phrases (with, say, more than five words)? Are there paraphasic errors or neologisms? Consider whether there is evidence of more widespread cognitive alteration indicating a delirium (with altered awareness, distractibility, fluctuating attention, and disorientation) or dementia.

Step 2: Test comprehension: start with single words ('point to the bed, the chair, the window'), then sentences of increasing complexity ('touch the watch with your finger', 'take this paper, fold it in half, then put it on the floor').

Step 3: Ask the patient to name objects. Are there phonemic or semantic paraphasias? Is the right answer given when presented with a choice (in Broca's, not in Wernicke's).

Step 4: Test repetition. Tongue twisters such as 'British constitution' can accentuate dysarthria. Repetition of lingual, labial, and velar consonants ('la-la-la', 'me-me-me', 'k-k-k') can then point to the major articulation problem. Repetition of meaningless phrases such as 'no ifs, ands, or buts' is impaired in most dysphasia syndromes, but preserved in transcortical aphasia and anomic aphasia.

Step 5: A comprehensive assessment includes assessing reading and writing. These are usually disrupted in parallel with spoken language, but there are rare situations when a dissociative deficit occurs. For example, a patient with pure word mutism cannot speak, but is able to write. Problems with reading or writing unrelated to core language function can occur in disorders of visual perception and praxis.

Next, look for associated signs to reach a neuroanatomical diagnosis:

Step 6: In patients with dysphasia, look for an associated hemiparesis, hemisensory loss, or visual field defect. Test other dominant hemisphere functions: calculation (read numbers, arithmetic operations) and praxis ('blow out a candle', 'salute', 'use a toothbrush', copy of meaningless hand gestures).

Step 7: In dysarthric patients, examine the cranial nerves, with particular attention to eye movements and ptosis; observe symmetrical palatal elevation; look at the tongue in the floor of the mouth to see fasciculations; observe tongue movements; and test the jaw jerk. Ask the patient to cough. Look for proximal weakness (neck flexion) and upper or lower motor neuron signs, as well as cerebellar signs in the limbs.

Step 8: Look for clues to the aetiology: examine the cardiovascular system for causes of stroke (hypertension, atrial fibrillation, endocarditis, etc.). Look for signs of systemic illness (weight loss, rash, lymphadenopathy).

Consider the time course of symptoms, and the context of the history, to narrow down the possible pathological differential diagnosis. Sudden onset dysphasia is probably due to stroke, whereas an insidious history might indicate malignant disease or neurodegeneration. Further investigations are often needed (see 'Other diagnostic tests'). Finally, look for complications, such as aspiration

Table 43.2 Main types of dysarthria

Dysarthria	Speech	Other findings	Lesion
Flaccid (neuromuscular, 'bulbar')	Breathy, nasal, indistinct consonants	Nasal escape Flaccid/fasciculating tongue Lax lips Drooling May have associated dysphagia and dysphonia	Muscle or neuromuscular junction Lower motor neuron (lower brainstem nuclei or cranial nerves)
Spastic (Upper motor neuron, 'pseudobulbar')	Slow, stiff, harsh voice, monotonous, 'plum in mouth'	Stiff, slow tongue Brisk jaw and facial jerks Impaired emotional control (pseudobulbar affect)	Corticobulbar connections, usually bilaterally
Extrapyramidal: hypokinetic	Soft, monotonous, slow or rapid and cluttered, festinant	Low volume (hypophonia) Hypomimia	Basal ganglia Parkinson's disease
Extrapyramidal: hyperkinetic	Variable rate and loudness, distorted vowels, sudden stoppages of speech	Dystonia Chorea	Basal ganglia
Ataxic	Irregular, explosive, staccato, unnatural separation of syllables Excess and equal stress (scanning if combined with spasticity)	Poor coordination of speech and respiration	Cerebellum

pneumonia, and associated respiratory compromise needing rapid intervention.

Specific clues to the nature of dysphasia

In the acute setting, dysphasia syndromes often do not easily fit into the categories shown in Table 43.1 and instead present a mixed type. Associated findings might point to the site of the lesion:

- A (right-sided) brachiofacial hemiparesis is often associated with anterior lesions (Broca), as is a degree of orofacial dyspraxia and mild dysarthria, because cortical areas in control of the bulbar musculature may be involved. There may be ipsilateral (left) arm dyspraxia.
- A homonymous hemi- or quadrantanopia can accompany posterior lesions (Wernicke).
- Hemiparesis, hemisensory loss, and hemianopia accompany global aphasias.

When dysphasia is progressive, with few other signs, consider a dementia, if there is no lesion on the scan.

Specific clues to the nature of dysarthria

Specific clues to the nature of dysarthria are as follows:

- In neuromuscular/bulbar dysarthria, look for symptoms and signs of myasthenia gravis: is there diurnal variation in symptoms? Double vision? Droopy eye lids? Look for fatigable ptosis, ophthalmoplegia, jaw weakness, deterioration of speech over time, neck weakness, and fatigable proximal limb weakness.
- In an acute syndrome with facial weakness, particularly bilaterally, look for absent deep tendon reflexes and sensory features—could this be part of Guillain–Barré syndrome?
- If there are multiple cranial nerve palsies, think about malignant infiltration/meningitis or inflammatory conditions.
- Is the tongue wasted and fasciculating? Look for other signs of motor neuron disease—weakness and wasting in the limbs, with normal or brisk reflexes.
- In upper motor neuron/spastic dysarthria, look for evidence of stepwise progression and history of strokes—is this cerebrovascular disease?
- Optic atrophy, internuclear ophthalmoplegia, cerebellar signs, and signs suggestive of spinal cord disease (e.g. para- or tetraparesis, sensory level) point towards multiple sclerosis.
- Frequent falls, symmetrical rigidity, and impaired vertical eye movements occur in progressive supranuclear palsy.
- A patient who is completely mute might have a severe global aphasia, be anarthric, have a frontal lobe syndrome with akinetic mutism, a severe extrapyramidal syndrome, or a psychogenic problem (e.g. catatonia).

Key diagnostic tests

Brain imaging is needed to clarify the nature of lesions in dysphasia. It is also helpful in dysarthria to reveal widespread vascular disease, demyelination, cerebellar atrophy, or lesions of the brainstem or skull base.

Other diagnostic tests

Other diagnostic tests are as follows:

- Neurophysiology with nerve conduction studies and EMG can help to show a neuropathy, or signs of denervation, as in motor neuron disease.
- CSF examination is indicated in suspected Guillain–Barré syndrome or malignant meningitis.

- Acetylcholine receptor antibodies are assayed in suspected myasthenia gravis.

Introduction to therapy

A number of different specific therapies may be needed, depending on the underlying cause (e.g. thrombolysis for acute ischaemic stroke). Speech and language therapy can often help with symptomatic management of dysphasia and dysarthria.

Therapy for dysphasia

A cognitive neuropsychological language processing model can be useful to assess areas of language comprehension and expression which are relatively impaired and intact and analyse individual patterns at single word/sentence level. Impairment-based therapy aiming to improve underlying language processing may be effective, including after the spontaneous recovery period. If central semantics (i.e. the store of word meanings) is significantly impaired, this is likely to be an effective area to target, as it impacts on comprehension and expression. This may be achieved, for example, by repeated spoken/written word to picture matching. It is important to select and work on a core vocabulary of greatest relevance to the patient. Depending on prognosis, therapy is likely to focus to a greater or lesser extent on using supportive communication techniques (e.g. the use of gesture, drawing, phonological/graphemic cueing to assist with word-finding difficulties). Using computer therapy and working with a patient's family can increase the frequency of therapy activities and improve outcome.

Therapy for dysarthria

There is some evidence that intensive oromotor and articulation exercises can help increase range and rate of movement of muscles to improve the intelligibility and quality of speech. This is most useful in non-progressive conditions (e.g. after stroke or traumatic brain injury).

Therapy particularly for progressive dysarthrias (e.g. in motor neuron disease) focuses on compensatory strategies to maximize intelligibility (e.g. using a slow speech rate, segmenting multisyllabic words, taking frequent breaths, managing fatigue). As the condition progresses, communication aids are usually introduced to supplement speech or as the main form of communication (e.g. an alphabet board; voice output communication aids, such as the Lightwriter™; or software packages on laptops or phones which can be accessed via a keyboard, switch, or eye gaze).

Prognosis

This depends on the nature of the underlying pathology. After stroke, most spontaneous recovery from dysphasia usually occurs within the first three months. Initial severity of the dysphasia is the single best predictor of outcome. Severe dysphasias might evolve into other dysphasia types; for example, a patient with severe global aphasia at the onset might develop Broca's with time. Overall, left-handedness is a positive prognostic marker.

How to handle uncertainty in the diagnosis

It is often difficult to put a dysphasia or dysarthria into a neat diagnostic category, and mixed types occur. In this case, focus on symptoms and signs in addition to the speech difficulty to reach a diagnosis.

44 Weakness

Cris S. Constantinescu and Su-Yin Lim

Definition of the symptom

Motor weakness is a decrease in muscle strength leading to an inability of a muscle or group of muscles to perform its usual function.

Differential diagnosis

The differential diagnosis of motor weakness ordered by probability is detailed in Box 44.1.

Various causes of motor weakness (Box 44.1) may be encountered in the primary and secondary care setting. Acute onset weakness is more frequently encountered in secondary care, whereas weakness of an insidious onset can present to both primary and secondary care.

CNS lesions may be caused by vascular disorders (haematoma, ischaemia), tumours, cysts, infections, cavitation/syrinx (spinal cord and brainstem), inflammation, or demyelination. Lesions in the brainstem are often vascular, inflammatory/demyelinating, or malignant in origin.

The list of conditions causing weakness associated with a generalized polyneuropathy is extensive and includes Guillain-Barré Syndrome (GBS), neuropathies associated with the vasculitides and connective tissue disorders, multifocal motor neuropathy, nutritional deficiencies (B₁₂, thiamine), drug or toxin-induced weakness (vinca alkaloids, isoniazid, heavy metals), malignancy (infiltrative and paraneoplastic), renal failure, endocrine disorders (hypothyroid or hyperthyroid), sarcoidosis, diabetes, paraprotein-related weakness, and amyloidosis. The most common hereditary neuropathy is Charcot-Marie-Tooth disease (CMT, or hereditary motor and sensory neuropathy).

Conditions that can affect the peripheral nerves in an asymmetrical pattern giving rise to a multiple mononeuropathy include vasculitides, connective tissue diseases, diabetes, sarcoidosis, Lyme disease, malignant infiltrative disease, HIV, and hepatitis C infection. Disorders of the cervical, brachial, or lumbosacral plexus can be caused by trauma, malignant infiltrative disease, vasculitis, infections (e.g. Lyme disease,

HIV) or may be idiopathic (e.g. neuralgic amyotrophy, known as brachial neuritis or Parsonage-Turner syndrome when it involves the brachial plexus).

Diseases of the muscles may be primary (muscular dystrophies) or secondary (thyroid myopathy, drug-induced myopathy) in origin, be associated with metabolic disorders (e.g. glycogen storage diseases) or mitochondrial disorders (Kearns-Sayre syndrome, chronic progressive external ophthalmoplegia, MELAS syndrome), or be part of a systemic inflammatory disorder (polymyositis, dermatomyositis). Disorders of the neuromuscular junction may be antibody mediated (myasthenia gravis, Lambert-Eaton myasthenia syndrome (LEMS)) or toxin induced (botulism). The main anterior horn cell disorders are motor neuron disease (MND), poliomyelitis, and spinal muscular atrophy.

Context

The origin of weakness may be localized to upper motor neurons, lower motor neurons (including nerve roots, nerve plexuses, and peripheral nerves), anterior horn cells, neuromuscular junctions, or muscles. The upper motor neurons responsible for voluntary movement consists of the neurons located in the motor cortex and corticospinal (or pyramidal) tracts and their various connecting interneurons. The lower motor neurons originate in the anterior horn of the spinal cord. On leaving the spinal cord, the lower motor neurons become organized into plexuses (cervical, brachial, and lumbosacral), subsequently forming peripheral nerves which synapse with the muscle cell membrane at the neuromuscular junction. In the brainstem, the lower motor neurons in the cranial nerve motor nuclei innervate the muscles responsible for eye movements, speech, and swallowing.

Approach to diagnosis

Clinical history

The patient's description of weakness must first be clarified and differentiated from malaise, lassitude, or fatigue, although fatigue itself is frequently present in neuromuscular diseases. A thorough history should include details of the onset and time course (acute, subacute, or chronic), pattern (e.g. generalized, hemiparetic, paraparetic, or monomelic; distal or proximal; symmetrical or asymmetrical; focal or multifocal), progression or worsening of symptoms, associated symptoms, past medical history, family history, drug history, travel history, and social history. Patients may volunteer examples of functional impairment pointing towards a pattern of weakness; for example, difficulty rising from a chair or from squatting may indicate proximal muscle weakness, whereas difficulty opening jars or tripping may indicate distal weakness in the upper limbs.

A general medical evaluation should be done, with particular attention paid to respiratory and cardiovascular function, skin changes, thyroid function, skeletal deformities, and the presence of lymphadenopathy, fever, or weight loss.

Examination

Examination of the motor system should include an assessment of muscle bulk, tone, strength, reflexes, and gait. Other associated neurological features such as cranial nerve dysfunction, visual field defects, speech abnormalities, ataxia, sensory disturbance, and musculoskeletal deformities should be sought.

Muscle bulk

Atrophy with fasciculations may appear within a few weeks of onset of weakness caused by a polyneuropathy. Fasciculations may

Box 44.1 Causes of motor weakness and main differential diagnoses

Cause of motor weakness

- central nervous system disorders
- peripheral nerve disorders
- neuromuscular junction disorders
- muscle disorders
- anterior horn cell disorders

Main differential diagnoses

- acute stroke or TIA
- brain tumour (primary or metastatic)
- demyelination (e.g. multiple sclerosis)
- generalized polyneuropathy (various causes)
- multiple mononeuropathy (various causes)
- plexopathy (various causes)
- myasthenia gravis
- botulism
- Lambert-Eaton myasthenic syndrome
- muscular dystrophies
- other myopathies (various causes)
- motor neuron disease; amyotrophic lateral sclerosis
- poliomyelitis

be localized in a radiculopathy. Muscle hypertrophy may be seen in some muscular dystrophies (e.g. pseudohypertrophy of the calf muscles, a classical finding).

Tone

Flaccid weakness points to a lower motor neuron disorder. However, acute upper motor neuron disorders can present with a flaccid weakness at onset. Hypertonia in upper motor neuron disorders appear days or weeks later, typically resulting in a 'clasp-knife' rigidity. Ankle clonus may be elicited in upper motor neuron disorders.

Strength

Muscle strength may be assessed manually by muscle resistance testing or by functional testing. Strength is usually graded using the 6-point BMRC (British Medical Research Council) scale (Table 44.1). Functional testing such as tiptoe and heel walking can be used to evaluate distal lower limb power, whereas the patient's ability to stand from sitting unaided reflects proximal muscle power. Grip strength can be quantitatively assessed using a dynamometer.

Typically but not always, pyramidal weakness of the upper limbs has a predilection for extensors over the flexor muscles, whereas in the lower limbs the flexors are weaker than the extensors. Testing for a pronator drift is useful for eliciting a mild pyramidal weakness.

Pattern and distribution of weakness

Table 44.2 summarizes the most common patterns of weakness which help localize the site of the lesion.

Reflexes

Tendon reflexes are diminished or absent in lower motor neuron disorders and exaggerated in upper motor neuron disorders. In lower motor neuron disorders, the distribution of the diminished reflexes can help to localize the lesion. For instance, a diminished/absent ankle jerk could indicate a lesion of the S1 nerve root or the sciatic nerve on the same side.

A spinal cord lesion may cause tendon reflexes to be diminished at the level of the lesion, but exaggerated below it. The plantar response is typically extensor in upper motor neuron disorders.

Tendon reflexes are preserved in myasthenia gravis (MG) and botulism but are reduced or absent in LEMS. In LEMS, facilitation of reflexes (appearance after repeated muscle contraction) is characteristic.

Tendon reflexes may be preserved or reduced in myopathies.

Gait

A waddling gait is typical of proximal muscle weakness. A high-stepping gait is seen in ankle dorsiflexion weakness (foot drop). A scissoring gait, caused by a tendency to adduct both hips, occurs in a spastic paraparesis.

Specific clues to the diagnosis

Symptom onset and time course

Sudden onset of weakness without warning is suggestive of a vascular cause such as an ischaemic or haemorrhagic stroke.

Table 44.1 Strength grading using the 6-point BMRC (British Medical Research Council) scale

BMRC scale	Evaluation
0	No movement observed
1	Flicker or trace of movement observed
2	Active movement with gravity eliminated
3	Active movement against gravity
4	Active movement against resistance
5	Normal strength

Adapted from Medical Research Council Aids to the examination of the peripheral nervous system, Memorandum no. 45, Her Majesty's Stationery Office, London, 1981. Used with the permission of the Medical Research Council.

Subacute onset over days is typical of GBS, vasculitic neuropathy, polymyositis, and acute CNS demyelination (e.g. multiple sclerosis, inflammatory myelitis).

A more insidious onset with progressive symptoms over weeks to months is seen in space-occupying lesions such as tumours and vascular malformations, neurodegenerative conditions such as MND, neurosarcoidosis, and many peripheral nerve diseases. Progression over years can be seen in certain muscular dystrophies.

Fluctuating weakness is characteristic of MG and mitochondrial and metabolic muscle disorders, where it is precipitated by activity.

Weakness caused by vasculitis, chronic inflammatory demyelinating radiculoneuropathy (CIDP), multiple sclerosis (MS), or porphyria may demonstrate a relapsing pattern.

A childhood history of poor motor skills or slow development point towards a hereditary or genetic cause of weakness, such as hereditary spastic paraparesis, muscular dystrophy, and various forms of CMT.

Involvement of the motor system only

Sensory signs are absent in myopathies, neuromuscular junction disorders, pure motor neuropathies, and anterior horn cell disease (e.g. MND), although some patients may complain of mild sensory symptoms. A pure motor neuropathy should be differentiated from MND. Variants of GBS, lead toxicity, and a subtype of CMT may present with a pure motor neuropathy.

Involvement of the sensory system

In upper motor neurons, sensory signs may be seen in cerebral, brainstem, and spinal cord lesions. In lower motor neurons, sensory signs are present in peripheral nerve disorders, including radiculopathies, plexopathies, mononeuropathies, and the various causes of polyneuropathies.

Involvement of the autonomic nervous system

Autonomic disturbance (e.g. orthostatic hypotension, cardiac arrhythmias, pupillary dysfunction, urinary retention) is often present in some polyneuropathies (e.g. in GBS, amyloidosis, and diabetes), LEMs, and botulism.

Involvement of the cranial muscles

An upper motor neuron pattern of facial weakness (forehead sparing) is seen in brainstem lesions of various causes. A lower motor neuron pattern of facial weakness is seen in vasculitis, neurosarcoidosis, Lyme disease, GBS, MG, botulism, HIV infection, myotonic dystrophy, mitochondrial myopathies, the fascioscapulohumeral and oculopharyngeal forms of muscular dystrophy, and idiopathic Bell's palsy.

Bulbar weakness causing dysarthria and dysphagia occurs in brainstem lesions, MND, GBS, MG, botulism, myotonic dystrophy, muscular dystrophy (oculopharyngeal form), thyroid myopathy, and inflammatory myopathies. Wasting and fasciculations of the tongue raises a strong suspicion of MND.

Weakness of the extraocular muscles giving rise to an ophthalmoplegia may be present in brainstem disorders, variants of GBS (e.g. Miller Fisher syndrome), MG, botulism, mitochondrial myopathies, and the oculopharyngeal form of muscular dystrophy.

Involvement of the sphincter muscles

Sphincteric disturbance (urinary retention and loss of anal tone) with a sensory level is highly suggestive of a spinal cord lesion.

Sphincteric disturbance with 'saddle' anaesthesia and lower limb weakness is suggestive of a lesion of the conus medullaris or cauda equina. Conus medullaris lesions tend to present with bilateral mixed upper motor neuron and lower motor neuron signs (brisk knee jerks and absent ankle jerks, occasionally with fasciculations) whereas cauda equina lesions present with lower motor neuron signs which are often unilateral or bilateral and asymmetrical.

Involvement of the respiratory system

Neuromuscular disorders may present with respiratory dysfunction due to diaphragmatic and respiratory muscle weakness.

Table 44.2 Weakness patterns that help localize the site of the lesion

UMN or LMN signs	Distribution of weakness	Likely location of lesion
UMN	Hemiparesis Hemiparesis with cranial nerve deficits Tetraparesis Tetraparesis with cranial nerve deficits Paraparesis of the lower limbs	Contralateral cerebral hemisphere Brainstem Spinal cord (cervical) Brainstem Spinal cord (thoracic)
LMN	All four limbs, facial, ocular, and bulbar weakness All four limbs, predominantly proximal weakness All four limbs, predominantly distal weakness Facial, ocular, and bulbar Focal, asymmetric (single limb) Multifocal, asymmetric (more than one limb)	Neuromuscular junction Muscle (myopathy, dystrophy) Peripheral nerves (peripheral neuropathy) Cranial nerves (cranial neuropathy) Nerve root (radiculopathy), plexus (plexopathy), or peripheral nerve (mononeuropathy) Peripheral nerves (multiple mononeuropathy)
Mixed UMN and LMN	All four limbs with bulbar and facial weakness but no ocular involvement Paraparesis of the lower limbs	Anterior horn cell Conus medullaris

Abbreviations: LMN, lower motor neuron; UMN, upper motor neuron.

Symptoms include dyspnoea, orthopnoea, and morning headaches and, if severe, may result in respiratory arrest. Acute onset of respiratory failure is seen in GBS, MG, and botulism, whereas a gradual, progressive worsening is seen in MND and the muscular dystrophies (Duchenne, myotonic dystrophy, and limb-girdle forms).

Damage to the spinal cord may result in diaphragmatic weakness (C3–C5) and intercostal muscle weakness (T1–T11).

Respiratory muscle function may be assessed at the bedside by asking the patient to cough or sniff (diaphragmatic function), observing for paradoxical abdominal movements on inspiration, and measuring their forced vital capacity (FVC). Elective intubation should be considered if FVC falls below 15 ml/kg.

Lesions of the brainstem can adversely affect respiratory function through depression of the respiratory drive.

Other signs and symptoms

Muscle pain or myalgia can occur in an inflammatory myopathy and myotonic dystrophy. Neuropathic pain often occurs with a vasculitic neuropathy, radiculopathy, and compressive neuropathy. Shoulder pain is usually present in brachial neuritis. Back pain is a typical feature of cord compression but may also appear in GBS.

Myotonia is the slow relaxation of skeletal muscle after contraction (e.g. with handgrip), typically seen in myotonic dystrophy. Other features characteristic of this condition include frontal balding and temporalis wasting (myotonic facies), cataracts, cardiac arrhythmias, and cardiomyopathy.

Muscle cramps and exercise intolerance may indicate a metabolic myopathy, mitochondrial myopathy, or a myotonic dystrophy.

Trophic changes may be present in peripheral nerve disorders. A skin rash is often a hallmark of a vasculitic process or may be associated with a connective tissue disorder.

Drug and social history

Chronic alcoholism and malabsorption syndromes predispose to subacute combined degeneration of the spinal cord (vitamin B₁₂ deficiency) and a thiamine deficiency-related sensory–motor neuropathy. Injecting drugs users are at risk of botulism and embolic strokes. Patients on statins or steroids can rarely suffer from a drug-induced myopathy. Certain cytotoxic chemotherapy drugs (e.g. vinca alkaloids) can be associated with a sensory–motor peripheral neuropathy.

Key diagnostic tests

Medical imaging

CT is useful in the emergency setting, such as when an intra-cerebral bleed, ischaemic stroke, solid tumour, or acute cord compression is suspected to be the cause of weakness. Magnetic resonance imaging,

however, is preferable over CT as a diagnostic aid due to the superior image resolution and sensitivity to soft tissue pathology. The finding of weakness with a possible upper motor neuron origin or weakness affecting the cranial muscles should prompt an MRI of the relevant segment of the neuroaxis. MRI is also useful in demonstrating nerve root impingement in radiculopathies, inflammation, or compression in plexopathies and to identify subclinical changes or the pattern of affected muscles in myopathies.

CSF analysis

Barring contraindications to lumbar puncture, CSF analysis may be undertaken to aid the diagnosis of an inflammatory, infective, or malignant cause of weakness affecting the central nervous system or spinal roots. In the context of weakness, raised CSF protein is seen in infections, intra-cerebral haemorrhage, malignant infiltration, and inflammatory disorders such as GBS, CIDP, and MS. Oligoclonal bands have a relatively high specificity for MS, although they may also be present in vasculitis of the CNS, neurosarcooidosis, Lyme disease, and viral infections.

Neurophysiological studies

Electromyography (EMG) may aid in the differentiation between weakness of a neuropathic cause or a myopathic origin and can assist in localizing the lesion in a plexopathies, radiculopathies, or mononeuropathies. Findings in MND characteristically reflect denervation (fibrillation potentials, giant motor unit potentials, and positive sharp waves) and reinnervation changes (increased jitter). Myopathies typically demonstrate spontaneous activity with fibrillations, positive sharp waves, and low-amplitude polyphasic action potentials of a short duration.

Nerve conduction studies can differentiate axonal from demyelinating peripheral neuropathies. In demyelination, distal motor latency is prolonged and motor conduction velocity is slowed. In axonal neuropathies, the compound muscle action potential is reduced but the distal motor latency and conduction velocity can be preserved. In nerve entrapment, there is slowing of nerve conduction at the site of compression.

Repetitive nerve stimulation is performed in suspected myasthenic syndromes, showing characteristic decrement in the compound muscle action potential in MG and an increment in LEMS.

Somatosensory, visual, and brainstem auditory evoked potentials are useful in the assessment of CNS conduction, particularly in cases of suspected MS.

Nerve and muscle biopsy

Peripheral nerve biopsy (usually sural or radial nerve) is indicated where a vasculitic or neoplastic cause of a peripheral neuropathy is suspected. Muscle biopsy (usually quadriceps) is performed in cases of suspected myositis, muscular dystrophy, and mitochondrial and metabolic myopathies, aided by immunostaining and electron microscopy.

Other diagnostic tests

In generalized polyneuropathies, tests that need to be considered include antiganglioside antibodies (in suspected GBS), thyroid function, fasting blood glucose, vitamins A, E, and B₁₂, erythrocyte sedimentation rate, antinuclear antibodies (ANA), antineutrophil cytoplasmic antibody (ANCA), serum electrophoresis, and serum angiotensin-converting enzyme (ACE).

Creatine kinase (CK) is released by muscles during breakdown. CK levels are raised in inflammatory and immune myopathies, Duchenne dystrophy, and Becker dystrophy. However, CK may also be increased in Afro-Caribbeans in the absence of pathology. Trauma, sepsis, or exercise can also increase CK levels.

Tests for metabolic and mitochondrial myopathies include serum and CSF lactate, urinary organic acids, and serum and urine carnitine levels.

In MG, anti-acetylcholine antibodies and/or muscle-specific kinase (MuSK) antibodies may be present. To aid in the diagnosis further, an edrophonium test can be performed, consisting of an intravenous bolus injection of edrophonium, a short-acting acetyl-cholinesterase inhibitor, which causes a brief but marked improvement of symptoms in patients with the condition.

Paraneoplastic causes of weakness are very rare and can take the form of a myelitis, motor neuropathy, myopathy, or a neuromuscular junction disorder. The underlying pathogenesis is believed to be autoimmune. However, in most cases, an antibody is not identified. Voltage-gated calcium channel antibodies are associated with LEMS, a neuromuscular junction disorder which may present as a paraneoplastic syndrome. A skeletal survey, chest and abdominal CT, or whole-body PET may help localize a malignancy in a suspected paraneoplastic syndrome.

Genetic tests are conducted in suspected hereditary neuropathies and myopathies, usually guided by the history, examination, and clinical findings. Techniques include cytogenetics, DNA mutation tests, and microarrays.

Introduction to therapy

Therapy is tailored to treating the underlying cause of weakness and symptoms that arise from it. Neurosurgical intervention may be sought for compressive or space-occupying lesions of the brain and spinal cord. Therapy for ischaemic stroke comprises of antiplatelet therapy, anticoagulation therapy, thrombolytic therapy (where indicated), secondary prevention, and neurerehabilitation. Disease activity in inflammatory and immune-mediated conditions may be controlled by steroids and/or immunosuppressants. Malignant tumours may be treated with surgical debulking, radiotherapy, and/or chemotherapy, depending on tumour type and location.

Supportive therapy in the form of mechanical ventilation may be required for patients with respiratory muscle weakness. Enteral feeding via a gastrostomy or jejunostomy should be considered in those with bulbar weakness who are at risk of aspiration. Skeletal muscle relaxants (such as baclofen and tizanidine) are used to treat spasticity and recurrent muscle spasms. Regular Botox injections can help relieve spasticity and dystonias. Further supportive care is provided by physiotherapists and occupational therapists.

Specific treatments

GBS is treated with intravenous immunoglobulin (IVIg) typically at a dose of 0.4 g/kg day⁻¹ for 5 days, or plasma exchange. Therapy is generally indicated if the patient is no longer able to walk. IVIg is preferred over plasma exchange, as it is much easier to administer. Patients require regular monitoring of their respiratory function (FVC) and cardiovascular function (cardiac rhythm and blood pressure).

CIDP can be treated with long-term corticosteroids, intravenous immunoglobulins, or plasma exchange. In patients who cannot have the aforementioned therapy or fail to respond adequately to them, immunosuppressive therapy (such as azathioprine and mycophenolate mofetil) may be considered.

Treatment for MND is largely supportive and consists of physiotherapy, occupational therapy, nutritional support, respiratory

support, and social support. Riluzole 50 mg orally twice a day may extend survival modestly, although it has not been shown to improve strength or quality of life.

Treatment strategies for MG depend on the severity of symptoms, the age of the patient, the presence of a thymoma, and other related comorbidities. Patients with mild symptoms may require only symptomatic therapy with an anticholinesterase drug (i.e. pyridostigmine). For those who remain symptomatic on anticholinesterases or have more generalized weakness, treatment with corticosteroids is usually initiated along with bone and gastric protection. Immunosuppressive therapy (e.g. azathioprine) is often used as a steroid-sparing agent and for those who do not adequately respond to pyridostigmine and steroids. Thymectomy may be considered in seropositive patients under 60 years of age, and in all patients with thymoma. In a myasthenic crisis, plasma exchange or IVIg is used as acute therapy.

Treatment for MS is predominantly with immunomodulatory drugs such as glatiramer acetate, interferon beta, and natalizumab, which aim to reduce relapse rates. High-dose corticosteroids are used in the management of acute relapses to aid in the recovery rate.

No specific therapy is available for the majority of the hereditary and metabolic neuromuscular disorders. Treatment is supportive.

Prognosis

Prognosis largely depends on the cause of the motor weakness, treatment, and the presence/absence of complicating factors. In many causes of neuromuscular weakness, prognosis is poorer in patients who have cardiorespiratory involvement and in those who acquire the disease at an older age. Nonetheless, the prognosis for many such disorders has vastly improved with the use of ventilatory support, cardiac intervention, antibiotics, and immunosuppressive and immune-modulatory treatments. Prognostic factors for specific conditions are discussed as follows.

Poorer prognosis in GBS is associated with older age, ventilator dependency, campylobacter infection, and axonal neuropathy. Mortality is as high as 8%. One-third of patients have significant residual disability despite treatment.

The vast majority of CIDP patients (90%) respond well to therapy. However, at least 50% relapse within 4 years, and less than a third achieve remission off treatment.

The prognosis of MND remains very poor. Mean survival time from diagnosis is 2 years in the classical form. Prognosis is worse in patients who are older and those with a rapid decline following initial diagnosis.

Poor prognostic factors in MS include older age of onset, male sex, progressive course at onset, early residual disability, short inter-relapse interval, and high early relapse rates. The majority of patients with relapsing–remitting MS eventually demonstrate secondary progression.

How to handle uncertainty in the diagnosis of this symptom

Not infrequently, investigative test results do not correlate with the clinical examination findings of weakness. The approach to this issue is to retake the clinical history and carefully re-examine the patient, either noting any inconsistencies or confirming one's earlier findings. Neurological signs and symptoms have a tendency to evolve over a period of time, often becoming clearer or more distinct as the illness progresses.

Tests results including imaging findings should be re-evaluated in the correct context. Diagnostic tests performed too early or in mild disease states may yield normal results. Examples include the frequent finding of a normal CT scan in an acute stroke, and normal cerebrospinal fluid markers with normal electrophysiological readings in early GBS.

Alternative diagnoses are often worth considering. Migraines and epilepsy can present with episodes of brief motor dysfunction which can mimic TIAs or strokes. In the elderly, fractures and joint dislocation may present with painless loss of limb function.

Non-neurological or non-organic muscle weakness is commonly encountered in the clinical setting. This could be considered if inconsistencies are demonstrated in the history, and examination findings with the clear presence of strong indicators of a somatization disorder in the patient's past medical history (which is usually notable for abnormal illness behaviour), their social history (substance abuse and self-harm are often evident,) and their mental state (frequently coexisting depression, anxiety, or a personality disorder).

45 Tremor and other abnormal movements

Susanne Schneider, Alexander Schmidt, Kailash P. Bhatia, and Peter G. Bain

Definition of the symptom

Tremor is a rhythmic involuntary oscillatory movement of a body part most commonly affecting the hands and arms but other body parts can also be affected including the legs, head, jaw, chin, palate, voice, and trunk.

Differential diagnosis

The broad differential diagnosis in primary and secondary care is shown in Table 45.1, ordered in decreasing probability.

Context

Tremor is the most common movement disorder. Estimates of the prevalence of tremor vary widely and range up to about 20% of the general population. It is more common in the elderly. For the most common type of tremor, essential tremor (ET), an annual incidence has been reported to be 23.7 per 100 000; and a prevalence of 0.4 to 6% has been reported for those over 40 years, and of 12% for those over 70 years.

There are multiple ways to classify tremor, for example, by clinical features, by tremor frequency, by aetiology, and so on. The International Movement Disorders Society classifies tremor according to the behavioural state in which it occurs, namely, at rest or on action, as this can give a clue towards the aetiology. The most common cause of rest tremor is idiopathic Parkinson's disease (PD). Action tremor comprises postural tremor (when the arms are outstretched) and kinetic tremor (during movement; this includes intention tremor which occurs during a goal-directed movement like the finger–nose test). The most common causes of action tremor are ET and cerebellar dysfunction resulting from different causes. Task-specific tremors are brought on by or are most prominent during a specific task, for example, hand tremor during writing or when playing a particular musical instrument.

Approach to diagnosis

The key to the diagnosis of different forms of tremor is the clinical examination of patients. As a first step, patients should be examined at rest for tremor of arms, legs, and the head. The arms should be relaxed and fully supported on chair rests to observe for rest tremor.

Next, the patients are instructed to hold their arms outstretched in front of them, which will bring out the postural component of tremor—sometimes after a pause (as in PD). Dystonic posturing may be present in the hands, arms, shoulder, or neck and indicates a dystonic tremor syndrome. The finger–nose test will disclose intention tremor, as in cerebellar disease. Further useful tests include writing, which brings on primary task-specific writing tremor, or drawing a spiral, which documents the tremor. Holding a cup or pouring water from one glass into another demonstrates the functional impact of arm tremor. If slowness or fatiguing of movements on repetitive finger and foot tapping is present, a parkinsonian disorder should be considered. A broad-based gait in addition to intention tremor can hint towards a cerebellar disorder.

Specific clues to the diagnosis

There are several specific clues from the medical history and clinical examination to the underlying diagnosis of different tremor types.

In primary care, common causes of tremor include:

- drugs (e.g. dopamine-blocking agents, antidepressants, lithium, sympathomimetic agents, antiasthmatics, sodium valproate, and other antiepileptics)
- toxins (e.g. amphetamines, caffeine, nicotine, alcohol)
- medical and metabolic conditions (e.g. hyperthyroidism); the presence of associated symptoms like diarrhoea, weight loss, or palpitations can help to confirm the diagnosis

A physiological form of tremor is seen in all healthy people during muscle activation and is a fine postural tremor with frequencies ranging from <6 Hz (in children) to 13 Hz (in adults). Normally, it does not interfere with daily activities but it can become aggravated in stressful situations, for example, from the anxiety before a public performance (enhanced physiological tremor), and in chronic anxiety states. In addition, many drugs and conditions will aggravate a preexisting physiological tremor. It is treated by reassurance, avoidance of the triggering factors, and treatment of any underlying anxiety disorder.

In secondary care, causes of tremor include (ordered in decreasing probability):

- ET
- PD
- atypical parkinsonism

Table 45.1 Differential diagnosis of tremor

Patient seen in primary care	Probability	Patient seen in secondary care	Probability
Drug-induced tremor (e.g. via dopamine-blocking agents, antidepressants, lithium, sympathomimetic agents, antiasthmatics (beta agonists), sodium valproate, or other anticonvulsants)	Common	Essential tremor	Common
Toxin-induced tremor (e.g. via caffeine, nicotine, alcohol)		Parkinson's disease	
Tremor due to medical conditions (e.g. hyperthyroidism)	Less common	Dystonic tremor	Less common
Enhanced physiological tremor		Cerebellar tremor	
Essential tremor		Atypical parkinsonism	
Parkinson's disease		Psychogenic tremor	
Cerebellar tremor		Orthostatic tremor	
Atypical parkinsonism		Peripheral neuropathies	
Holmes tremor		Holmes tremor	
Other (see less common causes of secondary care)	Wilson's disease		
	Palatal tremor		
	Chin tremor		
	Other (see common causes of primary care)		

- cerebellar tremor
- dystonic tremor
- Holmes tremor
- fragile X syndrome / FXTAS (Fragile X associated tremor ataxia syndrome)
- peripheral neuropathy
- Wilson's disease
- orthostatic tremor
- palatal tremor
- tremor of the chin and the lower jaw
- psychogenic tremor

ET

ET comes into consideration in patients of all ages, many with a positive family history of tremor. It is characterized by a symmetrical 4–12 Hz postural and kinetic tremor of the arms. In severe cases, the head and the voice may be also affected. Age of onset peaks in the second and sixth decades. Exclusion criteria are the presence of other neurological signs or a history of recent neurological trauma, a sudden onset, an isolated position- or task-specific tremor, and an isolated tremor of the voice, chin, tongue, or legs. Many patients (40%–75%) note improvement after alcohol intake but rebound worsening hours later is typical. A positive family history is common (50%–70%) and genetic linkage has revealed three regions of interest (2p22–25, 3q13, and 6p23) but no specific gene mutation has yet been reported. The location of the oscillator of ET also remains unknown but dysfunction of the cerebellum, the thalamus, and brainstem regions including the inferior olive, the nucleus coeruleus, and the red nucleus is suggested.

PD

PD should be considered in elderly patients where the tremor is present at rest. Although PD is a relatively common disorder, it is rare in community general practice, with a prevalence of about 100 to 150 cases per 100 000. The tremor typically presents as an asymmetric rest tremor, with a pill-rolling motion between the thumb and the index finger at rest at a frequency of 4–6 Hz being characteristic. An additional postural tremor at the same frequency or slightly faster is seen in over 50% of patients. Other features, including hypomimia, slowness and fatiguing of repetitive finger movements, small handwriting, slow gait, postural instability, and rigidity, support the diagnosis but may be subtle in the tremor-dominant variant of PD.

Atypical parkinsonism

Other parkinsonian disorders apart from PD, so-called atypical parkinsonism, may also present with tremor, but are rare. Although rest tremor is present in 30%–40% of patients with multisystem atrophy, a typical pill-rolling rest tremor (as in PD) is seen in only 8% of cases. In other atypical parkinsonian conditions like corticobasal degeneration and progressive supranuclear palsy, resting tremor is seen in approximately 20% of cases but again typical rest tremor (of PD) is not seen.

Cerebellar tremor

Cerebellar tremor, typically seen in multiple sclerosis, manifests as a low-frequency, coarse, terminal tremor during a goal-directed movement. Additional postural tremor may be present. Rest tremor is usually absent. Other signs of cerebellar disease may be present including ataxic gait, nystagmus, dysarthria with slurred or saccadic speech, hypometria, and dysdiadochokinesis. Causative lesions on imaging may be found within the cerebellum, particularly in the superior cerebellar peduncle and the dentate nucleus, as well as the afferent and efferent tracts but a clear correlation between location of the lesion and tremor features may not be ascertained. Other causes of cerebellar tremor include cerebellar infarction, spinocerebellar degeneration, and Friedreich's ataxia.

Dystonic tremor

Dystonic tremor is often present in patients with different types of dystonia. For example, patients with spasmodic torticollis often have tremor in addition causing a head shake. Sometimes tremor may even be more prominent than the dystonia, resulting in possible confusion with the diagnosis of ET. Tremor can be present in the part that is also affected with dystonia (dystonic tremor) or in

a part of the body that is separate from that affected by dystonia (dystonia-associated tremor). Head tremor in association with cervical dystonia is the most common presentation but the arms are also often involved, typically by a postural tremor that worsens during the performance of fine tasks. Patients often describe a sensory trick to improve their dystonia or dystonic tremor; for example, touching themselves lightly in the face or the neck (*geste antagoniste*) to control cervical dystonia. A broad range of tremor frequencies has been found (mainly less than 7 Hz).

Dystonic tremor may also have a resting component and may then be confused with PD tremor (discussed in the recent literature under the eponym SWEDDs (subjects without evidence of dopaminergic deficits)). It is thus important to carefully assess patients with a resting tremor for true bradykinesia and subtle signs of dystonia.

Holmes tremor

Holmes tremor is usually a unilateral or an asymmetrical tremor caused by lesions in the midbrain or thalamus. It typically consists of a combination of resting tremor, postural tremor, and severe intention tremor. Common causes include vascular lesions (e.g. Benedikt's syndrome), and toxoplasmosis in HIV-positive patients.

Fragile X syndrome

Fragile X syndrome is a trinucleotide-repeat disorder and the most common cause of inherited mental retardation. Recently, the permutation expansion (55–200 CCG repeats) has been related to the 'fragile X-associated tremor/ataxia syndrome' (FXTAS). The main clinical features are intention tremor and cerebellar ataxia, affecting men over 50 years. It may therefore be confused with multiple system atrophy in the elderly. Cognitive decline, parkinsonism, peripheral neuropathy, and autonomic dysfunction may be seen in FXTAS and these may be clinical clues towards this diagnosis. MRI brain scans show a characteristic appearance, with an increased T2 signal in the middle cerebellar peduncles and around the dentate nuclei.

Peripheral neuropathy

Peripheral neuropathies, particularly chronic inflammatory demyelinating neuropathies (especially during relapses), immunoglobulin M chronic paraproteinaemic demyelinating neuropathy, and the hereditary motor and sensory neuropathy type 1, are differential diagnoses of upper limb action tremor (postural and kinetic). Tremor can occur in the absence of sensory loss. Frequency is between 3 and 6 Hz in hand muscles.

Wilson's disease

Wilson's disease should be excluded in any patient with tremor under 50 years old. Other features that suggest this condition are dysarthria, dystonia, and parkinsonism. Serum caeruloplasmin is low in these patients (<20 mg per decilitre) and a Kayser-Fleischer ring of the cornea is visible in 99.3% of patients on slit lamp examination.

Orthostatic tremor

Orthostatic tremor is a distinct disorder defined by a high frequency (13–18 Hz) tremor of the leg muscles (quadriceps and gastrocnemius) when standing and is sometimes not visible but palpable only. Patients may report subjective unsteadiness during stance which is absent when walking.

Palatal tremor

Palatal tremor is defined by rhythmic contractions of the levator or tensor veli palatini muscle (1.5–3 Hz). Synchronous ear clicks accompany the movements in some patients.

Tremor of the chin and lower jaw

Tremor of the chin and the lower jaw (hereditary geniospasm) is a rare condition with autosomal dominant inheritance and early onset.

Psychogenic tremor

Psychogenic tremor is a positive diagnosis. Suggestive features include sudden onset, static course, spontaneous remission, clinical inconsistencies with distractibility of tremor frequency, lack of

responsiveness to treatment, somatizations, presence of psychiatric disease, and secondary gain.

Key diagnostic tests

Key diagnostic tests for the underlying diagnosis of different tremor types are routine blood tests, which should include those for thyroid function, liver function, and kidney function, as well as electrolyte status and protein electrophoresis. Serum caeruloplasmin and copper assays should be performed in all patients under 50 who present with tremor, to exclude Wilson's disease.

Other diagnostic tests

Other investigations used mainly in secondary care include electrophysiological investigations, particularly electromyography and accelerometry studies, which can help to evaluate tremor characteristics like frequency, amplitude, and coherence. Differentiation of ET and dystonic tremor from tremor due to PD or Parkinson-plus syndromes is facilitated by new imaging techniques (like dopamine transporter (DaT) SPECT or fluorodopa PET) used to visualize presynaptic dopaminergic neuron integrity, which is reduced in PD but normal in ET and dystonic tremor. Cerebral imaging methods (CT and MRI) and lumbar puncture can also help to identify tremor-causing diseases.

Introduction to therapy

Mild tremor does usually not require treatment. However, as severe tremor has an impact on the quality of life and daily activities, different drugs have been investigated for their efficacy to improve tremor. Overall, symptomatic drug treatment is unsatisfactory, as exemplified by the long list of drugs mentioned in the literature to improve tremor. In ET, a non-selective beta blocker, particularly propranolol or primidone (or a combination of them), are recommended as first-line treatments, with a Class A level of evidence. Other beta blockers may also reduce tremor but are usually less effective than propranolol. There is no difference between the long-acting and the normal formulation of propranolol. It is advisable to titrate propranolol or primidone carefully upwards to minimize side effects when these drugs are utilized. Second-line anti-ET drugs include benzodiazepines, topiramate, and gabapentin (Class B and C evidence). In PD, levodopa and dopamine agonists (like pramipexole or ropinirole) are first-line treatments for tremor, bradykinesia, and rigidity. Anticholinergics and beta blockers may also be considered, especially in tremor-dominant PD. Treatment of cerebellar tremor is more difficult. Clonazepam or beta blockers may be helpful. Botulinum toxin injections are

helpful in dystonic tremor and may improve tremor of head, jaw, chin, palate, and voice when oral drugs are ineffective.

Surgical intervention may be considered in patients with disabling drug-resistant tremors. The thalamus, which is involved in tremorgenesis of various tremor types, is the traditional target (particularly the ventral intermediate nucleus). However, the zona incerta is now considered the most effective target for suppressing most tremors. Historically, thalamotomy played a role but has now largely been replaced by deep brain stimulation (DBS) because of fewer adverse effects and greater functional benefits following DBS. Suppression of tremor by DBS ranged from 68% to 89% in patients with ET and from 71% to 94% in patients with PD. In multiple sclerosis, DBS tends to be less successful and is associated with a greater risk of adverse events. Most recently, noninvasive magnetic resonance-guided focused ultrasound has also been proposed for treatment of disabling tremor.

Prognosis

The prognosis of tremor depends on the underlying disease. In most tremor types, the life expectancy is normal. However, depending on tremor severity, it can be very disabling and socially embarrassing. The uncontrollable shakiness of the hands forces 15%–25% of patients with ET to retire prematurely, 60% of patients choose not to apply for a job or a promotion, and up to 55% of patients do not go shopping alone because of the tremor. If other neurological signs are present on clinical examination (e.g. slowness or fatiguing of movements, a broad-based gait) and parkinsonian or cerebellar disorders are suspected, the prognosis may be significantly impaired. Consequently, these patients need specialist neurologic workup.

How to handle uncertainty in the diagnosis of this symptom

Uncertainty in the diagnosis of tremor is rare, as this symptom is easy to recognize. However, establishing the correct aetiology of a particular tremor type may be very difficult, even for movement disorder specialists. If a detailed medical history and clinical examination of patients in combination with routine blood tests does not lead to a diagnosis, a specialist neurologic workup is needed.

46 Gait disorders

Richard Abbott

Introduction

Gait problems can arise from a number of different causes ranging from primary neurological to locomotor conditions. Prevalence increases with age, and causation is often multifactorial. Falls are a frequent consequence.

Definition of gait disorder

A gait disorder is an abnormality in the manner of walking; it results from a loss of smoothness, symmetry, or synchrony of movement patterns.

Patterns of gait disorder

Neurological and non-neurological patterns of gait disorder are given in Box 46.1.

Context

Difficulty with walking is a relatively common clinical problem, and the causation is often self-evident. Leg deformity resulting from previous trauma, and hemiparesis caused by a recent stroke, are examples. In a less simple scenario, pattern recognition may allow spot diagnosis by the experienced clinician. However, a full history and examination will usually be required to back up initial observation, and the presence of additional neurological signs, for example, nystagmus in the patient with a wide-based gait, will corroborate suspicions of cerebellar disease.

The clinical impressions may need to be followed by further investigations but the direction taken will be guided by the initial clinical assessment. More complex gait analysis techniques are rarely required for diagnosis but can be used as an aid to treatment and prognosis.

Approach to diagnosis

A detailed history is essential but, even prior to taking this, the opportunity will arise to watch the patient on entering the room. Observe whether they are accompanied and whether they require a walking aid. Do not assume that a patient in a wheelchair cannot walk, as there may be some other reason for the wheelchair,

such as reduced exercise tolerance or painful feet! In the ambulant patient, watch progress closely; observe the general demeanour, stance, and posture, look for asymmetry of limb movement, and assess whether balance appears to be an issue. Listening closely may also herald the high step and flop of a dropped foot or the dragging of a spastic leg.

While the history is being taken, the opportunity will arise to assess behaviour, personality, and mood, to observe the presence of involuntary movements, and to assess the speech. The presence of dysarthria, dysphonia, or dysphasia will hint strongly at the presence of a neurological disorder and also be a pointer to the neurological system involved.

Neurological examination will follow and it is often convenient to examine gait at the outset before the patient is disrobed and asked to climb onto the examining couch. A suggested approach to routine gait examination is to ask the patient to proceed as in Box 46.2.

Extrapyramidal problem

Observe rising from a low chair, an activity which may prove difficult. Problems in initiating gait, as well as slow movements, flexed posture, and reduced arm swing are seen with parkinsonism. Festination, a tendency to topple forwards when walking, may occur.

Observe walking through a doorway, an activity which may induce freezing. Perform the 'pull test' to look for postural instability, which is demonstrated by the patient taking a step backwards when a gentle pull is exerted (retropulsion).

Labyrinthine imbalance

The Unterberger stepping test is a variant of Romberg's test which can be performed in patients with vertigo and who are suspected of having vestibular pathology. The patient is asked to walk on the spot with eyes closed and arms outstretched for 30 seconds. Rotation to either the right or the left by more than 40 degrees is abnormal and indicates underaction of the ipsilateral labyrinth.

Proximal muscle weakness (myopathy)

A 'waddling'-type gait is typically caused by pelvic instability. The patient will have difficulty rising from a low chair. Ask him to stand from a sitting position with his arms folded. This will prevent him from pushing himself up using his arms, an accessory movement used to overcome the lower limb weakness. In more severe cases,

Box 46.1 Neurological and non-neurological patterns of gait disorder

- non-organic
- cautious gait

Box 46.2 Routine gait examination

1. Have the patient stand on a narrow base, with his feet together, his arms at his side, and eyes open; can he stand unsupported?
2. Have the patient close his eyes (Romberg test); loss of balance indicates a deficit of proprioception.
3. Have the patient stand on each leg in turn with eyes open; the unsteadiness may be lateralized.
4. Have the patient walk briskly the length of the room and observe the nature of his gait. Look for the presence of a wide-based gait. If the patient is mildly ataxic, have him walk in a circle, to exaggerate any deficit.
5. Have the patient walk as if on a tightrope (tandem gait, or heel-toe walking); even mild ataxia inhibits this manoeuvre.

Depending upon the findings or suspected site of the pathology, the examination can be extended accordingly.

ask the patient to rise from the supine position. He will need to pull himself up using a support or, alternatively, exhibit the Gower manoeuvre whereby he pulls himself up from the floor by 'walking up' his own body.

Specific clues to diagnosis

Peripheral motor weakness

Essentially, the gait difficulty will arise due to flaccid foot drop leading to a 'high step and flop' gait. Weakness of the dorsiflexors combined with reduced muscle tone necessitates a higher step in order to provide clearance of the toes from the ground when stepping. As the foot returns to the floor, it will slap down in a poorly controlled manner. The patient will tend to stub the toes when walking and finds difficulty with clearance when climbing stairs. Examination of the limb may reveal typical lower motor neuron signs, such as muscle wasting and areflexia. Long-standing pathology, such as, for example, hereditary motor and sensory neuropathy (Charcot–Marie–Tooth) may be associated with profound distal wasting and pes cavus.

Peripheral sensory loss

Loss of touch sensation in the feet will impair the ability to feel the ground when walking and the patient may say it is like walking on air or rubber. The patient will walk in a hesitant manner and balance may be affected. If, in addition, as is frequently the case, proprioception is lost, then sensory ataxia will result. Gait may be high stepping, as the patient is unaware of the exact position of the floor, and may stamp down as the foot reaches the floor. The gait is wide-based and significantly worse in the dark, when visual clues are no longer available. A positive Romberg test will differentiate from other causes of ataxia, and formal testing of proprioception will reveal impairment. As the pathology lies in the posterior spinal columns, vibration sense in the feet will also be impaired.

Hemiplegic gait

Due to the imbalance in muscle tone, the flexors are stronger in the affected arm while the extensors are stronger in the leg. The leg will tend to adduct at the hip, and the foot tends to plantar flex and invert. Knee flexion is weak. To overcome a tendency to catch the foot when walking, the limb circumducts at the hip as the leg moves forwards.

Spastic gait

The legs are stiff and inflexible and the feet will appear to be dragged along. The gait is slow and there is poor clearance of the foot from the ground. Foot drop may occur due to greater weakness of the dorsiflexors than the plantar flexors, but flopping is not seen because of the increase in motor tone. In severe cases of diplegia, such as may occur with cerebral palsy or hereditary spastic paraplegia, 'scissoring' may occur due to the exaggerated tone in the hip adductors. Milder forms of spasticity may only manifest after the patient has been walking for some distance. Examination typically reveals increased tone, hyperreflexia, and extensor plantars. Clonus may be evident.

Extrapyramidal

Idiopathic Parkinson's disease (IPD) is asymmetric at outset, and motor features commonly commence in the upper limb. Gait becomes affected when the ipsilateral leg is involved. The gait then appears almost hemiplegic, but the reduced arm swing and tremor are characteristic. The increase in tone has the typical cogwheeling feature, and pyramidal signs are absent. Instability, gait initiation problems, falls, et cetera, are features seen later as the disease progresses.

Gait and balance problems occurring early in the course of an extrapyramidal disease should arouse suspicions of an alternative diagnosis to IPD. Backward falls, for instance, occur early in the course of progressive supranuclear palsy and should trigger a close examination of the eye movements looking for upward gaze palsy. Likewise, early development of autonomic features such as impotence or postural hypotension may point to a diagnosis of multisystem atrophy. Vascular pseudoparkinsonism often affects gait, but facial expression and upper limb function may be normal—so-called lower-body parkinsonism.

Cerebellar disease

Charcot's triad of cerebellar disease is nystagmus, dysarthria, and intention tremor. Ataxia should, of course, be added to this. Gait is typically wide-based and, if the cerebellar lesion is lateralized, staggering will occur towards the ipsilateral side. Midline or chronic pathology may not be lateralized, but gait and speech involvement (scanning speech) are usually prominent.

Frontal pathology

Chronic bilateral frontal lobe pathology can lead to profound gait difficulty which can be mistaken for parkinsonism. Gait initiation failure, shuffling, and disequilibrium may be seen, but other typical extrapyramidal features, such as reduced arm swing, cogwheel rigidity, and tremor, are lacking. Unlike in Parkinson's disease (PD), the gait is wide-based. Small vessel vascular disease and normal pressure hydrocephalus are good examples.

Myopathic gait

A myopathic gait is typically waddling, with a swaying, wide-based characteristic and often with pronounced lumbar lordosis. The presence of myopathic facies, nasal speech, and proximal upper limb weakness may accompany the typical history of difficulty getting out of the bath or turning over in bed. A family history is important.

Non-neurological gait disorders

Locomotor disorders

These are common, particularly in the elderly, where degenerative joint disease is a frequent comorbidity with neurological disease. This can lead to confusion. As a generalization, pain is unlikely to exist with a pure neurological problem. For example, a patient with PD may state that his leg feels 'stiff'. Is he referring to increased tone due to his PD or does he mean pain and joint stiffness due, for instance, to osteoarthritis of his knee?

Low-back pathology is also a common explanation for gait difficulty. This can, not infrequently, have a non-organic basis.

Non-organic (functional) gait disorders

Non-organic gait disorders are not uncommon in neurological clinics and should be suspected when the gait pattern does not fit with an expected pattern, and 'hard' neurological signs are lacking. Often, the patient arrives in a wheelchair. When asked to stand, the patient may be reluctant but, on rising, may appear to dramatically lose balance only to stagger against a supporting object, never actually toppling to the ground. Another common presentation is the dragging leg, whereby the patient will move forwards apparently pulling the involved leg behind him with the limb externally rotated. Again formal examination fails to reveal convincing neurological signs such as wasting or reflex abnormalities. Give-way weakness may be apparent.

Cautious gait

Cautious gait is seen in patients with a previous history of falls. There may be an underlying neurological condition, such as gait apraxia, but many patients are merely afraid that they will fall again, and have lost their confidence. They will rise fearfully from a chair and show extreme reluctance to standing without gripping disproportionately strongly on the arm of a chair or the supporting carer. Gait initiation appears difficult and, when steps are finally taken, the gait is broad-based, the patient constantly expressing the desire to grab onto a support. Physiotherapy is often dramatically helpful in restoring confidence and full recovery.

Diagnostic tests

The pattern of clinical presentation should be a clear guide as to how investigation should proceed. By using the descriptions of gait pattern already described, it should be possible in most cases to decide in which neurological system the pathology lies. Thus, neurological imaging with MRI can target the brain in patients with clear-cut upper motor neuron signs, cerebellar disease, or features of gait apraxia. Spinal MRI will be appropriate in patients who exhibit spasticity without features suggestive of cerebral involvement.

More complex imaging tools are sometimes used. An example would be a form of SPECT scanning (123-I-FP-CIT DaT), which is a form of functional imaging used to study patients with suspected extrapyramidal disease and who exhibit a deficiency of dopamine neurotransmission.

Electromyography will be normal in CNS disease but is the investigation of choice for peripheral nerve disorders. It will distinguish axonal from demyelinating peripheral neuropathy, and neuropathic from myopathic pathology. Evoked potential studies are used when central conduction pathways are to be evaluated.

A useful tool in the neurological armamentarium is lumbar puncture, which is used selectively when pressure measurement or CSF analysis is likely to be diagnostically helpful. Examples would be CSF protein elevation in demyelinating neuropathy, or the presence of oligoclonal IgG in multiple sclerosis.

Blood tests may reveal a suspected diagnosis such as, for example, vitamin B₁₂ deficiency or thyroid disorder; measurement of creatine phosphokinase may point to muscle disease. Alternatively, DNA analysis may define the genetic basis of the condition.

Therapy

The availability of treatment will depend upon the underlying cause of the gait problem. Many neurological conditions are not amenable to intervention, but an accurate diagnosis will aid ongoing management and prognosis.

Drug treatment may be symptomatic rather than curative, the use of antispasticity drugs being a good example. Other drug treatments, such as levodopa for PD, are both symptomatically and diagnostically beneficial. Vitamin B₁₂ treatment for subacute combined

degeneration of the spinal cord, on the other hand, will significantly improve the condition and prevent recurrence.

Timely neurosurgical intervention in the appropriate case can have dramatic benefit upon gait and balance. Examples of where this might apply are posterior fossa tumours, normal pressure hydrocephalus, and cervical myelopathy.

Many conditions which impair gait are not amenable to curative intervention and are progressive in nature. Patients can be helped by acquiring an accurate diagnosis and a management plan, assisted by appropriate supportive therapies.

How to handle uncertainty in diagnosis

Gait disorders follow characteristic patterns as described. Experience and increasing familiarity with modes of presentation will make diagnosis easier. Atypical or variability of function should raise the suspicions of a non-organic disorder. Full neurological examination will normally display appropriate physical signs which corroborate the initial clinical impression.

Subsequent investigations should be targeted at confirming the diagnosis suspected following detailed clinical examination. A blunderbuss approach using tests uncritically may uncover the answer by chance, but is expensive and usually inconvenient and uncomfortable for the patient.

47 Sensory loss

Sarah Stoneley and Simon Rinald

Definition of sensory loss

Sensory loss relates to any alteration in perception of external stimuli such as pain, temperature, touch, or perception

Context

The presentation of sensory loss can be extremely varied and is frequently accompanied by motor dysfunction. To effectively assess and diagnose sensory disorders, an understanding of the relevant functional anatomy is required.

Neuroanatomy basics

To experience sensation, our body requires a stimulus to be detected. The sensory information is relayed via peripheral nerves, plexus, roots, and dorsal horns into the spinal cord and transmitted in either the dorsal columns or spinothalamic tracts to the brain. Sensory loss can be caused by pathology anywhere along this pathway. The sensory innervation of the skin is depicted in Figure 47.1.

The detection of cutaneous sensation begins with free nerve endings or end organs in the skin. Sensory information is divided into touch, proprioception, vibration, temperature, and pain, and

Figure 47.1 Sensory innervation of the skin. Cutaneous areas of distribution of spinal segments and sensory fibres of the peripheral nerves: (a) anterior and (b) posterior views.

Reproduced with permission from Walton J, *Brain's Diseases of the Nervous System*, Tenth Edition, Oxford.

Figure 47.1 (Continued)

each is transmitted to the brain differently. The first difference occurs at the level of the sensory nerve fibres. Large, extensively myelinated fibres (A- α and A- β) convey touch and pressure. Small, sparsely myelinated (A- δ) and unmyelinated (C) fibres convey temperature and different qualities of pain sensation.

In the spinal cord, the dorsal or posterior columns relay touch/pressure, proprioception (joint position sense), and vibration sense. These fibres synapse in the nuclei cuneate and gracile of the medulla, then cross, and ascend to the contralateral thalamus and sensory cortex via the medial lemnisci of the brainstem. The spinothalamic tracts convey pain and temperature to the contralateral sensory cortex. In contrast to the fibres in the dorsal columns, these fibres decussate to the contralateral spinothalamic tract typically within one to three levels of their entry into the cord, via the ventral white commissure. The ultrastructural organization of the spinal tracts is also important with respect to sensory dysfunction. At increasingly higher levels, crossing spinothalamic fibres are added to the medial aspect of the ascending tract, such that sacral fibres lie lateral to cervical fibres. The opposite situation exists in the dorsal columns.

In the thalamus, and particularly in the 'sensory homunculus' of the postcentral gyrus of the parietal lobe, representations of the face and hand are juxtaposed and subserved by disproportionately large areas of brain.

Approach to the diagnosis

The initial aim is to localize the lesion within the nervous system. Both the nature of the sensory symptoms and the parts of the body involved are important in this respect. A differential diagnosis can then be compiled which directs appropriate investigations.

Sensory disturbance can either be a complete loss (anaesthesia) or a reduction (hypoesthesia) in the ability to perceive the sensory input. Dysaesthesia is an abnormal increase in the perception of normal sensory stimuli. Hyperalgesia is an increased sensitivity to normally painful stimuli, and allodynia is the perception of usually innocuous stimuli as painful.

A complete loss of sensation is likely to be due to a CNS problem, while a tingling/paraesthesia (large fibre) or burning/temperature

(small fibre) sensation is likely due to an acquired peripheral nervous system problem. Shooting, electric-shock-like pains suggest radicular pathology, a tight-band spinal cord dysfunction. Positive sensory symptoms are usually absent in inherited neuropathies, even in the context of significant deficits on examination. It is also clear that patients often have great difficulty in satisfactorily describing abnormal sensory sensations when they are present.

The history also gives the first pointer to the distribution of the sensory syndrome: which limb(s) is it in, which side is it on, whether it is proximal or distal, symmetrical or asymmetrical. A report of a 'numb' or 'dead' limb may reflect weakness and should not be taken at face value. Ask specifically about any motor, bladder, bowel, and autonomic dysfunction. The tempo of onset and duration of symptoms may be indicative of the nature of the pathology. A near instantaneous development of maximal deficit suggests a vascular cause; progression over seconds implies epilepsy; over minutes, migraine; over days, multiple sclerosis; over weeks, neoplasia. Other parts of the history—such as additional generalized seizures, headaches, prior optic neuritis, weight loss—can back up this initial impression.

An appropriate neurological examination is important. Even with apparently purely sensory problems, however, it is almost always best to leave the sensory examination to last. For example, the reflex pattern may be more useful in 'localizing the lesion' than the sensory examination itself. Ideally, an hypothesis for the potential expected sensory abnormalities will have already been established on the basis of history and other aspects of the examination. Sensory examination is difficult and subjective, and can be tiring and confusing for both you and the patient. Approaching it blindly, without any thought to the possible differential diagnosis, is more likely to confuse than clarify the situation. Be wary of attaching great significance to unexpected minor qualitative differences, especially in pinprick. The most useful and reliable information is usually obtained by working from an area of abnormality to normality—having first demonstrated to the patient what 'normal' is.

Specific clues to the diagnosis

Having established an hypothesis, the expected abnormality can now be specifically sought. Common patterns of sensory loss and their causes are as follows.

Glove and stocking loss

Glove and stocking sensory loss is primarily a result of peripheral polyneuropathy.

Length-dependant axonal neuropathy

Length-dependant axonal neuropathy, sometimes called 'dying back' polyneuropathy, is the most common pathology. There is symmetrical damage to the axons of peripheral nerves, and the furthest extremities of the longest peripheral nerves are affected first (i.e. those in the feet). As the symptoms reach mid-calf, symptoms begin in the fingers, giving the glove and stocking distribution. Vibration is affected first and reflexes (especially at the ankles) are diminished as these are dependent on the largest fibres, which are usually primarily and predominantly affected. There are several causes, including diabetes, alcohol, vitamin B₁₂ deficiency, drugs, syphilis, HIV, uraemia, chemotherapy, and connective tissue diseases. Despite extensive investigations, a large majority of these cases remain idiopathic.

Demyelinating neuropathies

Demyelinating neuropathies are suggested clinically by globally depressed reflexes and weakness out of proportion to wasting. Although the sensory loss is often length dependent, weakness is usually more pronounced proximally.

Guillain-Barré syndrome

Guillain-Barré syndrome is an acute, inflammatory, demyelinating polyradiculoneuropathy. It often begins with back pain and paraesthesia of the hands and feet, although hard sensory signs are much less frequently found. The symmetrical weakness ascends from the legs to the arms, and often then to the cranial nerves and respiratory muscles. Most commonly, the limb weakness affects proximal more

than distal muscles. Areflexia is characteristic. There may also be autonomic dysfunction. There is a history of a recent infection, particularly a diarrhoeal or respiratory illness, in around 70% of cases. It is fatal in 3%–10% cases, and one-third of cases require admission to the ITU with respiratory failure. Treatment is with immunomodulatory therapy such as plasmapheresis or intravenous immunoglobulin (IVIg), which can shorten the duration of the disease.

Chronic inflammatory demyelinating polyradiculoneuropathy

Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) progresses over more than 8 weeks, or has a relapsing and remitting course. Typical features are those of a demyelinating neuropathy. Positive sensory symptoms and preferential loss of vibration and proprioceptive sensation are also common. Nerve conduction studies are mandatory for diagnosis. Steroids and IVIg are the mainstays of treatment.

Paraproteinaemic neuropathies

Paraproteinaemic neuropathies can be clinically indistinguishable from CIDP. Other cases have a **distal acquired demyelinating symmetrical (DADS)** phenotype—with slowly progressive, distal, and symmetric sensory loss, sensory ataxia, tremor, and little if any weakness—particularly in the presence of an IgM paraprotein and anti-MAG antibodies. Sometimes length-dependent axonal polyneuropathies are associated with a paraprotein. Whether this is pathologically relevant or simply an occasional coincidental finding remains uncertain.

POEMS syndrome

POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, skin changes) is a fortunately rare, haematologically benign, but neurologically and systemically malignant disorder. The neuropathy is of a mixed demyelinating and axonal type, affects motor and sensory nerves, and spreads aggressively from distal to proximal regions, sparing autonomic function and the cranial nerves. In addition to the core features noted in the acronym, other elements such as ascites, pulmonary oedema, thrombosis, and renal failure may be seen. It is associated with elevated levels of certain cytokines, most notably vascular endothelial growth factor (VEGF). Potent immunomodulatory therapy with cytotoxic agents, or even bone marrow transplant, is required to halt progression.

Inherited neuropathies

Inherited neuropathies can be either axonal or demyelinating, and present at an earlier age with foot deformities and motor loss. Patients frequently have few if any positive sensory symptoms.

Small fibre neuropathies

Small fibre neuropathies are characterized by predominant pain and other positive sensory symptoms such as paraesthesia and allodynia. Deficits in pain and temperature sensation can be seen but, as large fibres are not involved, vibration, proprioception, and the deep tendon reflexes are spared, and nerve conduction studies are normal. Thermal threshold testing and skin biopsy (assessing intra-epithelial nerve fibre density) are used for diagnosis.

Sensory level

Sensory loss below a certain dermatomal level implies spinal cord pathology. Such pathology usually additionally affects motor function and causes abnormalities of tone and of the deep tendon reflexes (see Chapter 233). Anterior compression or anterior spinal artery infarction predominantly affects pain and temperature conveyed by the spinothalamic tracts. In such cases, sacral and dorsal column involvement is associated with pathology affecting a larger cross-sectional area of the cord, and hence a poorer prognosis. Hemisection of the cord (Brown-Séquard syndrome), is where the ipsilateral side of the body has vibration, weakness, and reduced proprioception, and the contralateral side has reduced pinprick and temperature—reflecting the differing anatomical pathways of the corticospinal tract and dorsal columns.

Suspended sensory level

Symmetrical sensory loss involving several contiguous dermatomes, with normal sensation above and below, is also caused by spinal cord

pathology. In this case, the lesion lies in the central cord, taking out the decussating fibres of the spinothalamic tracts as they cross via the ventral white commissure (ventral to the central canal). This gives an isolated loss of pain and temperature sensation, typically beginning 1–2 dermatomes below the affected cord level. There may be additional weakness and/or reflex changes if the anterior horn cells or other tracts are involved. The classical situation is a cape-distribution deficit caused by a syrinx affecting cervical levels, but central cord syndromes related to multiple sclerosis are more common. Rarely, suspended sensory loss can be caused by ependyoma or central glioma.

Hemisensory disturbance

Hemisensory loss suggests contralateral disease in the brainstem, thalamus, or cerebral cortex. If the affected side of the face is opposite to the affected side of the body, the lesion is the brainstem (Wallenberg/lateral medullary syndrome). Thalamic infarcts give a contralateral sensory deficit. If the sensory cortex is affected, there is usually a small part of the body affected; there may be aphasia, neglect, or cortical sensory loss. Multiple sclerosis, stroke, and space-occupying lesions are important causes. Migraine and functional disorders can also present with hemisensory loss. With many of these pathologies, more patchy, discrete deficits involving parts of a limb, the face, or the trunk can also be seen.

Discrete abnormalities in a single limb

Mononeuropathies

Mononeuropathies result in symptoms and signs confined to a single nerve distribution. These are often caused by local compression. Common upper limb examples are median nerve (carpal tunnel), ulnar nerve (entrapment at the elbow), and radial nerve ('Saturday night palsy' causing wrist drop). Lower extremity examples are peroneal, femoral, and lateral cutaneous nerve of the thigh. There may only be small areas of paraesthesia due to the overlap of dermatomes. Multiple nerves are affected by **mononeuritis multiplex**, further described in 'Multifocal deficits' and most strongly associated with the vasculitides.

Plexopathies

Plexopathies affect the brachial or lumbosacral plexus. They often begin with excruciating pain felt over the plexus, followed by the development of sensory loss and weakness not confined to a single peripheral nerve or nerve root territory. Often these are dissociated—weakness in one or more myotomes with sensory loss in other dermatomes can be a clue. There is an association with diabetes, but many cases are idiopathic. Most are monophasic and steroids may help recovery. Bilateral plexus involvement is not uncommon. Infiltration from lymphoma or breast cancer, and radiation damage, are more serious and progressive causes.

Radiculopathies

Radiculopathies are lesions affecting the nerve root and are usually caused by either intervertebral disc herniation or narrowing of the foramina due to spondylosis, carcinomatosis, or focal extramedullary tumours. Neuropathic pain radiating along a limb is suggestive. Infection (varicella, Lyme disease, CMV) and particularly autoimmune/inflammatory causes (CIDP) often affect multiple levels. Usually, dermatomes and myotomes are involved.

Multifocal deficits

Other pathologies can initially have more patchy sensory involvement, sometimes developing an apparent length-dependent appearance as they progress.

Mononeuritis multiplex

Mononeuritis multiplex is characterized by painful asymmetrical motor and sensory loss involving damage to at least two separate peripheral nerves. Most often, the common peroneal or tibial nerves are affected first. As the condition progresses, it becomes less multifocal and more symmetrical, when it can begin to mimic a length-dependent process. In over half of all cases, mononeuritis multiplex

is caused by a systemic vasculitic process which incorporates the vasa nervorum. Diabetes, rheumatoid arthritis, atherosclerotic disease, HIV, and sarcoidosis are other notable causes.

Hereditary neuropathy with liability to pressure palsies

Hereditary neuropathy with liability to pressure palsies (HNPP) can produce a similar clinical picture to mononeuritis multiplex. Critically, however, the peripheral nerve dysfunction in HNPP is caused by compression and improves spontaneously thereafter, unlike vasculitic mononeuritis multiplex, which when untreated is relentlessly progressive.

Sensory ganglionopathies

Sensory ganglionopathies are rare. They are caused by the degeneration of the dorsal root ganglia. They present with sensory ataxia, absent reflexes, and sensory loss. Proximal and distal regions are affected, often asymmetrically. The trunk, face, and perineum may be involved. Crucially, given the site of the pathology, there is no weakness. They are associated with Sjögren's syndrome and paraneoplastic causes such as small cell lung cancer with anti-Hu antibodies.

Key diagnostic tests

It is important to take blood and check the full blood count, routine biochemistry, B₁₂ and folate, glucose, thyroid function, cholesterol, and inflammatory markers. Protein electrophoresis, ideally with immunofixation, and a chest X-ray complete a reasonable battery of first-line screening tests for length-dependent, axonal, polyneuropathies. The yield of further tests in this situation is low. Nerve conduction studies may be useful for single nerve lesions, multiple mononeuropathies plexopathies, and radiculopathies. If CNS problems are suspected, then an MRI is usually indicated. Further tests may be required, depending on the diagnosis suspected (e.g. paraneoplastic antibodies for suspected paraneoplastic neuropathy, CSF protein measurement in CIDP/Guillain-Barré syndrome).

Therapy

Therapy depends on the cause of the problem and ranges from supportive for some conditions to aggressive treatment such as neurosurgery and immunosuppression for others. Physiotherapy will play a big role in all diagnoses where there is accompanying motor loss. Foot care is important, particularly in the context of diabetic peripheral neuropathy. If there is an underlying cause, this should be identified and treated. Some mononeuropathies, radiculopathies, and spinal cord and brain lesions may be amenable to surgery but, otherwise, treatment is supportive. Often, the neuropathic pain experienced will need addressing with agents such as tricyclics or gabapentinoids.

Prognosis

Prognosis depends on the individual cause. Peripheral neuropathies are usually slowly progressive, while some radiculopathies and mononeuropathies may improve with conservative management alone. Sensory ganglionopathies may herald an untreatable and rapidly progressive small cell lung tumour. Neurosurgical decompression for radiculopathies and myelopathy is performed to prevent further deterioration and/or improve pain, although sometimes improvement can be seen. Damage to the brain by stroke may improve with physiotherapy and rehabilitation.

How to handle uncertainty

Most uncertainty can be eliminated by following the basic neuroanatomical principles detailed in this chapter. Once the distribution and nature of the sensory disturbance has been delineated, the site of pathology should be apparent. Reference to a dermatome chart can help, particularly for discrete abnormalities which may be caused by damage to a single nerve or root.

Difficulties tend to arise when the sensory exam does not 'make sense'. There is sometimes a temptation to immediately equate this

to a functional disorder. This may be the reason, but there are traps for the unwary. As ever, a functional diagnosis is best supported by clear positive signs. Characteristically, functional sensory loss has very sharply demarcated boundaries. Individual complete sensory loss affecting the whole circumference of a single limb—typically, an arm below the shoulder or a leg below the groin—is an anatomical impossibility. Hemisensory disturbance with a sharp demarcation between normal and abnormal falling absolutely in the midline is again suggestive. Dermatomes overlap in the midline; thus, in organic pathology, a transition to normal sensation begins before the midline is reached. A sensory level on the trunk should be higher posteriorly than anteriorly. Vibration sensation splitting the shin or skull is not reliable.

Labelling a symptom functional simply because the examination findings appear inconsistent or do not absolutely fit a textbook description risks misdiagnosis, however. Anatomical variation, difficulty in performing the examination, and the over-reporting of minor, insignificant differences by the well-meaning patient can all confound the situation.

In the extreme example, a clear neurological diagnosis has already been established following history and completion of the motor examination, which then appears to be contradicted by subsequent sensory findings. It is worth pausing to give thought to the possibility of a second pathology, but experience suggests excluding the discrepant sensory findings from the diagnostic formulation is sometimes the correct approach.

48 Headache

Paul Davies

Definition of headache/head pain

Headache is a pain in the head, with the pain being above the eyes or the ears, behind the head (occipital), or in the back of the upper neck. It may be secondary to numerous disorders such as meningitis (secondary headaches) or be a disorder in and of itself, such as migraine and cluster headache (primary headaches). Primary headaches are benign, diagnosed entirely on the history, and form the major morbidity in the problem of headache. They often exist in episodic and chronic forms. Secondary headaches may be acute or chronic, and benign or serious. Only some require investigation for their diagnosis.

In chronic headache management, it can be helpful to remember the International Association for the Study of Pain's definition of chronic pain: 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage' (see <http://www.iasp-pain.org/Taxonomy>). Patients' ideas and emotions (e.g. a fear of more serious disease, or frustration and anger from a failure to adequately understand or treat their pain) are often important components in the clinical problem.

Context

Headache is one of the most common of all complaints and affects most people at some stage during their lives. Much is self-diagnosed and managed adequately, if not optimally. Migraine is the most common severe form of primary headache; it affects about 6 million people in the UK in the age range 16–65 years, and costs the UK almost £2 billion a year in direct and indirect costs. Over 100 000 people are absent from work or school every working day because of migraine. Tension-type headache, although less severe than migraine, is more prevalent and results in as great a societal burden, causing as many days lost from work as migraine does.

Healthcare professionals often find the diagnosis of headache difficult, and often patients worry about serious but rare causes of headache, such as brain tumour. Often, it is difficult to explain benign headache, and patients with chronic benign headache may journey through opticians and eye, ENT, or neurology clinics, searching, in vain, for the cause or cure.

Migraine is under-diagnosed and under-treated. Sadly, much headache can be a result of inappropriate medical treatment (e.g. frequent opiate treatment of migraine, leading to medication overuse headache). Advances in headache treatment now mean most sufferers can be helped.

Approach to the diagnosis

Diagnosis of the headache syndrome is the first step in managing the patient, and recognizing serious causes of headache is paramount. Patients may present with acute, subacute, or chronic headache and, with there being over 200 medical causes of headache, making the correct diagnosis of headache can be challenging. Taking a good history is the key to the diagnosis of all headaches, and the only tool the clinician has for the diagnosis of most of them. Perhaps no other symptom in medicine is so heavily dependent on an accurate and detailed history for headache diagnosis and patient management. Some patients recognize more than one headache type, and a separate history should be taken for each. A comprehensive history may not be obtained at the first consultation. Questioning may vary depending on the clinical situation but serious causes of headache, although rare, even in a casualty setting, must not be missed.

Since a benign headache syndrome is the most likely diagnosis, a good awareness of these conditions, particularly the most common,

Table 48.1 Common headache types and their estimated lifetime prevalence

Headache type	Estimated lifetime prevalence (%)
Primary headache	
Tension-type headache	72
Episodic	69
Chronic	3
Migraine without aura	9
Migraine with aura	6
Cluster headache	0.3
Primary stabbing headache	1
Secondary headache	
Substances (not alcohol) or their withdrawal	3
Hangover headache	72
Non-cephalic infection	63
Metabolic disorder	22
Disorders of the sinuses	15
Head trauma	4
Disorders of the cranium/neck/eyes	3
Vascular disorders	1
Non-vascular cranial disorders	0.5

is essential (see 'Common diagnoses', but detail is beyond the scope of this chapter). For most patients, further investigations are redundant but many are investigated nonetheless.

Common diagnoses

Some common headache types, looking particularly at primary and secondary care, are shown in Tables 48.1 and 48.2.

Is there a serious cause for headache?

In general, if headache is the only symptom and it has been going on for more than 3 months in a well patient with no neurological abnormalities, then it is very unlikely there will be a serious cause. A short headache history, without the stereotypical pattern of primary

Table 48.2 Diagnosis of headache types in primary and secondary care

Diagnosis in primary care	Diagnosis in secondary care
Primary headache syndromes	
24% of total headache presentations: <ul style="list-style-type: none"> migraine: 73% tension-type headache: 23% cluster headache: 4% 	General neurology clinics: GPs refer 3% of headache patients Emergency room: About 1% of all referrals are for headache; majority of cases are migraine
Secondary headache syndromes	
6% of total headache presentations: <ul style="list-style-type: none"> 'sinus' headache: 83% 	General neurology clinics: Most cases are benign Emergency room: As in general neurology clinics but more haemorrhage and meningitis

Note: Most patients presenting to primary care with headache (4.4% of total consultations) are not diagnosed. Headache accounts for about 30% of new patient general neurology referrals.

Box 48.1 Causes of a 'thunderclap' headache

- subarachnoid haemorrhage
- cough headache (may or may not be benign)
- orgasm headache (should be investigated for possible intracranial haemorrhage unless it has occurred three or more times in that situation and no other)
- reversible cerebral vasoconstriction syndrome
- cerebral venous sinus thrombosis (although the onset is usually more chronic, causing headache and papilloedema)

headache disorders and with the pain being the only or major feature may not give much to go on. It is the features of that pain that help diagnosis. Red flags are now a key part of headache management guidelines; the key red flags are:

- sudden onset, severe headache ('thunderclap')
- persistent morning headache with nausea
- new onset headache in the elderly person
- headache only with actions which alter CSF pressure
- steadily worsening headache
- posturally related headache
- headache with immunosuppression/cancer

Sudden onset, severe headache ('thunderclap'): Intracranial bleeding?

The term 'thunderclap' is used to describe headache that is severe at onset and perhaps worsens a little over the next few seconds or so. Subarachnoid haemorrhage is the archetypal example but there are several other causes (see Box 48.1).

Persistent morning headache with nausea: Raised intracranial pressure?

Many migraine sufferers wake up with migraine headache and associated nausea but attacks last no more than 3 days (by definition). Persistent morning headache, especially with nausea, can be due to raised intracranial pressure but there may be other causes (see Box 48.2).

New onset headache in the elderly person: Consider temporal arteritis

Temporal arteritis must not be overlooked but benign headaches in the elderly are very common. About 5% of migraine presents over the age of 50 years. Temporal arteritis is extraordinarily rare below the age of 50 years.

Headache only with actions which alter CSF pressure: Posterior fossa disorder?

A number of headaches may relate, in essence, to carrying out a Valsalva manoeuvre. Some can be due to structural abnormalities such as a Chiari malformation, where the cerebellar tonsils lie low and extend into the foramen magnum, thereby acting as a 'plug' when intracranial pressure increases. Some have no detectable underlying cause. Investigation with MRI (not CT, as this does not show the foramen magnum very well) should be considered in all cases. Cough headache is headache occurring not only with coughing but perhaps with sneezing or bending over (as in tying your shoe laces). Benign forms of headache may respond to propranolol or indometacin.

Box 48.2 Some causes of morning headaches

- migraine
- medication overuse headache
- hangover headache
- sleep apnoea
- carbon monoxide poisoning
- nocturnal seizures

Steadily worsening headache: Could it be due to some form of growth, such as skull metastases?

Chronic headache which has gone on for more than 3 months, with no other symptoms, in a well person, and where the clinical examination is normal is unlikely to have any serious cause. However, worsening headache could, rarely, be due to skull bone metastases, and so worsening headache may need investigation.

Posturally related headache: Consider low intracranial pressure or a colloid cyst of the third ventricle (rare)

Headaches following a lumbar puncture are well known and characteristically are improved quite quickly by lying down and worsened by getting upright. Such headaches can occur spontaneously from a tear of the dura (usually cervical) due to arthritis. These headaches often have characteristic MRI appearances which greatly aid their diagnosis. They may settle spontaneously; otherwise, a lumbar blood patch (even if it is a cervical leak!) can be very effective treatment.

Headache with immunosuppression/cancer

Immunosuppression from HIV, monoclonal antibody treatments, or the use of steroids may modify the presentation of intracranial pathology. The threshold for investigation should be lowered in patients with such types of immunosuppression.

If a serious cause for headache has been considered and ruled out, then what is the diagnosis?*Is it a primary or secondary headache?*

All primary headaches and most secondary headaches are diagnosed on the history. Primary headaches are usually stereotyped and are considered to come in episodic and chronic forms (e.g. episodic tension-type headache and chronic tension-type headache). Some people recognize combined headaches such as migraine and tension-type headache. Perhaps a total of six diagnoses account for the vast majority of benign headaches (primary headaches: tension-type headache, migraine, and cluster headache; secondary headaches: medication overuse headache and (although controversial) cervicogenic headache). Determining headache periodicity (e.g. cluster headache), duration (e.g. 4–72 hours in migraine; see Box 48.3), and frequency, as well as the laterality of pain (see Table 48.3), are often key to forming the diagnosis.

Migraine pain generally builds up slowly over 30 minutes or more and, at its peak severity, patients like to keep still; in contrast, in cluster headache, the pain comes on rapidly and patients are restless. In chronic tension-type headache, the pain is dull and often 'band-like' and responds poorly to analgesics. Premonitory symptoms (previously called prodromal symptoms) only occur in migraine and may be overlooked unless specifically sought, as they are often rather vague symptoms such as tiredness with frequent yawning. Migraine aura comes in many forms but is usually visual and stereotyped and lasts 20–30 minutes before the headache starts (migraine with aura, previously termed classical migraine). Most migraine is without aura (previously termed common migraine). Careful enquiry about analgesic consumption will minimize the risk of overlooking medication overuse headache.

Box 48.3 Some causes of chronic daily headache (lasting ≥ 4 hours/day)*Primary headaches*

- chronic migraine
- chronic tension-type headache
- new daily persistent headache
- hemicrania continua

Secondary headaches

- medication overuse headache
- post-traumatic headache
- cervical spine disorders

Table 48.3 Illustration of some key pain factors (duration, attack frequency, and lateralization) in headache diagnosis; internationally accepted diagnostic criteria exist for each headache condition (see <http://www.ihs-headache.org/>)

Pain duration	Attack frequency	Lateralized?	Diagnosis
Constant or near-constant	No attacks	Not usually	Chronic daily headache (headache on most days for at least 3 months for which no underlying cause has been found). See Box 48.3 for causes.
4–72 hours	Up to 3/week	Often	Migraine
15–180 minutes	Up to 8/day	Always	Cluster headache
<1 sec	Up to 100s/day	Usually	Idiopathic stabbing headache
<i>Rare diagnoses</i>			
Continuous	No attacks	Always	Hemicrania continua
2–45 minutes	1–40	Yes	Chronic paroxysmal hemicrania
1–30 minutes	1–30	Yes	Episodic paroxysmal hemicrania
15–30 minutes	1–3/night	Sometimes	Hypnic headache
5–250 seconds	Up to 30/hr	Yes	SUNCT (Short-lasting neuralgiform headache with conjunctival injection and tearing)

Key diagnostic tests

Where there are red flag features, further investigation (usually CT in the A & E setting, MRI otherwise) is required, although significant pathology may not be found. Where there are no red flag features, if a specific diagnosis is not made, then the question of whether to do a brain scan may arise. Reports from headache clinics show that extremely few serious causes of headache found on scanning were unsuspected. Certainly, there is no place for routine scanning. Where asymptomatic groups of patients have had routine MRI head scans, significant pathology can be found in about 1%. Explaining to a patient that their arachnoid cyst is not the cause of their headache can be problematic.

Other diagnostic tests

The erythrocyte sedimentation rate is very helpful in suspected temporal arteritis, and the temporal artery biopsy can be diagnostic. Following normal imaging and, in particular, having ruled out venous sinus thrombosis, a lumbar puncture showing a raised opening pressure (>30 cm of water, if the patient is obese) but with normal constituents may confirm a diagnosis of idiopathic intracranial hypertension. CT scanning or plain X-rays of the sinuses may show sinus inflammation but this may not necessarily be the cause of headache. At least normal results exclude sinusitis, which is vastly over-diagnosed. MRI head scanning shows characteristic changes in low CSF pressure headache and has facilitated the diagnosis of spontaneous intracranial hypotension.

An introduction to therapy

Where recognizable pathology is found, the diagnosis and treatment options are usually clear. When no recognizable disease process is found, the situation can be more difficult but diagnosis should follow accepted diagnostic criteria, and treatment be evidence based. We know that as doctors we are more ready than patients to treat headache and we do not explain enough. Part of the problem is that we have terms, such as chronic tension-type headache, which we ourselves don't understand, even though we can recognize and manage the conditions associated with these terms. In approaching therapy, we need to know what the patient wants, be it just reassurance, explanation, treatment, or a brain scan. Furthermore, we must consider whether their goals are realistic.

Therapy of the different headache syndromes is beyond the scope of this chapter. Migraine (as it is the most common) and cluster headache (as it is the most painful primary headache syndrome) therapy will be outlined. Headache treatment can often be considered along the lines of:

- trigger identification and avoidance
- optimal acute attack treatment
- prophylaxis

Trigger identification and avoidance

Migraine may have many triggers. Common ones include relaxation after mental (or sometimes physical stress); menstrual or hormonal triggers (in women); problems with sleep (lack or excessive); environmental factors (e.g. bright light, strong smells); and dietary factors (e.g. missing meals; eating chocolate, cheese, or citric products; drinking alcohol). Carbon monoxide poisoning as a cause of intermittent headache must not be overlooked. Posture or repetitive movement may be important in cervicogenic headache. Alcohol triggers headache in about 50% of cluster sufferers (but only during the bout).

Optimal acute attack treatment

Migraine

Most people obtain adequate migraine relief from over-the-counter medications. Those who don't could be prescribed analgesic/anti-inflammatory agents with or without an anti-emetic. Soluble preparations work best. Suppository formulations should be considered in those who have a lot of nausea and vomiting (although some patients have diarrhoea). Ideally, any medication should be trialled three times before concluding on efficacy. Triptans have revolutionized the treatment of migraine. There are seven now available in the UK. Sumatriptan remains the market leader and is now available over the counter. There are two nasal sprays and one injection kit. Not everyone responds to triptans, and some only respond to the sumatriptan injection.

Cluster headache

The most effective therapies for cluster headaches are sumatriptan by injection, and high-flow oxygen. Sometimes sumatriptan or zolmitriptan nasal sprays can be effective but, in general, oral triptans are too slow in onset to be helpful. There is no place for analgesics such as opiates in the treatment of cluster headache.

Prophylaxis

Migraine

When trigger factors have been addressed and acute therapy optimized, prophylactic treatment should be considered if more treatment is required or if heavy reliance on acute therapy could lead to medication overuse headache.

The first-line agents for prophylaxis include:

Beta blockers: Propranolol is used the most. Evidence indicates that efficacy starts at 80 mg/day but it is sometimes initiated at lower doses. Efficacy may take several weeks to establish and a slow upward titration in dosage should be considered if there is a lack of response. Atenolol and metoprolol are also commonly used.

Sodium valproate: This is firmly established as a prophylactic agent.

Generally, the starting dose is 300 mg twice daily, with a view to 600 mg twice daily later if the lower dose is ineffective.

Topiramate: This is a more recent addition to the prophylactic agent repertoire. It must be introduced slowly (25 mg every 2 weeks), with a target dose of 50 mg twice daily.

Other agents: A number of other agents, such as pizotifen, calcium blockers (e.g. verapamil), and flunarazine may be used.

Cluster headache

First-line treatment for episodic cluster headache includes verapamil, steroids, and lithium. For chronic cluster headache, verapamil and lithium are commonly used.

Alternative treatments

Many patients look at alternative medicine, perhaps due to a lack of support or efficacy from conventional medicine. Often, the evidence base for alternative treatments is poor. Treatments that are recently introduced include botulinum toxin injections for chronic migraine with or without medication overuse, and occipital nerve stimulation.

Prognosis

Prognosis is determined by the diagnosis. Primary headache syndromes are not curable. Treatment is aimed at symptom control. Migraine, in general, improves with age but in women may start at the menopause or worsen at this time. Migraine usually disappears during pregnancy (especially during the last two trimesters) but may soon return post delivery. In many sufferers, episodic migraine can move into a chronic form. Factors driving this transformation are now beginning to be understood.

Cluster headache, like migraine, can be a lifelong condition but tends to improve with age. In women, the effect of pregnancy on cluster headache has not been well studied.

How to handle uncertainty in the diagnosis of this symptom

Uncertainty in diagnosis is usually due to an uncertain headache history. Specifically asking about red flag features in this situation is a priority. A thorough examination may then be all you can do at that consultation. If there are no red flags, then it may be best to give the patient a dedicated headache diary to complete, and then arrange a timely review. Merely asking the patient to record their own symptoms is unlikely to be too revealing.

The question of scanning commonly arises. The worried patient and the uncertain doctor can be enlightened by an MRI head scan but asymptomatic pathology may be seen in about 1% or more of scans and create additional problems. In general, relevant pathology revealed on brain imaging is seldom unsuspected.

49 Loss of vision

Susan Mollan and Alastair Denniston

Definition of the symptom

Loss of vision describes reduction in vision that cannot be corrected by glasses or contact lenses. Patients who complain of changes in their vision may have loss of visual acuity, distorted vision, or visual field loss.

The World Health Organization (WHO) classifies visual impairment as blindness or low vision. Blindness is defined as visual acuity of less than 3/60 in the better eye (ICD-10:54 visual impairment categories 3, 4, and 5). Low vision is present when the visual acuity is less than 6/18 but equal to or better than 3/60, in the better eye (ICD-10 categories 1 and 2).

Differential diagnosis

The aetiology of permanent visual loss is diverse and depends on the region studied. No large studies have documented referral practices within primary and secondary care. In the UK, visual impairment registration data shows the leading causes to be 'degeneration of the macula and posterior pole' (including age-related macular degeneration (AMD)), glaucoma, diabetic retinopathy, optic atrophy, and cataract.

Context

In the UK, 2.5% of the population have some degree of visual impairment which is not correctable by glasses. Worldwide, cataract is the leading cause of poor vision (48%), followed by glaucoma (12%), and AMD (9%). In developed countries, AMD is the commonest cause, followed by diabetes-related eye diseases.

Any degree of visual loss can be a great concern. Patients with sudden changes in vision tend to present acutely, whereas gradual loss may not be noticed, particularly when it is unilateral.

Approach to diagnosis

Visual loss may indicate serious systemic pathology that requires timely medical intervention. A structured history will help narrow the differential diagnosis.

Is it transient or persistent?

Transient loss of vision is generally due to a temporary or subcritical vascular event, and is often a sign of impending systemic vascular pathology (Table 49.1). Persistent loss of vision suggests a more permanent insult (Table 49.2).

Was it sudden or gradual?

Sudden loss of vision is usually vascular in origin, caused by either an occlusion or a haemorrhage (Table 49.2). Gradual loss of vision is usually due to degenerations or depositions (Table 49.3).

Does it affect one or both eyes?

Unilateral events indicate a local cause, whereas bilateral involvement may suggest a systemic process (e.g. giant cell arteritis (GCA) or migraine).

Central or peripheral visual field loss?

Central blurring suggests macular pathology. Unilateral peripheral loss may arise from a vascular retinal event (e.g. branch retinal vein occlusion (BRVO) or branch retinal artery occlusion (BRAO)), optic nerve pathology (e.g. glaucoma, non-arteritic anterior ischaemic optic neuropathy (AION)), or other retinal disease (e.g. retinal detachment). Bilateral peripheral loss can result from retinal or optic nerve disease, and any lesion involving the optic tracts to the visual cortex.

Any pain?

Ocular pain usually indicates disease at the front of the eye (e.g. anterior uveitis, keratitis, primary angle closure glaucoma). Painless loss of vision is typically due to disease of the posterior part of the eye (e.g. cataract; macular and other retinal problems; optic nerve disease). Note that optic neuritis and GCA can present with or without pain.

Associated timing?

Cortical ('spoke-like') cataracts can cause glare from headlights at night or in bright sunlight. Episodes of eye pain with 'haloes' occurring in dim light conditions may suggest angle closure glaucoma.

Previous eye surgery or disease

Common post-operative problems include thickening of the posterior capsule after cataract surgery ('posterior capsule opacification').

Drug history

Drugs which can cause reversible or permanent visual changes include chlorpromazine, clofazimine, corticosteroids, ethambutol, hydroxychloroquine/chloroquine, isotretinoin, sildenafil, tamoxifen, thioridazine, topiramate, and vigabatrin.

Table 49.1 Differential diagnosis of transient visual loss

Diagnosis	Eye	Duration	Vision	Other features	Ocular examination
Headaches with visual aura (migraine)	Bilateral; any age	Minutes up to less than 1 hour	Resolves completely with or without headache	Zigzags, flashing, or scintillating scotoma	Normal
Amaurosis fugax	Unilateral; age >50 years	Seconds to minutes	Resolves completely	Atrial fibrillation, carotid bruit, or heart murmur	Likely normal; refractile emboli may be seen in vasculature
Transient visual obscurations	Bilateral or unilateral; any age	Minutes	Resolves completely	Raised intracranial pressure symptoms	Papilloedema; enlargement of physiological blind spot

Table 49.2 Differential diagnosis of sudden persistent visual loss

Diagnosis	Typical presentation	Visual loss	Other features	Fundal examination
<i>Vascular</i>				
'Wet' age-related macular degeneration	Unilateral; age >55 years; female > male	Variable (mild to HM)	Distorted vision; distorted Amsler grid	Large central macula changes with or without haemorrhage
Branch retinal vein occlusion	Unilateral; age >65 years (15% <45 years)	Normal or mild reduction	Horizontal visual field defect	Flame-shaped haemorrhages and CWS in one quadrant
Central retinal vein occlusion	Unilateral; age >65 years (15% <45 years)	Moderate (6/36–HM)	RAPD +	360° flame-shaped haemorrhages and CWS
Central retinal artery occlusion	Unilateral; age >50 years	Severe (CF-PL)	RAPD +	Normal optic disc; retina is pale with 'cherry red spot' of the macula
Branch retinal artery occlusion	Unilateral; age >50 years	Normal or mild reduction	Horizontal visual field defect	Refractile emboli may be seen in arterioles
Giant cell arteritis (Arteritic AION)	Unilateral; can progress rapidly to bilateral involvement; age >55 years	Severe (amaurosis fugax precedes visual loss in 25%)	RAPD +; tender temporal arteries; new onset headache, malaise, weight loss, and jaw claudication	Swollen optic nerve and CWS
Non-arteritic AION	Unilateral; age >50 years	Variable (normal to severe (NPL))	RAPD +/-; 'altitudinal' visual field defect	Segmental or diffusely swollen optic disc
Vitreous haemorrhage	Unilateral; any age	Variable	History of diabetes	Hazy fundal view
<i>Structural</i>				
Angle closure glaucoma	Unilateral; any age	Moderate to severe	Pain ++; nausea and vomiting	Red eye; cloudy cornea; poorly reactive pupils
Retinal detachment	Unilateral; any age	Variable	Flashing lights, floaters, and shadow	Retina bowing forwards
<i>Inflammatory</i>				
Anterior uveitis	Unilateral; any age	Variable	Red, painful, photosensitive eye	Red eye
Posterior uveitis	Unilateral or bilateral; any age	Moderate to severe	Floaters	Hazy view with haemorrhages and retinal changes
Central serous retinopathy	Unilateral; age: 20–50 years	Moderate	Red desaturation; distortion or scotoma on Amsler grid	Disturbance at macula
<i>Demyelinating</i>				
Optic neuritis	Unilateral; age: 15–45 years	Severe (HM to PL)	Discomfort on eye movement; RAPD +; red desaturation	Optic nerve may or may not be swollen
<i>Degenerative</i>				
Macular dystrophies	Bilateral; variable age groups	Variable	Positive family history	Alteration of macula architecture

Abbreviations: AION, anterior ischaemic optic neuropathy; CF, counting fingers; CWS, cotton-wool spot; HM, hand movements; NPL, no perception of light; PL, perception of light; RAPD, relative afferent pupillary defect.

Specific clues to the diagnosis

Both transient and permanent sudden visual loss can indicate significant pathology (Tables 49.1 and 49.2). There should be a high index of suspicion for GCA as it can present with an arteritic AION, amaurosis fugax, a vascular occlusion (arterial or venous), or double vision. An important distinction is whether the visual loss was sudden or gradual. Sudden loss tends to indicate a more serious event (Table 49.2) than a gradual reduction does (Table 49.3). An exception is diabetic maculopathy, where macular oedema may cause gradual loss but requires urgent treatment.

Functional visual loss is a diagnosis of exclusion and requires careful ophthalmic assessment, as it can coexist with genuine pathology.

Key diagnostic tests

Visual acuity

When testing for visual acuity, use the patient's distance correction (glasses or contact lenses). Here, a pinhole test is invaluable: punch a 1 mm hole in a card and then hold the card in front of the patient's eye while other eye is occluded, and recheck vision. If the vision improves, it is likely that there is a refractive error or a non-urgent condition present (Table 49.3).

'Swinging flashlight' test

A swinging flashlight can be used to detect a relative afferent pupillary defect (RAPD). The normal response when a bright light is shone into one eye is for both pupils to constrict symmetrically. Swing the torch to the other eye, and the pupils will remain the same, or constrict minimally. An RAPD is present if the pupil dilates to a larger size. Both pupils will then constrict when the light is shone back in the unaffected eye. This test is only positive when there is severe retinal and optic nerve injury (Table 49.2) in one eye.

Confrontational visual fields

Some patients report unilateral loss of vision even though both eyes are affected. This is common in homonymous hemianopia, where patients may only notice the loss in the eye where the temporal field is affected. Defects respecting the horizontal midline (i.e. superior or inferior defects) represent a hemispheric vascular event (e.g. BRVO, AION) or glaucoma. Defects respecting the vertical midline represent a neurological lesion such as a stroke or compressive lesions. Central defects are caused primarily by AMD. In any macular disease, patients get a positive scotoma (i.e. a 'spot' in the vision is seen and reported). Conversely, in optic nerve disease, a negative scotoma is present, but not reported (i.e. the defect is not 'seen' by the patient, but can be detected on examination).

Table 49.3 Differential diagnosis of gradual visual loss

Diagnosis	Typical presentation	Vision	Other features	Ocular examination
<i>Degenerative</i>				
Cataract	Bilateral; age >50 years	Pinhole improvement	Glare reported	Red reflex is dulled centrally or dark opacities seen
Dry or atrophic age-related macular degeneration	Bilateral; age >50 years	Reduction with pinhole; affected by ambient lighting	Distorted vision; distorted Amsler grid	Yellow drusen deposits or pigmentary changes at macula
Macular hole	Unilateral (20% bilateral involvement); age >50 years	Reduction with pinhole	Distortion or central scotoma on Amsler grid	Macula disturbance may be seen
Corneal disease	Bilateral; any age	Pinhole improvement; may vary through day	Can present with pain	Corneal opacity may be seen
Hereditary retinal disease (e.g. retinitis pigmentosa)	Bilateral; any age	Variable	Positive family history	Abnormal retinal appearance (e.g. pigmentation)
<i>Vascular</i>				
Diabetic maculopathy	Unilateral or bilateral; any age	Mild-to-moderate loss	Distortion noticed on Amsler grid	Exudates and microaneurysms at macula
<i>Inflammatory</i>				
Intermediate uveitis	Bilateral (often asymmetric)	Variable	Increasing floaters	Hazy fundal view and macula changes
<i>Other</i>				
Compressive lesions of the optic pathways	Unilateral or bilateral; any age	Variable; reduced colour vision	Visual field defects	Normal or pale optic nerves
Refractive errors	Bilateral; any age	Pinhole improvement	None	Normal

Other diagnostic tests

Colour vision test

A colour vision test checks optic nerve function. If no formal tests (e.g. Ishihara pseudo-isochromatic plates) are available, ask the patient to assess the colour quality of a bright red object (e.g. the top of a red pen or bottle). A relative difference between the eyes indicates pathology affecting the optic nerve (e.g. optic neuritis).

Amsler grid

The Amsler grid test checks macular function. The chart is a 10 cm grid, split into 0.25 mm² squares, with a central dot for the patient to fixate on. Distortion will be reported if macular pathology exists (AMD or macular oedema). A central scotoma may be detected in optic nerve disease.

Blood tests

In suspected GCA, the erythrocyte sedimentation rate (ESR) and C-reactive protein level (CRP) will be raised and, in the majority

of GCA cases, a thrombocytosis will be present. However, some cases of temporal artery biopsy-proven GCA have normal inflammatory markers. Conversely, there are many other causes of a raised ESR and CRP (e.g. infection, malignancy, and other types of vasculitis).

Introduction to therapy

The aetiology of visual loss is diverse, and the majority of cases will need primary care input to manage the systemic risk factors, and timely input from specialist ophthalmic services. Routine referrals can be made for cataracts and posterior capsular opacification when the visual loss interferes with the patient's quality of life. The management of loss of vision is shown in Table 49.4.

Prognosis

Prognosis depends on the working diagnosis. WHO estimates that up to 75% of all visual impairment is preventable or treatable.

Table 49.4 Management of loss of vision

Diagnosis	Management
Amaurosis fugax	Exclude GCA; perform complete cardiovascular and neurological examinations; direct referral to transient ischaemic attack clinic for carotid imaging; perform modifications of risk factors and consider antiplatelet therapy, if it is not contraindicated
Arterial occlusion (CRAO and BRAO)	Discuss with local eye services urgently, as occasionally treatment within 24 hours can dislodge the emboli; exclude GCA; complete a cardiovascular examination
GCA	Immediate high-dose intravenous corticosteroid therapy to prevent loss of sight in other eye; often managed jointly by ophthalmology and rheumatology
Optic neuritis	The majority of patients resolve spontaneously, with recovery starting within 10 days; corticosteroids do not alter the long-term visual prognosis, but may hasten recovery
Retinal detachment	Urgent ophthalmic assessment for treatment
Vein occlusions (CRVO and BRVO)	Perform a complete cardiovascular examination; uncontrolled diabetes mellitus, hypertension, GCA, and hyperviscosity syndromes must be identified and managed; consider antiplatelet therapy if it is not contraindicated; refer to ophthalmic outpatient department
Vitreous haemorrhage	Urgent ophthalmic assessment (e.g. to exclude retinal detachment)
'Wet' AMD	Urgent referral to local rapid-access AMD clinic

Abbreviations: AMD, age-related macular degeneration; BRAO, branch retinal artery occlusion; BRVO, branch retinal vein occlusion; CRAO, central retinal artery occlusion; CRVO, central retinal vein occlusion; GCA, giant cell arteritis.

How to handle uncertainty in the diagnosis of this symptom

As loss of vision can be a sign of serious pathology, discuss your full history and examination findings with a local ophthalmologist or emergency eye department.

50 The red eye

Susan Mollan and Alastair Denniston

Definition of the symptom

'Red eye' is a term used to describe the colour of the conjunctiva when there is either dilation of the blood vessels (hyperaemia) or a ruptured blood vessel (subconjunctival haemorrhage). It can be characterized by its distribution:

- diffuse (generalized hyperaemia, which can be superficial or deep)
- focal (hyperaemia only in one sector)
- circumcorneal (hyperaemia at the junction of the cornea and conjunctiva)

Differential diagnosis

There is a multitude of different etiologies that present with 'red eye'. It is seen and managed in all healthcare settings, including optometry services. Table 50.1 presents conditions that can usually be successfully managed in the primary care environment, and others that need immediate or elective management in more specialized services.

Context

Red eye is one of the commonest ophthalmic complaints. Although the majority of causes are self-limiting and treated in the primary care setting, some cases require early and urgent assessment by the ophthalmologist. Even in the absence of specialist equipment, a careful history and general examination will crystallize a diagnosis and identify those conditions that are potentially sight threatening.

Approach to diagnosis

A structured history and examination will differentiate between benign and sight-threatening pathology. The following information is particularly useful:

- onset
- any subjective change in vision, and whether it clears on blinking
- any known precipitations (such as contact lens wear; infectious contacts; hay fever; chemical injury; history of trauma, DIY, grinding, or drilling)

- associated features (such as pain, discharge, and photophobia (see Table 50.2))
- previous eye surgery or disease

The key to diagnosis is to determine whether there is any effect on the vision, as any significant reduction of vision suggests serious pathology (see 'Key diagnostic tests'). Many healthcare professionals feel uncomfortable examining the eye; however, even a simple external examination can provide diagnostic clues, such as preauricular lymphadenopathy (associated with viral conjunctivitis), periocular eczema (associated with atopic conjunctivitis), or acne rosacea (commonly associated with blepharitis and marginal keratitis).

A bright torch can be used to assess the clarity of the cornea and highlight if a white spot (infiltrate or abscess) is present. It can also assess pupil reactions (brisk or sluggish). Gently pull down the lower lid to look at the distribution of hyperaemia and assess the mucus or discharge collecting on the inside of the lower lid and in the fornix. On the inside of the lower lid is the palpebral conjunctiva, and it is here that papilla or follicles can be seen (swollen and irregular). In the primary care setting, a direct ophthalmoscope can give a useful magnified view (dial in the +10 dioptre lens). Instil fluorescein drops and use a blue light or blue filter on the direct ophthalmoscope to highlight any stains caused by corneal epithelial defects (seen in abrasions and ulcers).

Specific clues to the diagnosis

Most bilateral red eye is due to ocular surface disease, which generally causes mild foreign body discomfort and transient blurring of vision that clears on blinking. A unilateral painful red eye with reduced vision is an indicator of more serious pathology (Table 50.2).

Key diagnostic tests

The key to diagnosis is to determine whether there is any effect on the vision. If a vision chart is available, test the vision with the patient's normal distance glasses or contact lenses, each eye separately.

If no chart is available, consider using any text that is available (such as a book (tests near visual acuity levels N6–N8) or newspaper (tests N6)). Test each eye in turn. Remember, patients who normally wear reading spectacles should use these for the test.

Table 50.1 Causes of red eye

	Primary care	Secondary care
Eyelids	Blepharitis (chronic inflammation of the eyelids) Floppy eyelid syndrome	Molluscum contagiosum
Conjunctiva	Subconjunctival haemorrhage Allergic conjunctivitis Bacterial conjunctivitis Viral conjunctivitis Chemical injury Inflamed pterygium or pingueculum	Atopic conjunctivitis Vernal conjunctivitis Chlamydial conjunctivitis Neonatal conjunctivitis (ophthalmia neonatorum) Inflammatory conjunctivitis (ocular mucous membrane pemphigoid; graft-vs-host disease) Neoplastic conjunctivitis (squamous cell carcinoma) Chemical injury
Cornea	Foreign body Abrasion Dry eye syndrome	Microbial/bacterial keratitis Marginal keratitis Viral keratitis
Sclera	Episcleritis	Scleritis
Anterior segment		Uveitis Angle closure glaucoma

Table 50.2 Clues to the diagnosis of red eye

Diagnosis	Visual acuity	Location	Redness	Pain/discomfort	Type of discharge	Other features
Blepharitis	Normal	Bilateral	Mild/diffuse	Mild	–	Crusty lids
Dry eye syndrome	Normal	Bilateral	Mild/diffuse	Mild	Watery +/-	Foreign body sensation
Bacterial conjunctivitis	Normal	Bilateral	Diffuse	Mild	Purulent discharge	Foreign body sensation
Viral conjunctivitis	Normal	Bilateral	Diffuse	Mild	Watery ++	Preauricular lymph nodes
Allergic conjunctivitis	Normal	Bilateral	Diffuse	Mild	Watery +/stringy mucus	Itch
Subconjunctival haemorrhage	Normal	Unilateral	Confluent area of haemorrhage	None to mild	None	–
Inflamed pterygium or pingueculum	Normal	Unilateral (sectoral)	Focal	None to mild	None	Other eye has fibrovascular tissue in same distribution
Episcleritis	Normal	Unilateral (sectoral)	Focal or diffuse (superficial)	None to mild	None	–
Corneal abrasion or foreign body	Normal or reduced	Unilateral	Focal or diffuse	Mild to moderate	Watery	History of trauma (e.g. from DIY/grinding)
Marginal keratitis (sterile ulcer)	Normal	Unilateral	Focal	Moderate	Watery +/-	Associated with blepharitis and acne rosacea
Bacterial keratitis (corneal ulcer)	Reduced	Unilateral	Diffuse	Moderate to severe	Watery +/- or purulent	Photophobia; history of contact lens wear or trauma
Viral keratitis/dendritic ulcer	Reduced	Unilateral	Diffuse	Moderate	Watery	Photophobia; dendritic ulcer
Chemical injury	Reduced	Unilateral or bilateral	Diffuse	Severe	Watery	History of contact with chemicals
Uveitis	Reduced	Unilateral	Diffuse or circumcorneal	Moderate to severe	Watery	Photophobia; irregular pupil
Scleritis	Normal or reduced	Unilateral	Diffuse and deep	Severe	None	Associated systemic diseases
Acute angle closure glaucoma	Reduced	Unilateral	Diffuse or circumcorneal	Severe	Watery	Photophobia; hazy cornea; poorly reactive pupil

Other diagnostic tests

Routine laboratory tests are generally not necessary; however, other diagnostic tests include:

- cultures, which must be taken in all neonates and immunocompromised patients
- conjunctival scrapings for Giemsa stain and or direct chlamydial immunofluorescence for chlamydial conjunctivitis
- samples taken from corneal ulcers by the attending ophthalmologist, for microbiology (as appropriate)

Scleritis requires a full evaluation for associated systemic disease.

Introduction to therapy

The following points regarding therapy should be noted:

- redness itself should not be treated without a specific diagnosis

- any patient with red eye should not wear contact lenses
- non-ophthalmologists should refrain from prescribing topical steroids without prior consultation: topical steroids can induce corneal melts, glaucoma, and cataracts
- treatment of the common causes of red eye is outlined in Tables 50.3 and 50.4

Immediate ophthalmic input is required in certain conditions to prevent loss of sight:

- any chemical burn should have copious irrigation with normal saline before direct referral to accident and emergency or eye department
- conjunctivitis in children under 1 month old (ophthalmia neonatorum) is a notifiable disease and needs immediate referral to the local eye department for culture and management
- contact-lens-related keratitis or a severe mucopurulent bacterial conjunctivitis is a potentially sight-threatening condition and should be referred promptly

Table 50.3 Treatment of common causes of red eye

	Condition	Treatment
Eyelids	Blepharitis	Lid hygiene, warm compress, and lubrication is the main advice given; however, there is insufficient evidence for recommendation of any one regimen
Conjunctiva	Subconjunctival haemorrhage	Reassurance; the red eye will resolve within 2 weeks; lubrication
	Allergic conjunctivitis	Avoidance of the allergen; systemic antihistamines and topical antihistamines or a mast cell stabilizer
	Bacterial conjunctivitis	Usually self-limiting; however, use of topical antibiotic is associated with a quicker clinical and microbiological resolution; as it is contagious, advise hygiene measures
	Viral conjunctivitis	Usually self-limiting; lubrication; as it is contagious, advise hygiene measures
	Chemical injury	Immediate normal saline irrigation until pH normalizes; then, emergency referral
	Inflamed pterygium or pingueculum	Lubrication
Cornea	Foreign body	Removal of foreign body; antibiotic ointment
	Abrasion	Antibiotic ointment; patching has not been proven to be of benefit
	Dry eye syndrome	Lubrication
Sclera	Episcleritis	Lubrication

Table 50.4 Advice for the patient on lubrication and antibiotic therapy

Treatment	Advice
Lubrication	Use topical artificial tear supplements frequently throughout the day, and an ointment at night can be prescribed to relieve mild-to-moderate discomfort
Topical antibiotic	Should be administered at least every 2 hours, then at a reduced frequency as the infection is controlled; continue 48 hours after healing
Ointment antibiotic	Should be used at night (when using drops during the day) or 3–4 times/day if used alone

Prognosis

Prognosis depends on the presumed diagnosis. Conditions where the vision is not affected are mostly self-limiting, and the prognosis is good. In conditions where vision is affected, prompt referral may well help limit the potential visual damage.

How to handle uncertainty in the diagnosis of this symptom

The patient should be referred for slit lamp examination if there is any of the following:

- loss of vision
- moderate-to-severe pain
- severe purulent discharge
- any corneal involvement
- history of previous herpetic eye disease
- lack of response to treatment

51 Hearing loss

James Ramsden

Definition of the symptom

Poor hearing is defined by the patient but affects the ability to hear sounds and discriminate speech. This usually presents with reduced clarity ('why are they all mumbling'), absent sounds ('I can't hear the birds') or communication difficulties ('Granny is going deaf'). In children, this can often present as behaviour difficulties at school or home, without complaints from the child. As a rule of thumb, 20 dB HL (decibels Hearing Level) is taken as the lower limit of normal hearing.

Differential diagnosis

A side-by-side comparison outlining the differential diagnosis in primary care and secondary care, ordered by probability, is shown in Table 51.1.

Context

Hearing loss is a common complaint in primary care. It causes communication difficulties and substantially reduces quality of life. While most causes of hearing loss can be managed in primary care without specialized investigation, the clinician should be aware of rare, but serious, causes, which would need investigation. Furthermore, the correction of hearing loss is usually straightforward and rewarding.

Approach to diagnosis

Simple in-office tests can establish the likely cause of hearing loss, and direct further management. Few patients require sophisticated investigation.

Several particularly important points should be appreciated to guide diagnosis and treatment:

- Unilateral hearing loss suggests pathology, and a cause should be sought.
- Hearing loss must be divided into conductive hearing loss (CHL) and sensorineural hearing loss (SNHL). CHL is caused by sound not reaching the cochlear (abnormality of the ear canal, tympanic membrane, middle ear, or ossicles), whereas SNHL is a condition affecting the cochlear or auditory (eighth cranial) nerve. This division is most easily achieved in the office by use of a 512 Hz tuning fork (see 'Specific clues to the diagnosis') and confirmed with a pure tone audiogram (PTA).
- Hearing loss may be accompanied by other cardinal signs of ear disease, such as otalgia (pain), discharge from the ear, vertigo, facial nerve palsy, and tinnitus, which guide the diagnosis.

Other factors which determine the differential diagnosis include:

Age: In young children, middle ear effusion related to immature Eustachian tube function is the most common cause of hearing loss.

More than 60% of children will have a period of reduced hearing related to middle ear effusions following an upper respiratory tract infection at some point during childhood, although less than 5% fail to resolve spontaneously within 3 months. In the elderly, presbycusis is the most common cause of hearing loss, with a progressive high-frequency SNHL.

Previous ear surgery: A previous history of ear surgery may suggest a conductive-middle-ear cause for the hearing loss.

Medical history: Some conditions predispose to hearing loss. These include Wegener's granulomatosis (middle ear involvement), vasculitis (cochlear artery involvement), syphilis (dizziness and hearing loss), meningitis, and many neurological conditions.

Noise-induced hearing loss: Even many years later, noise-induced hearing loss (NIHL) due to industrial or military noise exposure can cause subsequent hearing loss, with a characteristic loss greatest at 4 kHz, although it will often progress to affect other frequencies.

Medication history: Some medications are ototoxic. These include aminoglycosides such as gentamicin/streptomycin, which can cause irreversible vestibular and cochlear toxicity, especially if renal excretion is impaired or loop diuretics are co-administered. An X-linked mitochondrial genetic susceptibility to aminoglycosides can lead to cochlea injury after a single dose. Other common potentially ototoxic medications include cisplatin, carboplatin, vancomycin, macrolides, loop diuretics, aspirin, and quinine.

Family history: The presence of other members of the family with deafness at ages <50 suggests a genetic cause, of which the most common would be otosclerosis.

Specific clues to the diagnosis

The most important diagnostic step is to establish whether the hearing loss is SNHL or CHL. This can be tested with a tuning fork. In the Rinne test, the degrees of air conduction (AC) and bone conduction (BC) are determined by placing a 512 Hz tuning fork beside the ear, and on the mastoid bone behind the ear, respectively. It is important to firmly press the tuning fork onto the mastoid bone to ensure good BC. Normally, AC > BC. If AC < BC, then there is a CHL on that side. This should be confirmed by placing the tuning fork on the vertex (Weber's test). If there is CHL, then the sound should localize to the affected ear. Other clues to the diagnosis of SNHL and CHL are given in Tables 51.2 and 51.3.

The other important diagnostic step is to examine the external canal and tympanic membrane. If there is wax occluding the view, it should be removed by syringing or microscope-assisted clearance. No assessment is complete until the pars tensa and pars flaccida of the tympanic membrane has been visualized.

Key diagnostic tests

The tuning fork tests just described will guide the clinician. Other important tests include:

PTA: This should be conducted by an experienced audiologist and will give air-conduction and/or bone-conduction thresholds. Masking allows the testing of each ear independently.

Tympanometry: This allows the compliance of the tympanic membrane to be assessed, as well as, indirectly, determine middle ear pressure. It can confirm the diagnosis of middle ear effusion, perforated tympanic membrane, or reduced middle ear pressure.

Speech audiogram: Speech perception is the most important function of hearing, and tests of speech discrimination can aid diagnosis.

Table 51.1 Causes of hearing loss

Primary care	Secondary care
Wax	Presbycusis
Presbycusis	Noise-induced hearing loss
Otitis externa	Middle ear effusion
Acute otitis media	Otosclerosis
Perforated tympanic membrane	Cholesteatoma/chronic otitis media
Noise-induced hearing loss	Congenital
Otosclerosis	Vestibular schwannoma
Cholesteatoma/chronic otitis media	Ototoxicity
Congenital	Meniere's disease

Table 51.2 Clues to the diagnosis of sensorineural hearing loss

Sensorineural hearing loss	Diagnosis	Other features
Gradual onset, patient over 60, bilateral symmetrical SNHL	Presbycusis	Sloping hearing loss with high-frequency loss, normal canal, and normal tympanic membrane; consider NIHL if occupational/military exposure to >85 dB without ear defenders
Sudden SNHL, usually unilateral	Idiopathic SNHL; better outcome with course of steroids; normal TM	Needs MRI to exclude vestibular schwannoma (rare, but can present with sudden SNHL)
SNHL from birth, may be uni- or bilateral	Congenital SNHL	If severe and bilateral, may require cochlear implantation
Unilateral SNHL with vertigo	Meniere's disease (>1 attack) Labyrinthitis Vestibular schwannoma	MRI to exclude vestibular schwannoma
Bilateral rapidly progressive SNHL	Autoimmune inner ear disease Ototoxicity	May respond to steroids; check recent medication very carefully
SNHL after trauma	Cochlea injury; usually associated with severe vertigo	Much more likely if facial nerve also injured

Abbreviations: MRI, magnetic resonance imaging; NIHL, noise-induced hearing loss; SNHL, sensorineural hearing loss; TM, tympanic membrane.

Other diagnostic tests

It is unusual to require further tests. If there is asymmetrical SNHL, then MRI of the vestibular–cochlear nerve is required to exclude a vestibular schwannoma, although only ~1% of patients prove to have a vestibular schwannoma.

Table 51.3 Clues to the diagnosis of conductive hearing loss

Conductive hearing loss (CHL)	Diagnosis	Other features
CHL with itching in ear, pain, swollen canal, scanty discharge	Otitis externa	Often starts following water exposure to ears
CHL with severe pain, profuse mucoid discharge, pyrexia	Acute otitis media	Duration <2 weeks
CHL with profuse discharge, smell, granulations, or perforated tympanic membrane	Chronic otitis media with or without cholesteatoma Tumour of ear canal (rare)	Duration >3 months
CHL with effusion, usually painless	Otitis media with effusion, commonest in children	If fails to spontaneously resolve, may require treatment
CHL with wax	May be all of above or just simple wax	Wax alone does not cause more than a mild hearing loss
CHL with recent trauma	Haemotympanum CSF leak, if skull fracture Ossicular disruption	Haemotympanum is the commonest and should resolve over a few weeks
CHL with no abnormality seen, especially if family history	Otosclerosis	Usually asymmetrical; commonest cause of adult CHL with normal tympanic membrane

If there is chronic discharge and suspected chronic otitis media with or without cholesteatoma, or an unexplained CHL, then CT of the temporal bone may be indicated, although interpretation of the findings requires specialist skills and a synthesis of clinical and radiological findings.

Specialist tests such as stapedial reflexes or vestibular tests are rarely helpful.

Introduction to therapy

The treatment depends on the diagnosis.

Wax may be safely treated by irrigation, although it is important to be gentle to avoid trauma to the tympanic membrane and to use body temperature water to avoid a caloric effect causing vertigo. It is important to avoid irrigation if there is a history of previous perforated ear drum or a single hearing ear.

If the hearing loss is caused by infection and discharge, then topical treatment (e.g. with ciprofloxacin ear drops) combined with dry mopping is much more effective than systemic antibiotic treatment.

Many otological ear drops, except quinolone drops such as ciprofloxacin, are potentially ototoxic if they enter the middle ear. Evidence suggests that there is little risk from a short course of drops in an inflamed middle ear, as the thickened middle ear mucosa does not permit the entry of chemicals to the inner ear. Extreme caution should be used with long courses (>5 days) of potentially ototoxic drops in ears with perforated tympanic membranes if there is no obvious discharge.

SNHL is best treated with a digital hearing aid, of which there are various types specific to different losses. Severe/profound bilateral SNHL not benefiting from hearing aids may require cochlear implantation.

CHL treatment depends on the cause. Common options include digital hearing aid. If it is not possible to fit an aid because of chronic discharge or abnormalities of the ear canal, then a bone-conduction hearing aid (or a bone-anchored hearing aid, which is osseointegrated) may be appropriate. Middle ear effusions may be treated with grommet insertion. Otosclerosis can be corrected by stapedotomy, and ossicular abnormalities by ossicular chain reconstruction.

With all hearing loss, however, the most important ear is the better hearing ear, as hearing disability is largely determined by the air-conduction threshold of the best ear.

Prognosis

The prognosis depends upon the pathology.

How to handle uncertainty in the diagnosis of this symptom

Important points to remember when assessing an ear are as follows:

- Sudden SNHL should be promptly assessed and treated in an ENT department (same day).
- Unilateral symptoms require a search for pathology, and this may require specialist input.
- Unilateral SNHL needs to have a vestibular schwannoma excluded.
- If a patient has only one hearing ear, then be very careful.
- If the parents think a child is deaf, or the child is not speaking words by the age of 18 months, then the child needs paediatric audiological assessment.
- If there is hearing loss with other symptoms such as facial nerve palsy, fever, vertigo, or altered behaviour, then look for other conditions, including complications of middle ear infections. Otogenic infection is still the most common cause of temporal lobe brain abscesses, which can be surprisingly silent clinically.

52 Facial pain

Paul Davies

Definition of facial pain

Facial pain occupies the area below the orbitomeatal line, above the neck and anterior to the pinnae. It comes in many forms and may or may not be accompanied by other symptoms. It may be acute, subacute, or chronic, arise from local pathology (e.g. dentition, parotid gland, sinus), be referred from other structures (e.g. pain behind the eye may be due to cervical spondylosis or sphenoidal sinusitis) or be part of a neurological syndrome such as trigeminal neuralgia or persistent idiopathic facial pain (previously termed atypical facial pain).

Differential diagnosis

There is a wide differential diagnosis (Box 52.1). As with headache, serious causes are rare. Some benign conditions are particularly painful (trigeminal neuralgia, cluster headache) but have effective treatment. Most facial pain is dealt with in primary care.

Context

Facial pain is common in primary and secondary care. The site of the pain and its associated features makes the diagnosis obvious in many cases. In secondary care patients with facial pain are commonly seen by ophthalmologists, maxillofacial surgeons, ENT surgeons, and neurologists.

Sometimes localizing the causative pathology is difficult. Facial pain is transmitted via the trigeminal nerve. The central pain pathway then descends to the upper cervical spinal cord to connect with cervical afferents. This trigeminocervical complex then passes rostrally to higher pain centres. It is this complex anatomy which explains referred pain. However, pain remains ipsilateral to its cause. Pain just above the eye, without other diagnostic features, might imply frontal sinusitis but amongst other causes a cervical origin is possible. The physical signs may be diagnostic, for example, orbital pulsation and bruit, as in carotico-cavernous fistula. Often, investigations are essential to confirm a diagnosis or exclude alternatives

Box 52.1 Causes of facial pain

Local pathology

- dental pathology
- sinus (e.g. sinusitis, trauma, carcinoma)
- nose (e.g. nasal injury, upper respiratory tract infection)
- ear (e.g. otitis externa and media)
- mastoiditis
- parotid gland (e.g. parotitis, calculi, obstruction, tumour)
- eye (e.g. glaucoma)
- temporomandibular joint
- temporal arteritis

Neurological causes

- trigeminal neuralgia
- persistent idiopathic facial pain
- cluster headache
- migraine
- tension-type headache (can occur as a facial pain)
- post-herpetic neuralgia
- neck-related (cervicogenic) pain

Approach to the diagnosis

Taking a good history is the start to every diagnosis and may be the only information available for the diagnosis of many. The history for a diagnosis of trigeminal neuralgia or cluster headache is unique, and there are no abnormal findings on examination or investigation. On the other hand, persistent idiopathic facial pain does not have a unique history and so a focused examination and, if necessary, investigations (both of which should be normal) are needed for the diagnosis. Sometimes the physical signs may be diagnostic, for example, bilateral parotid swelling in mumps, or the typical rash of herpes zoster. Investigations can be helpful in excluding diagnoses; for example, clear sinuses on X-ray or CT examination exclude sinusitis as a cause of pain, but may be misleading (e.g. a CT scan showing marked sinus disease does not necessarily explain the cause of pain).

Deciding whether the pain is due to focal pathology is essential and dictates the referral pathway.

Demographics

Dental problems may occur at any age. Persistent idiopathic facial pain is a condition of middle-aged women. Cluster headache is predominantly a condition of males, with peak age of onset in the 20s and 30s. Trigeminal neuralgia is typically a condition of the elderly and, if it occurs in young people, consider an underlying cause (e.g. demyelination at the trigeminal nerve root entry zone). Teeth grinding as a cause of jaw pain is more common in anxious people. Shingles and post-herpetic neuralgia are more common in the elderly. Sometimes it relates to immunosuppression. A history of Paget's disease or myeloma may make you consider bone pathology as a cause of pain. Mumps may occur for the first time in adults. Sarcoidosis is associated with parotid disease. Polymyalgia rheumatica overlaps with temporal arteritis. Systemic conditions may be relevant to the diagnosis of the facial pain.

Specific clues to the diagnosis

Specific clues to the diagnosis are nearly always in the history:

Severity: Severity of pain can be difficult to judge but trigeminal neuralgia, cluster headache, and dental abscess pain is severe. The first two conditions, very treatable if not curable, do not respond to analgesics. Persistent idiopathic facial pain and tension-type headache (which may be behind the eyes or across the nose rather than more typically a headache) are mild but persistent pains and do not respond well to over-the-counter analgesics.

Duration: The duration of the pain is often the key to the diagnosis. Trigeminal neuralgia is a brief shooting but repetitive pain, with each paroxysm lasting 1–4 seconds. Short-lasting neuralgiform headache with conjunctival injection and tearing (SUNCT) paroxysms are 5–250 seconds long. Cluster headache is 15–180 minutes long. Sometimes, particularly when trigeminal neuralgia is very active, a constant similarly localized facial pain may also occur due to a trigeminal nerve 'wind-up' phenomenon. This can also occur in very active cluster headache. Facial migraine is not common, considering how common migraine is in the population; the pain is, by diagnostic criteria, 4–72 hours in duration. Idiopathic facial pain is constant or near-constant.

Pain frequency: Trigeminal neuralgia may relapse and remit with varying frequency. During cluster headache bouts, pain attacks can occur up to eight times a day (often at night).

Triggering: Triggering (e.g. touching the face/talking, in trigeminal neuralgia; chewing, as in temporomandibular joint dysfunction; or jaw pain on chewing (claudication) in temporal arteritis) may be a characteristic feature. In cluster headache, alcohol may be a trigger, in up to 50% of sufferers, but only during the cluster bout. Pain onset is generally abrupt. In facial migraine, some link to stress or hormonal factors may be seen and, typically, migraine pain builds up slowly to peak severity in 30–60 minutes.

Periodicity of the pain: Trigeminal neuralgia may remit and relapse, whereas episodic cluster headache has typical periodicity (e.g. pain recurs frequently often at night over several weeks or months then remits for a year or so). It may be seasonally linked. Morning jaw pain may be from teeth grinding at night and be relieved by a tooth guard.

Unilaterality of the pain: Some conditions are strictly unilateral; for example, bilateral trigeminal neuralgia is very rare and suggests serious intracranial disease; cluster headache is always unilateral, although it may change sides between attacks. Some conditions are often unilateral but not uncommonly may be bilateral (e.g. idiopathic facial pain). Cervicogenic headache is a term used to describe pain which is felt on the head or face but which is due to pathology in the (usually upper) cervical spine. Its existence is not disputed but its frequency, characteristics, and treatment remain controversial—at least amongst neurologists. It is often a unilateral persistent pain.

Site of pain: The site of pain is important. Trigeminal neuralgia is nearly always in Divisions 2 or 3 of the trigeminal nerve. If a pain with similar characteristics is around the eye, and associated with marked tearing, consider SUNCT. Cluster headache is usually centred around one eye but may occur in the jaw (so-called lower-half headache) and it may spread even to the neck and shoulder. Pain over the nose, particularly if worsened by wearing glasses, is often tension-type headache.

Associated features: Associated features—depression in idiopathic facial pain; redness; watering/running of the ipsilateral eye and/or nostril during a cluster headache attack—can be revealing. However, they may potentially mislead (e.g. nasal discharge ipsilateral to cluster headache versus sinus disease).

Key diagnostic tests

Tests are done to try and confirm or rule out a diagnosis of structural disease as a cause of pain. Some are not completely accurate and may have to be repeated; for example, early in temporal arteritis, the erythrocyte sedimentation rate may be normal. Many conditions have no diagnostic tests (e.g. trigeminal neuralgia, cluster headache, migraine). MRI is usually the imaging modality of choice but bone is not well seen on MRI. For suspected sinusitis, sinus X-ray or CT scanning can help. Dental X-rays may be important.

Introduction to therapy

The diagnosis leads to prognosis and treatment. Ideally, the cause of the problem should be treated (e.g. use steroids for temporal

arteritis, and antibiotics for a dental abscess). Sometimes the cause is never found or the diagnosis rests largely on tests having excluded a cause (e.g. idiopathic facial pain). Sometimes there is a cause, for example, an aberrant artery causing trigeminal neuralgia, but it may not be best to start off by treating it. If there is no specific therapy, then symptomatic therapy, doing nothing, or learning to cope with the condition are the only alternatives.

Prognosis

The prognosis depends on the diagnosis. Even if there is no cure for the problem, telling patients what they have got and giving them a good understanding of the condition is key to successful management. Cure may not be a realistic goal for neurological causes of facial pain such as cluster headache and trigeminal neuralgia but there are many treatment options, and such patients should be managed by specialists in that area.

How to handle uncertainty in the diagnosis

As with headache management, ruling out serious pathology (and convincing the patient that it has been done) is the first step. Uncertainty at this stage should lead to investigation or referral onwards. A good knowledge of the benign conditions (the majority of causes of facial pain) and a clear history from the patient is needed for a certain diagnosis (e.g. trigeminal neuralgia and cluster headache). Sometimes poor historians need to be instructed on keeping a diary of symptoms, and then a timely review may reveal the diagnosis. Sometimes asking patients to read up about the suspected diagnosis can be helpful (e.g. a suspected cluster headache sufferer may read accounts of that condition on the cluster headache UK charity website (<http://ouchuk.org/home>)). Basing a diagnosis on a trial of treatment is potentially misleading and can be dangerous. A good response to steroids can occur in temporal arteritis as well as facial pain due to cervical spondylosis. However, a lack of response to subcutaneous sumatriptan should lead to a reappraisal of the diagnosis of cluster headache.

Sometimes it is the patient who is uncertain of the diagnosis. Problems with management arise particularly when patients are not convinced of the benign nature of their condition and when 'the cause' has not been demonstrated to their satisfaction. This can be particularly true for patients with idiopathic facial pain.

Persistent idiopathic facial pain (atypical facial pain) is associated with psychiatric morbidity. As with trigeminal neuralgia-like symptoms, it can be associated with previous dental procedures. Sometimes it is hard to know which came first.

53 Dizziness

Linda Luxon and Louisa Murdin

Definition of the symptom

'Dizziness' as defined by the Barany Society refers to a sensation of disturbed or impaired spatial orientation without a false or distorted sense of motion. It is distinguished from vertigo, which is the sensation of self-motion when no self-motion is occurring or the sensation of distorted self-motion during an otherwise normal head movement. However, patients using this term may be referring to many different sensations. Its inherent subjectivity can make it hard for sufferers to describe their experience and for clinicians to translate the history into a differential diagnosis. A systematic approach is therefore required, and patients complaining of dizziness should be strongly encouraged to describe the sensation further.

Table 53.1 shows the causes of dizziness encountered in secondary care, although the ranking will vary according to the age of the patient.

Context

Dizziness is one of the commonest presenting symptoms in primary care; 5 in 1000 per year visit their GP for symptoms classified as 'vertigo', and 10 in 1000 per year visit their GP for dizziness or giddiness, according to statistics from The Royal College of General Practitioners/Office for National Statistics. It is a major cause of chronic ill health, with an associated reduction in quality of life. There are major economic and social implications associated with dizziness, since it is a frequent cause of inability to work and attendant social benefits claims.

Approach to diagnosis

The most valuable part of the assessment is the history. First, the symptom itself needs clarification: is the patient describing vertigo, light-headedness, disorientation, or something else? Vertigo is suggestive of an audiovestibular disorder, whereas a cardiac cause of dizziness is more likely to be experienced as light-headedness. Patients may experience many types of dizziness, and each should be characterized. It is crucial to clarify the time course of the symptom. Is this a single acute presentation, a recurrent episodic disorder, a continuous symptom, or some combination of these? The onset of the disorder, associated symptoms, and triggering/relieving factors should also be recorded.

Physical examination should begin with a careful assessment of blood pressure, especially in the elderly, in whom postural hypotension, often secondary to antihypertensive drugs, is a common cause

of dizziness. To maximize sensitivity, patients should lie down for at least 10 minutes before the first reading is made. Blood pressure should then be recorded immediately on standing and then again after 3 minutes of standing. Neuro-otological examination comprises examination of the external ear and otoscopy; eye movement examination assessing horizontal and vertical gaze, smooth pursuit, saccades, and characterization of nystagmus; a head-thrust test (see 'Specific clues to the diagnosis'); a Romberg test; gait assessment; and positional testing. One commonly used positional test is the Dix-Hallpike manoeuvre. In this test, the patient starts in a sitting position with legs extended along the couch. The head is turned 45° towards the side to be tested. The patient is then moved quickly to a supine position, and any resulting nystagmus is observed. The patient is then restored to a sitting position, with any further nystagmus noted. This manoeuvre is used to diagnose benign paroxysmal positional vertigo (BPPV). The nystagmus of the commonest type of BPPV (canalolithiasis of the posterior canal) is torsional and geotropic (upper pole of the eye beating towards the ground) with a latency of a few seconds. It fatigues (lessens in intensity with repeated manoeuvres) and can reverse on assumption of the seated posture. Other types of positional nystagmus are less common, and are seen in BPPV of the horizontal or anterior canals, vestibular migraine, and central vestibular disorders.

Specific clues to the diagnosis

Associated symptoms are frequently useful in pinpointing the diagnosis, and should be specifically sought. Hearing loss, tinnitus, and aural fullness are all suggestive of an otological disorder. Migrainous headache, phono- and photophobia, motion sickness, childhood episodes of dizziness/vomiting, and a family history may point towards vestibular migraine, one of the commonest causes of recurrent episodic vertigo. Cerebellar signs and symptoms such as intention tremor, dysarthria, past-pointing, saccadic hypermetria, broken smooth pursuit, and central-type nystagmus (e.g. bidirectional or vertical nystagmus) are helpful in localizing the problem to the CNS and will require further investigation.

The head-thrust test is a particularly useful test, both in the acute care and outpatient settings. This test involves asking the patient to fixate on a target, such as the bridge of the examiner's nose, while a passive high-velocity rotation of the head is made in the horizontal plane. If the vestibulo-ocular reflex is intact, the patient will be able to maintain visual fixation during these movements. If the vestibulo-ocular reflex is disrupted, as by a peripheral vestibular lesion, then the patient will be unable to maintain fixation. The examiner will then see

Table 53.1 Causes of dizziness encountered in secondary care

Common	Uncommon	Rare
Vestibular neuritis/labyrinthitis	Ménière's disease	Tumour
Drugs	Bilateral vestibular failure	Foramen magnum compression (e.g. Arnold–Chiari malformation)
Psychological disorder (e.g. panic disorder)	Post-traumatic vertigo	Neurovascular compression
Cardiac arrhythmia/valvular disease/outflow obstruction/carotid sinus disease	Multiple sclerosis	Autoimmune inner ear disease (systemic or localized)
Postural hypotension	Posterior circulation vascular disease	Superior semicircular canal dehiscence
Benign paroxysmal positional vertigo	Haematological: anaemia, hyperviscosity	Genetic disorders (e.g. episodic ataxias)
Vestibular migraine	Metabolic: hypoglycaemia	Vestibular paroxysmia

a 'catch-up' saccade in the contralateral direction when the head is rotated towards the lesion.

One rare but distinctive presentation is that of dizziness triggered by loud sounds or increases in intracranial pressure, the so-called Tullio phenomenon, which can be caused by superior semicircular canal dehiscence.

Key diagnostic tests

The correct diagnostic test will depend on the information provided by the history and examination. Blood tests can diagnose anaemia, hypoglycaemia, and inflammatory or autoimmune disorders. If a cardiac cause is suspected, then ambulatory ECG recording and echocardiography may be required. For neurological disorders, imaging is usually required, and frequently MRI scanning. Magnetic resonance angiography can also be helpful in cases where vascular disease is suspected.

In suspected vestibular disorders, caloric testing is the cornerstone of diagnosis. Water is irrigated sequentially into each external ear canal at 30°C and 44°C, and the vestibular response (duration or maximum slow phase velocity of the induced nystagmus) is recorded. The information obtained can be used to identify and lateralize a peripheral vestibular disorder. Pure tone audiometry can also be used to characterize a hearing loss such as the low-frequency hearing loss of Ménière's disease and identify more subtle subclinical deficits.

Other diagnostic tests

Specialist neuro-otological centres can further characterize vestibular disorders with techniques such as eye movement recordings, video head impulse testing, rotating chairs, vestibular evoked myogenic potentials, and platform posturography. Tilt-table and other autonomic function testing can be helpful where autonomic neuropathies are suspected.

Introduction to therapy

Therapy will be guided by an appropriate diagnosis.

In **acute peripheral vestibular pathology** (e.g. vestibular neuritis/labyrinthitis), the experience of severe dizziness *per se* can be extremely frightening and distressing for patients. In many cases, patients who can be reassured that there is no sinister pathology will experience a reduction in symptom intensity. Vestibular suppressant drugs (e.g. cinnarizine, cyclizine) and anti-emetics (e.g. prochlorperazine) are frequently used in the acute phases of an illness to alleviate symptoms. However, studies on animals have suggested that prolonged use of these medications can slow down recovery that occurs through cerebral compensation for a peripheral deficit. Most experts would therefore recommend that use of these medications is strictly limited to management of acute symptoms only, aiming for a maximum period of use of 1 week.

For **BPPV**, particle-repositioning manoeuvres are an extremely satisfying (for both patient and clinician) and effective treatment. Such patients should **not** be treated with medication. The Epley and modified Semont manoeuvres are both in common use in clinical practice for the treatment of posterior canal disease.

For **vestibular migraine**, acute and prophylactic medications can be used, and principles are similar to those used in other kinds of migraine. Careful consideration needs to be given to the timing of vestibular rehabilitation therapy in patients with migraine since frequent headaches can interfere with recovery and with adherence to exercise programmes.

For **Ménière's disease**, treatment in the acute phase comprises vestibular suppressants and anti-emetics, frequently by absorption through the buccal membrane. Betahistine is sometimes used, but convincing evidence either for or against its efficacy is lacking. Many experts recommend a low-salt diet and/or diuretics such as bendroflumethazide, but, again, the evidence base is currently weak. Trials of intra-tympanic medications such as gentamicin or dexamethasone are underway. Preliminary results suggest some benefit, but with an attendant risk of adverse effects such as infection, perforation of the tympanic membrane, and hearing loss.

It is also known that, for peripheral vestibular disorders, physical activity is important in recovery, and patients should be encouraged to mobilize as soon as is practical. Customized vestibular rehabilitation programmes supervised by an appropriately trained therapist have been shown to be beneficial, with maximum benefit sustained when the programme is begun early.

Patients with chronic dizziness can frequently develop secondary psychological symptoms and disorders, especially related to anxiety, panic, agoraphobia, and depression. For successful recovery from a vestibular disorder, it is essential that such disorders are acknowledged and addressed appropriately, either through medication or through psychotherapy such as cognitive behavioural therapy.

Prognosis

The prognosis depends greatly on the underlying cause, ranging from the self-limiting or eminently treatable (e.g. BPPV) to conditions which can cause progressive problems over many years (e.g. Ménière's) to the acute and life-threatening (cerebellar haemorrhage). For vestibular disorders, prognosis in general is better when conditions are identified and treated early, before the development of maladaptive physical or psychological responses.

How to handle uncertainty in the diagnosis of this symptom

One of the principle aims of assessment is to identify the minority of patients presenting with dizziness or vertigo, who have a potentially serious or life-threatening condition such as cerebellar haemorrhage or posterior fossa tumour. Careful examination for cardiac abnormalities, central neurological signs, and, where appropriate, imaging can render such conditions highly unlikely. Once such conditions have been excluded, patients may be treated expectantly, with regular reviews, to identify new diagnostic features which may become apparent during the natural history of the disorder, such as the hearing loss of Ménière's disease or the headache of migraine. Patients with chronic subjective dizziness, and no physical disorder identified after appropriate assessment, can be managed with a combination of physical and psychological therapy to address activity levels and maladaptive behaviours. Selective serotonin reuptake inhibitors appear to be helpful in some cases.

54 Disorders of sleep

Sophie West

Definition of the symptom

Typically, disorders of sleep cause disturbance either to the sufferer or to their bed partner. If total sleep time is reduced, this may lead to problems with excessive daytime sleepiness, which can affect work, driving, concentration, and relationships. 'Sleepiness' implies an intrusive desire to fall asleep, caused by some form of sleep deprivation or sedative drugs; this is different from 'tiredness', which implies general fatigue, lethargy, and exhaustion and which is caused by a range of conditions, including depression, chronic disease, or a busy lifestyle.

Adults sleep on average for 8 hours per night. Normal sleep consists of periods of deep or slow-wave sleep, interspersed with shorter periods of dreaming or rapid-eye-movement (REM) sleep. Periods of REM sleep lengthen towards the morning and hence some people remember their dreams on waking. Different disorders of sleep can affect any of these sleep stages.

Differential diagnosis

Snoring is very common and many people seek help from primary care. It is important to determine if there is any suspicion of obstructive sleep apnoea (OSA). So-called simple snorers are those with intrusive snoring, but no suggestion of OSA. Much less commonly, narcolepsy or parasomnias (sleep disorders associated with abnormal behaviours, such as sleep walking) occur. Conditions in which the day–night cycle is disturbed include phase shift disorder, shift work disorder, and circadian rhythm disorder.

Context

Sleep disorders are common but in most people are transient (e.g. sleep disorders related to jet lag, shift work, or stress). Attention to good sleep patterns (or 'sleep hygiene') minimizes sleep problems for most people. Good sleep hygiene includes a regular bedtime; regular wake time; minimal caffeine, nicotine, and alcohol consumption, particularly in the evening; a bedtime wind-down routine; avoidance of stimulatory 'blue-light' activities at bedtime, such as use of the television, computer, or mobile telephone; and avoidance of daytime naps in order to promote sleep at bedtime.

Approach to diagnosis

A careful sleep history, including details of snoring, witnessed apnoeas, sleep patterns, restless legs, night-time behaviour, and a quantification of daytime sleepiness will usually give clear pointers to the diagnosis. It is not uncommon for people who are seen in specialist sleep clinics for suspicion of a sleep disorder to have fundamental sleep hygiene issues causing their problems. Dealing effectively with these can be invaluable.

Daytime sleepiness can subjectively be given a value using a tool such as the Epworth sleepiness score, an 8-point questionnaire referring to a person's current way of life, in which they ascribe a score to how likely they are to doze off in certain situations.

Specific clues to the diagnosis

OSA: The patient complains of unrefreshing sleep, daytime sleepiness, and possibly a sensation of choking at night. The bed partner complains of loud snoring, witnessed apnoeas, and restless sleep. There is a strong association with obesity, and a collar size of greater than 17 inches. Symptoms worsen with weight gain. Sleep

studies show repeated episodes of apnoea, and oxygen desaturation, terminated by an arousal or awakening, occurring possibly hundreds of times a night.

Central sleep apnoea: This is also known as Cheyne–Stokes respiration, or periodic breathing. There is reduced ventilation during sleep, without evidence of upper airway obstruction, as well as absence of respiratory effort, and apnoeas. It is much less common than OSA. The bed partner may complain of witnessed apnoeas.

Restless legs syndrome: This encompasses a range of sensory symptoms affecting the legs (or, less commonly, the arms) and which are characteristically uncomfortable, creating an overwhelming urge to move the limbs. Movement relieves the sensation, as long as the movement continues. Symptoms are worse at rest and in the evening and night. Can occur at any age; symptoms are mild at first but progress with age. Restless legs may be primary (either idiopathic or familial (with positive family history in 60%–90%)) or secondary (occurring during pregnancy; due to iron-deficiency anaemia, end-stage renal disease, or peripheral neuropathy). The pathophysiology is not completely understood; it is predominantly a CNS disorder, with dopaminergic dysfunction in subcortical systems. Patients have a reduced concentration of ferritin and increased transferrin in their CNS, despite normal serum ferritin levels. Diagnosis is clinical. Neurological examination and neurophysiological tests are normal (including EMG and nerve conduction studies); these are not usually required for diagnosis.

Periodic leg movements during sleep: Periodic leg movements during sleep (PLMS) occur in 80%–90% of restless leg sufferers. Polysomnography using anterior tibial electrodes demonstrates involuntary repetitive movements—stereotypical flexor withdrawal reflex movements of the limbs, lasting up to 5 seconds and occurring every 5–90 seconds. Approximately one-third of these movements are associated with a cortical arousal, and thus interrupted sleep and daytime sleepiness can occur. The partner's sleep is often affected by the recurrent limb movements.

Narcolepsy: This is severe irresistible daytime sleepiness and cataplexy, a sudden loss of muscle tone triggered by strong emotions such as laughter or anger. It typically affects face muscles, head control, and knees. Sleep paralysis, hypnagogic and hypnopompic hallucinations, vivid dream recall, and difficulty differentiating dreams from reality may also occur. Short naps are refreshing. It typically presents in adolescence or early adulthood with excessive daytime sleepiness. It may not be recognized or diagnosed for years. It is caused by deficient hypocretin (or orexin) secretion from the hypothalamus. The DQB1 0602 allele predisposes towards narcolepsy and is identified in 85%–90% of narcolepsy patients. Diagnosis is with polysomnography, primarily to exclude other sleep disorders, and multiple sleep latency testing, which typically shows sleep-onset REM within 15 minutes. Low hypocretin levels are found in the CSF, although lumbar puncture not usually necessary in patients with clear history of cataplexy.

Idiopathic hypersomnia: This is persistent daytime sleepiness despite adequate sleep. Affected individuals sleep for longer than 11–12 hours on 24-hour sleep monitoring. They also take long naps of 1–2 hours, which are typically unrefreshing. The cause of idiopathic hypersomnia is unclear. Polysomnography is normal.

REM behaviour disorder: This is one of the parasomnias. Loss of normal muscle atonia during REM sleep leads to dream-enacting behaviours, which are often violent, with shouting, or the bed partner being hit. Typically occurs in over-50s, but can occur after treatments with tricyclic antidepressants, fluoxetine, or monoamine oxidase inhibitors, and after alcohol withdrawal. Polysomnography is not essential to make the diagnosis, but loss

of muscle atonia during REM is noted. This disorder may be a precursor to Parkinson's disease. Treatment is with clonazepam at bedtime. Tolerance can develop, and intermittent drug holidays are advised.

Sleepwalking: This is common in young children, and occurs in 3%–4% adults. It is a so-called arousal disorder, with incomplete waking. It occurs during slow-wave sleep. There is limited emotional or autonomic activation, but motor activity, which ranges from sitting in bed fiddling with covers to walking downstairs and opening the front door, is observed. Treat with good sleep routines, safety measures (door lock, stair gate, etc.), and nocturnal sedation, if required.

Circadian rhythm sleep disorders: These include jet lag, shift work sleep disorder, and delayed sleep phase syndrome.

Key diagnostic tests

It may be appropriate to perform an overnight sleep study to clarify events. A variety of studies can be performed, such as polysomnography, with full sleep staging via EEG; limited sleep study, predominantly looking at respiratory and cardiovascular signals; actigraphic monitoring, using small devices to determine periods of activity and rest, showing circadian rhythms, and screen for restless legs. Sleep diaries can be helpful to determine the exact day/night pattern a patient has and how much sleep they are getting. Usually, referral to a physician with an interest in sleep disorders (usually in respiratory medicine or neurology) is appropriate to arrange diagnostic tests.

Other diagnostic tests

These depend on the likely sleep disorder. It is important to exclude hypothyroidism in those patients suspected of having OSA or daytime sleepiness. As there is a strong correlation of OSA with obesity and type 2 diabetes, it is sensible to check blood glucose also. In restless legs, check ferritin levels.

Introduction to therapy

For symptomatic OSA, continuous positive airway pressure is the mainstay of treatment. The positive pressure applied acts as a 'splint' to the upper airway, preventing upper airway obstruction, apnoeas, and hence awakenings. Sleep is improved and daytime sleepiness is resolved. Patients should inform the DVLA of the diagnosis. A mandibular advancement device may be appropriate for those with mild OSA or simple snorers.

In restless legs and PLMS, patients should strive for good sleep hygiene and avoid aggravating factors such as sleep deprivation and standing or sitting for prolonged periods. Diuretics, antidepressants (especially tricyclics), calcium channel antagonists, phenytoin, and anti-emetics can aggravate symptoms. Iron replacement should occur if levels are low or low normal. Drug treatment may be required if simple measures have not helped and/or sleep is being disturbed. The dopamine agonists pramipexole, ropinirole, and transdermal rotigotine are used first line. Second-line treatments include levodopa, gabapentin, carbamazepine (particularly if pain is a feature), clonazepam, and opiates.

In narcolepsy, the first-line treatment is modafinil, a long-acting wake-promoting drug. Second-line drugs include methylphenidate and amphetamines. Specific treatment for cataplexy may be required if this is particularly problematic, usually with non-sedating antidepressants. Regular sleep-wake cycles are encouraged, with attention to standard sleep hygiene issues. Patients should inform the DVLA of the diagnosis.

Prognosis

Sleep disorders are not usually life limiting, but predominantly cause morbidity due to daytime sleepiness. Appropriate treatment can resolve this, but accurate and correct diagnosis is essential. Treatment which does not resolve symptoms should prompt further investigation, as two sleep disorders with different etiologies, such as narcolepsy and OSA, can often coexist.

How to handle uncertainty in the diagnosis of this symptom

If the diagnosis is not clear, involving a sleep specialist can be helpful. While a person has daytime sleepiness, either due to an uncertain diagnosis or prior to effective treatment, they should not drive, to protect both themselves and other road users. Driving is permitted when satisfactory control of symptoms is achieved.

55 Haematuria

Aron Chakera, William G. Herrington, and Christopher A. O'Callaghan

Definition of the symptom

Haematuria is the presence of blood in the urine. Haematuria may be either macroscopic (frank or visible haematuria) or detectable only on urine dipstick (microscopic or non-visible haematuria).

Differential diagnosis

See Table 55.1 for the differential diagnosis of haematuria in primary and secondary care.

Context

Frank haematuria can appear quite dramatic and usually leads patients in the community to seek medical attention. The high incidence of urinary tract infections as an underlying cause means that patients often have associated dysuria and frequency. Significant haematuria can lead to clot formation in the urinary tract and obstruction. The resulting symptoms are equivalent to those from obstruction due to stones (see Chapter 166). Microscopic haematuria is usually noted as an incidental finding.

Approach to diagnosis

Frank haematuria always requires further investigation usually necessitating fast-track referral to the urology department to exclude underlying malignant disease (unless a secondary cause is obvious). Usual initial investigations include a CT urogram and flexible cystoscopy.

Patients with microscopic haematuria should be questioned to determine whether it is a new finding (e.g. the persistent benign haematuria of thin basement membrane disease), and whether there is a family history of haematuria. A full urological and gynaecological history should be taken and any recent renal trauma noted. Examination should include inspection for evidence of bleeding elsewhere, (which may be consistent with over-anticoagulation or other bleeding diathesis), and palpation for renal masses or an enlarged prostate. Patients

older than 40 are usually referred to the urology service in most centres to exclude malignancy (as for macroscopic haematuria).

A dipstick should always be performed with both micro- and macroscopic haematuria. Haematuria with positive leukocytes and nitrites is consistent with a urinary tract infection. Urine microscopy may reveal dysmorphic red blood cells with glomerular bleeding. The presence of coexisting proteinuria occurs with glomerulonephritis. In acute cases, red blood cell casts may be present (see Chapter 157, Figure 157.1(b)). Serial urine collections for cytology should be performed where there is a high index of suspicion of urothelial malignancy.

Blood tests to document renal function and clotting parameters should be done routinely and, if bleeding is heavy, blood should be grouped and saved.

Specific clues to the diagnosis

Long-standing microscopic haematuria, associated with raised serum IgA levels and episodes of frank haematuria with upper respiratory tract infections, is characteristic of IgA nephropathy (see Chapter 159). Thin basement membrane disease is often familial, and is associated with persistent (usually microscopic) haematuria, and normal renal function. A family history of deafness and progressive renal impairment suggests Alport's syndrome. The presence of loin pain or a renal angle mass should raise the suspicion of renal cell cancer. Metastatic disease primarily occurs in the liver and lungs, and can lead to shortness of breath or jaundice.

Severe colicky loin pain radiating towards the groin is a feature of ureteric obstruction, which may be related to stone disease (see Chapter 166), or a clot obstructing the ureter. Infections invariably result in irritative symptoms with frequency and urgency.

Key diagnostic tests

A urine dipstick is essential to confirm the presence of blood in the urine and whether there is any protein, or evidence of infection.

A coagulation profile should be requested if a bleeding diathesis is suspected and the renal function should normally be determined.

Investigations for urinary tract malignancy include a CT urogram and cystoscopy.

Immunological tests are indicated if a glomerulonephritis seems likely, and a renal biopsy may be performed in these cases.

Conditions mistaken for haematuria/other causes of dark urine include:

- myoglobinuria
- porphyria
- medications that discolour urine (e.g. rifampicin)
- heavy beetroot consumption (discolours urine)

Other diagnostic tests

Urine microscopy may help determine the source of bleeding (dysmorphic red cells from the glomerulus). Urine cytology can be performed if urothelial malignancy is suspected.

Introduction to therapy

The management of haematuria is entirely dependent on cause. Malignant diseases of the renal tract are usually treated with surgery and/or chemotherapy, depending on the stage and the patient's functional status. Benign causes of haematuria (e.g. thin basement membrane disease) require reassurance only. However, as most patients

Table 55.1 A side-by-side comparison outlining the differential diagnosis in primary care and secondary care, ordered by probability

Primary care	Secondary care

(Exclude menstrual bleeding)	

receive a clinical diagnosis without proceeding to renal biopsy (as the risks of biopsy are thought to outweigh the benefits of a definitive diagnosis), it is prudent to monitor renal function over time. Renal tract infections or stones should be treated as discussed in Chapters 158 and 166, respectively.

Prognosis

Uncomplicated stones or infections generally have a good prognosis, although patients may suffer from repeated attacks. Renal cell cancers confined to the kidney and completely excised also carry a good prognosis. Microscopic haematuria in association with thin basement membrane disease is a benign condition. However, IgA nephropathy, the major differential diagnosis for thin basement membrane disease, causes progression to end-stage renal disease in up to 40% of patients.

How to handle uncertainty in the diagnosis of this symptom

The major area of uncertainty is the need for urological investigation in younger patients presenting with microscopic haematuria.

In this group, the risk of underlying malignancy is low and the tests are invasive (cystoscopy) and require exposure to ionizing radiation. Decisions should be made on an individual basis.

56 Oliguria and anuria

Aron Chakera, William G. Herrington, and Christopher A. O'Callaghan

Definition of the symptom

Oliguria is defined as a urine output of less than 400 ml in 24 hours, and is a marker of kidney injury (see KDIGO classification of acute kidney injury in adults in Chapter 162, Table 162.1). Anuria is the complete absence of urine production. Some sources consider a serum creatinine that increases by $100 \mu\text{mol/l day}^{-1}$ to represent an 'anuric rate of rise', a rise consistent with the absence of any meaningful renal function. Normal urine production is approximately 0.5 ml/kg h^{-1} .

Differential diagnosis in primary care and secondary care

Oliguria can be caused by any factor that affects renal function, or the free passage of urine down the urinary tract. Complete anuria most commonly occurs in men as a consequence of bladder outlet obstruction from an enlarged prostate. It can also arise in patients who have a single functioning kidney which then becomes obstructed or loses its vascular supply. Other causes of complete anuria to be considered are:

- anti-glomerular basement membrane (GBM) disease (Goodpasture's)
- bilateral renal vascular occlusion/aortic occlusion
- massive rhabdomyolysis

See Table 56.1 for a side-by-side comparison outlining the differential diagnosis in primary care and secondary care, ordered by probability.

Context

Oliguria occurs commonly in hospitalized patients, is usually secondary to impaired renal perfusion, and is often predictable. The elderly and more unwell patients, for example, those in critical care settings, are most at risk. The presence of oliguria tends to reflect the severity of the underlying disease processes. The commonest cause of complete anuria is bladder outflow obstruction from an enlarged prostate. This may be precipitated by prostatitis or constipation in a

patient with benign prostatic hypertrophy. In catheterized patients, a blocked catheter must be excluded.

Approach to diagnosis

The causes of oliguria can be considered anatomically, and divided into prerenal, renal (intrinsic), or post-renal etiologies. Obstructive causes should be excluded early, and the history should focus on symptoms suggesting prostatic disease or bladder or bowel dysfunction. In women, a gynaecological history should be taken. A detailed list of all current medications should be sought, including over the counter preparations, asking specifically about NSAIDs. In hospitalized patients, fluid balance, operative notes, and anaesthetic notes should be reviewed, blood pressure recordings checked for episodes of hypotension, and current medications documented. Examination should include an accurate assessment of intravascular fluid balance, focusing on capillary refill, pulse, blood pressure (both supine and standing, if possible), jugular venous pressure, and any evidence of pulmonary oedema. The presence of peripheral oedema does not correlate well with intravascular fluid status. The abdomen should be palpated to exclude an enlarged bladder, and the kidneys balled. Enlarged kidneys, for example, secondary to hydronephrosis, will sometimes be palpable. If there is a urinary catheter in situ, it should be flushed if there is any concern that it may be blocked. Investigations will be guided by the results of the history and examination, but will usually include a renal tract ultrasound, to exclude significant hydronephrosis or obstruction. For thin individuals, experienced ultrasonographers or radiologists can usually assess renal perfusion and flow characteristics within the renal artery and vein.

Specific clues to the diagnosis

A palpable bladder or distended bladder on ultrasound suggests an obstructive aetiology. The presence of a rash, neuropathy, or joint involvement, particularly if associated with active urinary sediment (e.g. blood and protein) or constitutional symptoms, may suggest an underlying immune aetiology. Documented hypotension, administration of IV contrast or treatment with NSAIDs, angiotensin-converting-enzyme inhibitors, or angiotensin II receptor blockers should raise suspicion of ischaemic renal injury. The passage of cola-coloured urine (associated with red-cell casts on microscopy), may indicate a rapidly progressive glomerulonephritis. There may be concurrent haemoptysis from pulmonary haemorrhage. Dipstick evidence of haematuria without the presence of red blood cells on microscopy may represent myoglobinuria; the serum creatinine kinase should be checked.

Key diagnostic tests

Key diagnostic tests include serial measures of renal function (urea and creatinine), including urgent assessment of potassium if acute renal failure is suspected. A dipstick urinalysis should always be performed, and the urine should be examined by microscopy and, if appropriate, sent for culture. A renal tract ultrasound will help exclude post-renal causes and can often provide information on renal perfusion.

Other diagnostic tests

If intrinsic renal disease is suspected, immunological tests should be requested (see Chapter 159) and a renal biopsy may be indicated. Complete anuria in the absence of post-renal obstruction requires

Abbreviations: ACE-I, angiotensin-converting-enzyme inhibitor; ARB, angiotensin II receptor blocker; NSAIDs, non-steroidal anti-inflammatory drugs.

urgent renal vascular imaging, a serum creatinine kinase test, and assessment for anti-GBM antibodies.

Introduction to therapy

As the presence of oliguria or anuria is a marker for significant renal disease, initial therapy should be directed at identifying and treating any life threats. Major problems include pulmonary oedema, hyperkalaemia, and metabolic acidosis. These should be treated as discussed in Chapters 139, 173, and 178, respectively.

Where patients are stable, close observation is indicated, with regular review of fluid balance, urine output, and renal function. Any potentially nephrotoxic medication should be stopped and the doses of other medications adjusted for the degree of renal impairment. The rate of change of renal function with time should be noted, and evidence of ongoing decline or of worsening clinical state should prompt referral to specialist renal services (or intensive care) for consideration of renal replacement therapy if indicated.

Prognosis

The development of oliguria or anuria is associated with increased morbidity and mortality. The vast majority of cases in hospital are secondary to inadequate renal perfusion, leading to acute tubular necrosis. If treated early, the prognosis in these cases may be good, but tends to depend on the severity of the underlying condition(s)

leading to renal impairment. Oliguria secondary to obstruction recovers rapidly if the onset was acute. Chronic obstruction can result in permanent renal impairment. Details of outcomes from particular syndromes can be found in Part 6.

How to handle uncertainty in the diagnosis of this symptom

In many cases, the cause of oliguria is multifactorial. As post-renal causes can usually be readily excluded following examination and an ultrasound if needed, where diagnostic uncertainty persists, management should focus on optimizing renal perfusion and function. This includes avoiding nephrotoxins, preventing obstruction, and supporting renal perfusion, while seeking an underlying cause(s). Where investigations have been inconclusive, a renal biopsy may help establish a diagnosis.

57 Polyuria

Aron Chakera, William G. Herrington, and Christopher A. O'Callaghan

Definition of the symptom

Polyuria describes the passage of more than 3 l of urine a day. This is an arbitrary definition, and the term is commonly applied to patients who are complaining of passing larger than normal volumes of urine. As water excretion is tightly regulated by the body to maintain normal osmolality, water excretion varies greatly depending on intake. Polyuria may be physiological or pathological.

Major causes of polyuria

The causes of polyuria can be divided into:

- excessive fluid intake (e.g. polydipsia)
- exposure to diuretic compounds (e.g. furosemide, hyperglycaemia, hypercalcaemia)
- failure of renal tubular water reabsorption (diabetes insipidus, chronic kidney disease, or recovering acute tubular necrosis)

Table 57.1 outlines the differential diagnosis of polyuria in primary and secondary care, ordered by probability.

Diabetes insipidus is a rare but important cause of polyuria as it is may be readily treatable. It results from a failure of vasopressin, also known as antidiuretic hormone (ADH), to regulate collecting duct water reabsorption. It can be caused by damage to the hypothalamus or pituitary gland (central diabetes insipidus) or resistance to its action (nephrogenic diabetes insipidus) (see Table 57.2.)

Context

A patient with polyuria often presents with nocturia, urination overnight that disturbs sleep. It is usually accompanied by polydipsia (to maintain normal fluid balance). In hospital the commonest causes of polyuria are diuretic therapy and recovery from an acute kidney injury (e.g. acute tubular necrosis or obstruction). This polyuric phase can result in an impressive diuresis (8–10 l/day) before tubular cells recover their ability to concentrate urine. During this period, patients are vulnerable to dehydration and may require intravenous fluid replacement. Following pituitary surgery, the urine output should be closely monitored for evidence of new diabetes insipidus.

Approach to diagnosis

Polyuria can be confirmed by collecting urine for 24 hours. In catheterized patients, a urine output that is persistently above 125 ml/h suggests polyuria.

Table 57.1 Major causes of polyuria

Primary care	Secondary care
Diuretic medications	Recovery from acute tubular necrosis
Compounds with diuretic effects, e.g. alcohol, tea, and coffee	Recovery from obstructive renal failure
Diabetes mellitus	Central diabetes insipidus, e.g. post neurosurgery or trauma
Chronic kidney disease	Rare endocrine causes, e.g. Addison's disease
Diabetes insipidus	
Psychogenic polydipsia	

Table 57.2 Causes of diabetes insipidus

Central diabetes insipidus	Nephrogenic diabetes insipidus
Pituitary surgery/trauma	Lithium
Pituitary infiltration (tumour/sarcoid)	Hypercalcaemia
Post-meningitis/encephalitis	Hypokalaemia
	Tubulointerstitial diseases
	Congenital

Specific clues to the diagnosis

The onset and severity of the polyuria may provide important clues to the diagnosis. Intermittent polyuria suggests an exogenous cause, and a careful drug and dietary history may uncover the causative agent. Transient polyuria also occurs with supraventricular tachyarrhythmias, and any history of palpitations should be noted. Diabetes mellitus should be considered in patients with a history of progressive polyuria with a prodrome of weight loss or recurrent infections (e.g. candidiasis or urinary tract infections).

Diabetes insipidus most commonly occurs following neurosurgical procedures involving or near to the pituitary gland. Central diabetes insipidus is usually characterized by a sudden onset.

Key diagnostic tests

If diabetes insipidus is suspected, blood and urinary osmolality are requested. Urine osmolality will be inappropriately dilute (<250 mOsm/l) despite a high blood osmolality. A water deprivation test will help differentiate diabetes insipidus from psychogenic polydipsia and central and nephrogenic diabetes insipidus (see Chapter 175). In psychogenic polydipsia, urine will become concentrated during water deprivation, whereas it will not with diabetes insipidus. Central diabetes insipidus responds to the administration of synthetic vasopressin (desmopressin), whereas nephrogenic diabetes insipidus does not.

Urinary frequency can be an indicator of polyuria. However, bladder irritation is a more common cause of urinary frequency and results in the passage of regular small volumes of urine that do not amount to 3 l a day. The commonest cause is a urinary tract infection (see Chapter 158).

Other diagnostic tests

Diabetes mellitus is confirmed by a random blood sugar above 11.1 mmol/l or a fasting plasma glucose above 7.0 mmol/l. Serum creatinine, electrolytes, and calcium measurement may be useful. Diabetes insipidus can cause hypernatraemia.

Addison's disease causes hyponatraemia and hyperkalaemia and, if suspected, early morning cortisol and short tetracosactide tests should be performed.

Introduction to therapy

Treatment of the underlying cause of polyuria may resolve the problem. Normoglycaemia will halt the diuresis in diabetes mellitus. Cranial diabetes insipidus may be effectively treated with intranasal synthetic vasopressin (desmopressin). Careful dosing is required to avoid overcorrection. Nephrogenic diabetes insipidus is more difficult to treat.

Prognosis

Polyuria does not carry a poor prognosis in itself. Most of the causes are treatable. In the case where treatment is limited, compensatory polydipsia can maintain normal fluid balance.

How to handle uncertainty in the diagnosis of this symptom

The diagnosis is usually straightforward. Diagnostic uncertainty may arise in patients with psychogenic polydipsia as it can mimic

diabetes insipidus. The water deprivation test is helpful under these circumstances.

58 Dysuria

Jackie Sherrard and Graz Luzzi

Definition of the symptom

The term dysuria denotes painful urination, or disturbance of urination.

Differential diagnosis

In adults, the differential diagnosis differs to some extent between males and females, age of the patient and sexual behaviour (Table 58.1).

Context

Dysuria is most often caused by inflammation of the urethra. In males, the main differential diagnosis is between urinary tract infection (UTI) and sexually acquired urethritis.

Although UTI may be diagnosed in all age groups, the likelihood of UTI as the cause of dysuria increases with age and in sexually inactive men. Urethritis rarely causes urinary frequency, and so this associated symptom suggests UTI as the cause of dysuria. Dysuria associated with urethritis is often mild and may take the form of irritation or itching during urination; the exception is dysuria associated with herpes simplex virus (HSV) which may be very painful and can provoke urinary retention.

In females, dysuria is most commonly associated with UTI and much less commonly with sexually acquired urethritis. For anatomical reasons, vulvitis may be associated with dysuria because of involvement of the urethra in the inflammatory process.

Approach to diagnosis

Adult males

A thorough history should be taken, to include:

- duration and abruptness of onset (severe dysuria with abrupt onset is more suggestive of UTI than urethritis)
- associated symptoms, which are helpful in distinguishing between UTI and urethritis; associated frequency and haematuria are

suggestive of UTI; associated urethral discharge is very suggestive of urethritis, although purulent urethral discharge is described in UTI caused by *E. coli*

- a full sexual history, covering at least the previous 3 months, including type of sexual intercourse (vaginal, oral, rectal) and use of condoms

A careful physical examination should be conducted, focusing on the genital area, lower abdomen, and inguinal regions.

- Urethritis is suggested by urethral meatal reddening (inflammation) and/or urethral discharge (gonorrhoeal urethritis is typically purulent; the discharge from urethritis caused by chlamydia or *Mycoplasma genitalium* is typically clear or turbid). UTI may be associated with bladder (suprapubic) or renal (loin) tenderness.
- Acute epididymitis typically causes unilateral, painful, tender swelling of the epididymis or testicle.
- Acute prostatitis typically presents with symptoms of UTI, pain of prostatic origin (penile tip and perineum), a swollen, tender prostate on rectal examination, and systemic symptoms (fever, malaise, sometimes rigors).

Adult females

A thorough history should be obtained, to include:

- duration and severity of symptoms (severe dysuria suggests UTI or genital herpes)
- associated symptoms, including frequency, vulval itching or pain, and vaginal discharge
- a full sexual history, covering at least the last 3 months, including type of sexual intercourse (vaginal, oral, rectal) and use of condoms

A careful physical examination should be conducted, focusing on the vulva, vagina, pelvis, and inguinal areas.

- Vulvitis is characterized by diffuse reddening of the vulval skin, which may be swollen and fissured in severe cases. Candidal vulvovaginitis, *Trichomonas vaginalis* infection, and vulval eczema can all cause this appearance.
- Primary vulval HSV infection causes a severe vulvitis with multiple, very tender, shallow ulcers around the introitus, and inguinal lymphadenopathy.
- Other skin conditions (which may present with characteristic appearances) can involve the vulva, including lichen sclerosus, lichen planus, lichen simplex chronicus, and vulval intra-epithelial neoplasia.

Specific clues from immediate investigations

See Table 58.2 for specific clues from immediate investigations, including key diagnostic tests.

Specific clues to other diagnoses

Males

Urethral stricture or bladder outlet obstruction

Clues indicating urethral stricture or bladder outlet obstruction include difficulty initiating urination (hesitancy), poor urine flow, and need to strain. Urethral stricture is now a rare complication of urethritis; bladder outlet obstruction is most commonly caused by benign prostatic hyperplasia.

Males	Females
Urinary tract infection	Urinary tract infection
Urethritis <ul style="list-style-type: none"> • chlamydia • gonorrhoea • <i>Mycoplasma genitalium</i> • genital herpes 	Urethritis <ul style="list-style-type: none"> • chlamydia • gonorrhoea • genital herpes
Urethritis associated with <ul style="list-style-type: none"> • epididymitis • prostatitis 	Urethral syndrome
Urethral obstruction <ul style="list-style-type: none"> • urethral stricture • meatal skin conditions (e.g. lichen sclerosus) • urethral carcinoma or other malignancy (extremely rare) 	Interstitial cystitis
Other causes of urethral irritation/inflammation <ul style="list-style-type: none"> • soaps, e.g. shower gel, spermicide 	Vulvitis <ul style="list-style-type: none"> • <i>Candida</i> • eczema and other inflammatory skin conditions

Table 58.2 Investigatory clues as to the different diagnoses of dysuria

Diagnosis	Urine dipstick	Gram-stained urethral smear	Urine culture	Other diagnostic tests
Urinary tract infection	Leucocytes+ Nitrite+ Blood+/-	+/- for leucocytes	+	
Urethritis ● gonorrhoea ● chlamydia ● <i>Mycoplasma genitalium</i>	Leucocytes +/- Nitrite - Blood -	+ for leucocytes (Gram-negative diplococci in gonorrhoea)	-	Chlamydia NAAT; <i>Neisseria gonorrhoeae</i> culture or NAAT; NAAT for <i>Mycoplasma genitalium</i>
Genital herpes	Leucocytes +/- Nitrite - Blood -	+/- for leucocytes	-	HSV detection by PCR
Vulvitis	Leucocytes +/- Nitrite - Blood +/-	Not indicated	-	Candida culture (vaginal swab)

Abbreviations: HSV, herpes simplex virus; NAAT, nucleic acid amplification test; PCR, polymerase chain reaction.

Meatal stenosis

A clue indicating meatal stenosis is reduced meatal size (it may be pinhole size); meatal stenosis may be idiopathic or related to a penile skin disorder, especially lichen sclerosus. Typical appearance includes pallor, scarring, telangiectasia, and areas of erythema.

Epididymitis

Epididymitis is usually acute onset, with painful swollen epididymis; it may involve the whole testicle (reactive hydrocele) and is rarely bilateral. It may be associated with urethritis or dysuria. In men aged <35 years, it is usually sexually acquired (chlamydia is the commonest cause). In older age groups, it is usually a complication of UTI (positive urine culture).

Prostatitis

For clues indicating acute prostatitis, see 'Approach to diagnosis'. Chronic bacterial prostatitis typically causes recurrent UTI caused by the same organism (clue: same antibiotic sensitivities). Chronic pelvic pain syndrome (commonly called prostatitis) is a non-infective cause of penile and perineal pain in men and may be associated with mild urinary disturbances including dysuria and variable or reduced urine flow.

Other diagnostic tests

For uncomplicated presentations of urethritis and UTI, additional diagnostic tests are not generally indicated, although recurrent UTI may require further investigation of the urinary tract by imaging. If there are associated symptoms suggestive of lower urinary tract obstruction, these should be investigated further by uroflowmetry and urinary tract ultrasound (for residual bladder volume). These would most often be undertaken after referral to a urologist.

Presentations of lower urinary tract malignancy that may cause disturbance of urinary flow, including bladder carcinoma in situ (with prostatic invasion), prostate cancer, and urethral cancer are mostly diagnosed by urologists and present very rarely to genitourinary medicine or sexual health departments.

Introduction to therapy

In general, treatment is indicated for a presumptive diagnosis of UTI or urethritis (presumed chlamydial) based on the history and results of the urine dipstick test, until the results of the chlamydia nucleic acid amplification (NAAT) test and urine culture are known.

In males, treat presumptive UTI with a minimum of 7 days of a suitable antibiotic such as trimethoprim or amoxicillin (depending on local policy, which is based on prevailing antibiotic resistance patterns) while awaiting the results of urine culture and sensitivities; non-specific urethritis (presumed chlamydial until NAAT

result is known) should be treated with 1 doxycycline 100mg twice daily for 7 days. Advise avoidance of sexual intercourse for at least 1 week, until the results are known and until after the sexual partner has also been treated.

Purulent urethritis (presumed gonorrhoea until proved otherwise) should be referred to a specialist service such as a genitourinary medicine or sexual health clinic, for microscopy of a urethral smear and culture or NAAT test. There is well-documented resistance to all available treatments for gonorrhoea, so follow-up is essential. If treated presumptively, intramuscular ceftriaxone 500 µg in 1% lignocaine together with azithromycin 1 g orally as a single dose should be used. If these are unavailable, ciprofloxacin 500 mg single dose can be given but this is associated with a significant risk of treatment failure.

In females, presumptive UTI should be treated with 3 days of a suitable antibiotic such as trimethoprim or amoxicillin (depending on the local policy) while awaiting the results of urine culture and sensitivities. Dysuria presumed secondary to vaginitis should be treated empirically with anticandidal therapy while waiting for results (e.g. with 150 mg fluconazole oral single dose or clotrimazole 500 mg vaginal pessary single dose).

Complicated infections (acute epididymitis, acute prostatitis, suspected chronic bacterial prostatitis) require specific investigation and longer courses of antibiotic treatment, appropriate to the condition involved. Suspected urethral stricture or other cause for outflow obstruction, unexplained persistent urethral symptoms following treatment, or suspected interstitial cystitis should be referred to urology.

Prognosis

Prompt treatment of UTI and urethritis usually leads to rapid resolution of symptoms within a few days (usually 1–3 days). Failure to treat the sexual partner of patients with sexually acquired urethritis is associated with a risk of reinfection and recurrence of symptoms.

Delayed treatment of UTI may lead to complications, including acute epididymitis, acute prostatitis, and septicaemia. Delayed treatment of chlamydial urethritis may lead to complications including chlamydial epididymitis and urethral stricture (rare). Delayed treatment of urethral gonorrhoea may lead to complications, including abscess formation in the accessory glands of the genital tract, gonococcal epididymitis or prostatitis, and disseminated gonococcal infection.

How to handle uncertainty in the diagnosis of this symptom

Not infrequently, the cause of dysuria remains uncertain when the results of tests are available (when urethral smear, urine culture, and

tests for chlamydia and gonorrhoea are all negative). In the absence of associated features, the prognosis is generally good, and these patients should be reassured.

Persistent dysuria with associated features (unexplained microscopic haematuria, urethral bleeding, bladder symptoms) should always be followed up with further investigations, especially in older age groups. Appropriate, timely referral to urology may be indicated for consideration of urethrocystoscopy and investigations to exclude benign prostatic hyperplasia, prostate carcinoma, and interstitial cystitis.

59 Urinary incontinence

Simon Jackson and Natalia Price

Definition of the symptom

Urinary incontinence is the complaint of any involuntary leakage of urine. It can be classified as:

Stress urinary incontinence: This is involuntary leakage of urine on effort, exertion, sneezing, or coughing.

Urge urinary incontinence: This is involuntary leakage of urine accompanied by, or immediately preceded by, a strong desire to pass urine (void). Urgency with or without urge urinary incontinence and usually with frequency and nocturia is also defined as overactive bladder syndrome (OAB).

Mixed urinary incontinence: The involuntary leakage of urine associated with both urgency and exertion, effort, sneezing, or coughing. Usually, one of these is predominant; that is, either the symptoms of urge incontinence, or those of stress incontinence, are most bothersome.

Overflow incontinence: This occurs when the bladder becomes large and flaccid and has little or no detrusor tone or function. It is usually due to injury or insult, occurring post surgery or post-partum. The bladder simply leaks when it becomes full.

Incontinence due to a fistula: This is incontinence resulting from a vesicovaginal, ureterovaginal, or urethrovaginal fistula.

Congenital incontinence: This is incontinence due to congenital causes (e.g. ectopic ureter).

Differential diagnosis/secondary causes

The following causes of urinary incontinence should always be considered:

- urinary tract infection
- bladder outflow obstruction; uncommon in women unless there is past pelvic or incontinence surgery, but common in men, due to prostatic enlargement; severe constipation can also cause bladder outflow obstruction
- psychological and metabolic causes of polydipsia and polyuria, such as diabetes mellitus, diabetes insipidus, or excessive fluid consumption
- neurological abnormalities (spinal cord injuries, spina bifida, multiple sclerosis, and other causes of upper motor neuron disorders)
- drugs (e.g. loop diuretics)

Context

Urinary incontinence is a common problem throughout the world. In the UK, there are more than 3.5 million sufferers. Patients are categorized according to their symptoms into stress, mixed, or urge urinary incontinence. Overall, half of all incontinent women complain of pure stress incontinence and 30%–40% have mixed symptoms of stress and urge incontinence. Women with mixed urinary incontinence, who have an involuntary leakage associated with urgency and also with exertion, are treated according to the most troublesome symptom. Initial treatment should commence on this basis.

Approach to diagnosis

History

History taking in urinary incontinence guides the investigation and management, by evaluating symptoms, their progression, and their impact on lifestyle, including how daily life and social, personal, and sexual relationships are affected.

The onset of urinary symptoms and their duration and severity should be recorded. The predominant bother symptom (e.g. urgency, urge incontinence, or stress incontinence) should be identified. As different underlying conditions cause similar urinary symptoms, history alone is a poor predictor of pathophysiology.

Colorectal symptoms and genitourinary prolapse should be asked about. Accompanying symptoms that may indicate a more serious diagnosis and which require referral, such as haematuria, persisting bladder or urethral pain, or recurrent urinary tract infection (UTI), should also be identified from the history.

Clinical examination

Clinical examination should include an abdominal examination to exclude abdominal mass or palpable bladder, a bimanual examination to exclude pelvic mass, and a vaginal examination. Neurological assessment of the lower limbs and perineum is required if a neurological cause is suspected.

Vaginal examination should include an assessment of urethral and bladder neck descent on straining, anterior vaginal wall mobility, and concurrent uterovaginal prolapse. An assessment of pelvic floor strength should be made in women with urinary stress incontinence. Vaginal examination is performed to palpate the levator ani muscles. Pelvic floor strength is graded 0 to 5 on a modified Oxford scale, and endurance (i.e. length of time of maximum contraction) and number of repeated contractions are also recorded.

Specific clues to the diagnosis

Specific clues to the diagnosis are as follows:

- From the history, explore possible etiological factors and ask about neurological disease, past obstetric trauma, and previous gynaecological and urological surgery.
- If polyuria is present, exclude secondary causes (e.g. diabetes mellitus, diabetes insipidus, or hypercalcaemia). However, most patients will have primary polydipsia, and simple advice regarding fluid restriction is sufficient to resolve urinary frequency.
- The predominant symptom (e.g. urgency, urge incontinence, or stress incontinence) should be identified.

Key diagnostic tests

Key diagnostic tests are as follows:

Urinalysis: Reagent strip testing of urine for leukocyte esterase, nitrates, protein, blood, and glucose is a sensitive and cheap screening test.

Urine culture: Perform urine microscopy and culture for those with a positive screening test result. Exclusion of infection is mandatory, as symptoms of detrusor overactivity overlap with those of UTI.

Residual check: A post-void residual check should be carried out (either ultrasound scan or catheterization) if there are symptoms suggestive of incomplete bladder emptying.

Urinary diary: Diagnosis is assisted with the use of a frequency/volume chart (urinary diary). This is a simple and practical method of obtaining objective quantification of fluid intake, functional bladder capacity, and voiding behaviour. Frequency and times of voiding, voided volumes, and leakage episodes (day and night) are all recorded for at least 24 hours and typically 3 days.

Urodynamic investigations: These include uroflowmetry, post-void residual measurement, and cystometry. It is important that any clinician referring a patient for such tests has an understanding of

what the tests entail and the indications for it. Clinical indications for urodynamic assessment are:

- complex mixed urinary symptoms (urge incontinence and stress incontinence)
- symptoms suggestive of detrusor overactivity unresponsive to pharmacotherapy
- voiding dysfunction with incomplete bladder emptying
- neuropathic bladder disorder (videourodynamics preferred)

Other diagnostic tests

Imaging of the urinary tract

Imaging of the lower urinary tract is not routinely justified in all women presenting with urinary symptoms, but should be targeted at specific indications. The available diagnostic procedures include:

Ultrasonography: This is used to (1) exclude incomplete bladder emptying; (2) check for congenital abnormalities, calculi, and tumours; and (3) detect cortical scarring of the kidneys.

X-ray: Plain abdominal X-ray film is useful for screening for foreign bodies and calculi.

Intravenous urography: This is indicated in women with neuropathic bladder or suspected congenital or acquired abnormalities (e.g. uterovaginal fistulae).

Micturating cystourethrography: This is useful to demonstrate bladder and urethral fistulae, vesicourethral reflux, and anatomical abnormalities of the lower urinary tract, such as urethral diverticula.

CT: This can detect and characterize solid renal masses as well as renal tract calculi, renal and perirenal infections, and associated complications.

MRI: This remains a research technique for incontinence and prolapse, due to cost and availability. It is mainly used for characterization of renal or pelvic masses, and tumour staging.

Introduction to therapy

Urge urinary incontinence

Start with the simplest of conservative therapies and progress through to treatments that are more radical, if necessary. Reducing fluid intake, if the urinary diary suggests this is excessive, and cutting caffeine out of the diet often has a dramatic effect. This simple advice may be all that is required to cure frequency and urgency. Drugs (e.g. diuretics and antipsychotics) altering bladder function should be reviewed.

Bladder training should be offered as first-line treatment to patients with OAB, often in combination with anticholinergic therapy. The three main components of bladder training are patient education, timed voiding with systematic delay in voiding, and positive reinforcement. The patients should be asked to resist the sensation of urgency and void according to a timetable. A self-completed urinary diary should be used to monitor the times of voids. Continence rates of up to 90% have been reported but the cure rates could be considerably lower than this.

Pharmacological suppression of detrusor overactivity with anticholinergics (antimuscarinics) is the most widely used treatment. Anticholinergic drugs block the muscarinic receptors that mediate detrusor smooth-muscle contraction and have a direct, relaxing effect on the detrusor muscle. There are a number of drug treatments available, which differ in their selectivity for various muscarinic receptors; some drugs have additional actions, such as direct smooth-muscle effects. In postmenopausal women with vaginal atrophy, intra-vaginal oestrogens can be tried for OAB symptoms.

Surgery is recommended for intractable detrusor overactivity only when medical and behavioural therapy has failed. Procedures such as bladder distension, detrusor myectomy, and augmentation cystoplasty have limited efficacy and high rates of complication. Permanent urinary diversion is occasionally indicated in women with intractable incontinence.

Some new treatments, such as intra-vesical botulinum toxin injections, neuromodulation, and sacral nerve stimulation are showing considerable promise. Botulinum toxin A may revolutionize OAB

management. It blocks neuromuscular transmission, causing the affected muscle to become weak. The toxin is injected cystoscopically under local or general anaesthesia into the detrusor muscle in 10–30 different locations, sparing the trigonum. Cure, or improvement rates of 60%–93%, has been reported at initial follow-up. The duration of response to a single dose is on average 9 months (range 3–12 months). The most common complication is voiding dysfunction and urinary retention (5%–20%), resolving as the effect of the treatment wears off. This treatment shows promise as a therapy for overactive bladder symptoms, but little controlled-trial data exist on benefits and safety.

Neuromodulation and sacral nerve stimulation provide continuous stimulation of the third sacral spinal nerve root via an implanted electrical pulse generator and improves the ability to suppress detrusor contractions. It is being used increasingly in the treatment of refractory detrusor overactivity. Overall, neuromodulation has a 30%–50% clinical success rate. It is a very expensive treatment, as the implant alone costs approximately £10 000. Insertion of the implant is an invasive procedure, and lifelong follow-up is required.

Stress urinary incontinence

Conservative treatment is usually initiated in primary care. This involves treating the symptoms of stress incontinence, for example, through adjustment of lifestyle (weight reduction if BMI > 30; smoking cessation; treatment of chronic cough and constipation), pelvic floor exercises, and pharmacotherapy.

Pelvic floor exercise is an appropriate first-line treatment for most women. The aim of pelvic floor exercise is to promote the woman's awareness of her pelvic floor muscles and to improve their contractility and coordination. Wherever possible, an appropriately trained physiotherapist should make an assessment of the pelvic floor musculature.

Surgery for stress urinary incontinence is considered when conservative measures have failed and the woman's quality of life is compromised. It is important to be clear about the underlying cause of the incontinence, as the effects of surgery are largely irreversible. The options depend on the woman's fitness for anaesthesia and whether there is any coexisting prolapse. Burch colposuspension used to be a 'gold-standard' procedure for many years, with a success rate of 85%–90%. The retropubic space is entered through a small suprapubic incision, and two or three permanent sutures are placed on either side of the bladder neck to the corresponding ileopectineal ligament. This procedure can also be performed laparoscopically. There are also a variety of 'sling' procedures that can be performed abdominally or vaginally, with rectus sheath, fascia lata, or synthetic materials. The commonest of these is the tension-free vaginal tape procedure, which has a success rate of between 80% and 90%.

Injectables or bulking agents are appropriate, if previous surgery has failed or in very elderly patients. Various compounds, including collagen, have been used, with success rates of around 50%.

Complications for all these procedures include post-operative voiding difficulty, bleeding, infection, de novo detrusor overactivity, and suture or mesh erosion (in 'sling' procedures).

Prognosis

Incontinence can be cured or significantly improved in most women, providing they are appropriately investigated and treated. However, for a small number of women, a cure may be impossible. For this group, containment with pads, devices, or even catheters may be the most appropriate therapy. Bladder catheterization (using an intermittent or indwelling urethral or suprapubic catheter) should be considered for patients in whom persistent urinary retention is causing incontinence, symptomatic infection, or renal dysfunction, and in whom this cannot otherwise be corrected. Clean intermittent self-catheterization is a technique that can be taught to patients or carers (e.g. by a continence nurse) to facilitate bladder emptying in case of urinary retention with large residuals. This may relieve overflow incontinence.

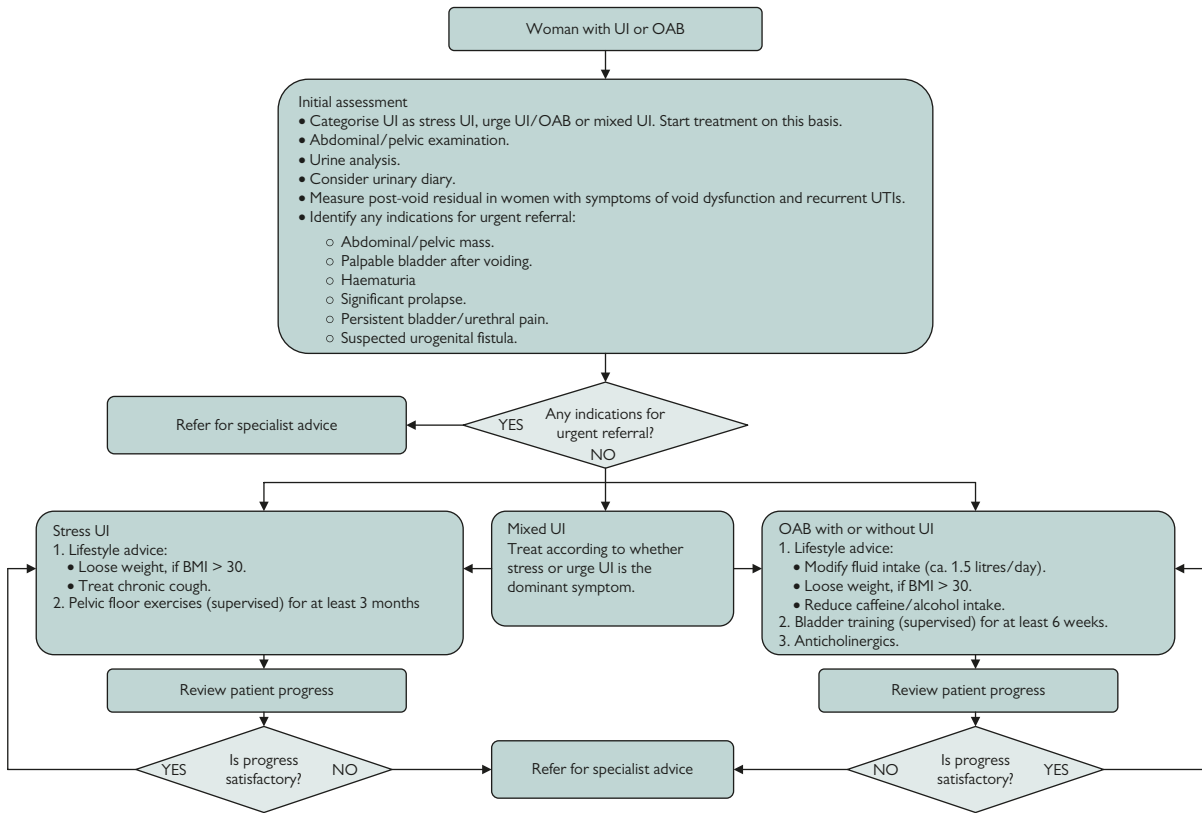

Figure 59.1 Initial assessment and management of women with urinary incontinence.
Data from Urinary incontinence in women: management, NICE clinical guideline cg717, 2013 nice.org.uk/guidance/cg171.

How to handle uncertainty in the diagnosis of this symptom

Figure 59.1 illustrates the initial steps in diagnosis and assessment of women with urinary incontinence, and shows the conservative management steps to be undertaken before referring for specialist advice on surgical management.

60 Faecal incontinence

Udi Shmueli

Definition of the symptom

Faecal incontinence (FI) is the recurrent uncontrolled passage of faecal material.

It is important to subdivide it into passive leakage, when the patient is unaware of stool loss, and urge incontinence, when there is insufficient time to reach the toilet. The inadvertent escape of flatus and partial soiling of undergarments with liquid stool is graded as minor incontinence, and the involuntary excretion of solid faeces as major incontinence.

Context

Estimates of the prevalence of FI vary widely in studies, depending on the definition used and the population studied, but about 2% of adults are incontinent of faeces about once a week. The problem increases with age to affect up to a third of residential and nursing home patients. It is a highly embarrassing problem that patients try to hide, and avoid talking about to their spouse or their doctor. The presenting complaint may be diarrhoea, a change in bowel habit, or with the symptoms of irritable bowel syndrome and it may take direct questioning to elucidate the problem.

Approach to diagnosis

A careful history is the key to diagnosis. Establish if there is passive leakage, when the patient is unaware of stool loss until the underpants are actually soiled, or urge incontinence, when the patient is aware of the need to defecate but has insufficient time to reach the toilet. Determine the frequency and severity of the FI and if there has been a change in bowel habit, which would require further investigation. Move on to a general history, including any obstetric and surgical history, and concentrate on the presence or absence of neurological or spinal disorders, diabetes, cognitive impairment, behavioural abnormalities, or physical impairment that might impair access to the toilet. Apply your finding to Table 60.1 to obtain a differential diagnosis.

Physical examination of the abdomen perianal area and rectum is essential, looking for rectal or anal tumours, inflammatory change, faecal impaction, fistulae, or rectal prolapse. Assess anal sensation, resting tone, and squeeze pressure. Gaping of the anus when the buttocks are parted or the inability to contract the anus on command suggests significant sphincter damage or neurological problems. Be aware, however, that, unless there is a gross abnormality, digital examination is a poor determinant of sphincter integrity and function.

Specific clues to the diagnosis

With urge incontinence, it is essential to establish if the patient has had a change in bowel habit to looser stools, as this would require further investigation. Diarrhoea that responds to small doses of loperamide is likely to be functional, but may still need to be investigated. Be aware that a patient with urge incontinence may actually be constipated, even if complaining of frequent defaecation. In a constipated patient, physical activity or a gastrocolic reflex after eating may bring on an urgent call to stool, with incontinence in those unable to reach a toilet in time. Sometimes the only clue to constipation is a history of unsatisfying defaecation with small hard stools or mucous. An abdominal X-ray is occasionally necessary to demonstrate a colon loaded with stool.

Table 60.1 Common causes of faecal incontinence

Causes	Mechanisms
<i>With mainly urge incontinence</i>	
External anal sphincter dysfunction Vaginal delivery Surgery for fistulae Haemorrhoidectomy Other trauma	Direct trauma to the anal sphincters; damage to the pudendal nerve by stretching of the pelvic floor during pregnancy
Inflammatory conditions Ulcerative colitis Crohn's disease Radiation proctitis	Inflammation of the rectal mucosa causes a much more urgent call to stool; chronic inflammation and fibrosis can reduce rectal compliance; diarrhoea, which may be of large volume
Functional faecal incontinence	As part of an irritable bowel syndrome, often with a prominent gastrocolic reflex; defined as faecal incontinence with abnormal functioning of normally innervated and structurally intact muscles
Other physical or behavioural problems	The patient may be unable or unwilling to reach the toilet in time
<i>With mainly passive incontinence</i>	
Constipation Common in the elderly, institutionalized and inactive people, or those taking strong analgesics	Passive leakage due to inhibition of the internal sphincter; they may also complain of diarrhoea (due to overflow) and deny any possibility that they are constipated; constipation may also be associated with a prominent gastrocolic reflex, which in the poorly mobile may lead to urge incontinence
Neuropathy and spinal injury Multiple sclerosis Diabetes Spinal trauma Pregnancy causes partial denervation of the pelvic muscles and anal sphincter by stretching and compressing the pelvic floor	Diminished sensation and diminished or absent external sphincter activity to oppose bowel contraction; exacerbated in multiple sclerosis by constipation with overflow; exacerbated in diabetes by diarrhoea due to autonomic neuropathy, metformin, or small bowel bacterial overgrowth
Internal anal sphincter dysfunction	Degeneration of unknown cause; radiotherapy (e.g. for prostate or cervix); systemic sclerosis

With passive incontinence, it is vital to look for faecal impaction by rectal examination, even if there are factors in the history such as radiotherapy that may explain the problem.

Key diagnostic tests

Endoscopic assessment of the rectosigmoid mucosa is recommended in most patients. Diarrhoea must be appropriately investigated. Endoscopy may not be necessary in constipation unless there are alarm symptoms such as bleeding, weight loss, or a family history of bowel cancer.

Other diagnostic tests

These are used in patients with suspected sphincter damage who do not respond to simple treatment.

The internal and external anal sphincters can be imaged by endo-anal ultrasound and MRI. Small defects are common and may not be related to symptoms. Large sphincter defects may be amenable to surgical repair, but patients with additional neurological damage do less well with surgery. Dynamic MRI can also demonstrate pelvic floor motion.

Anorectal manometry is performed with a catheter assembly that includes a balloon positioned in the rectum and pressure transducers in the anal canal. A low resting anal pressure suggests dysfunction of the internal anal sphincter. A reduced squeeze pressure is associated with external anal sphincter dysfunction. Impaired sensation means that techniques such as biofeedback are unlikely to be successful.

The pudendal nerve is tested by stimulation with a glove-mounted electrode while the anal sphincter EMG response is measured. A prolonged conduction time indicates pudendal nerve damage. EMG recordings of the anal sphincter detect proximal neurogenic or myopathic lesions.

Introduction to therapy

Treatment will depend on the underlying cause and the severity of the symptoms. Most patients will be improved by medical therapy aimed at restoring normal bowel habits. Constipated patients should have aggressive therapy with laxatives, and usually enemas or suppositories.

Loperamide is used in patients with loose stools and occasionally in patients with normal stools and FI, as hard stools are easier to retain. Loperamide will slightly increase internal sphincter tone in addition to reducing bowel frequency, but the dose of loperamide has to be carefully titrated in order to avoid constipation. Loperamide can be taken before bed for people with night-time or early morning problems, before physical activity, or before meals for those with a prominent gastrocolic reflex. Patients with a prominent gastrocolic reflex may also benefit from hyoscine or mebeverine.

Another approach is for the patient to use rectal suppositories or a self-administered micro enema to clear out the rectum in the morning, or before going out. This may prevent significant incontinence and enhance confidence.

A toilet access 'Just Can't Wait' card and a 'RADAR' key to allow access to 'disabled' toilets in the National Key Scheme can be obtained from the Bladder & Bowel Community, who also provide patient information including information on continence products.

Perianal hygiene is vital. The anus should be cleaned with water whenever possible and dried by gentle dabbing. Barrier creams such as zinc oxide or calamine can help prevent skin damage. Irritation may

be due to a fungal infection or dermatitis and should be treated with appropriate creams.

Patients should be encouraged to strengthen the anal sphincters with pelvic floor exercises, such as repeatedly tightening and relaxing the anus.

Patients who fail to improve with medical therapy should be referred to specialist centres, where a range of investigation and treatment techniques are available. These include biofeedback therapy, sacral nerve stimulation, and surgery.

Surgical intervention is occasionally necessary but carries the risk of worsening the incontinence. The best results are with a relatively simple overlapping repair to a single defect in the external anal sphincter, or an abdominal rectopexy to repair a rectal prolapse, as this may restore internal sphincter function. However, patients with internal sphincter defects, pudendal nerve neuropathy, multiple defects, or external sphincter atrophy are unlikely to benefit from surgery. A colostomy is used in severe FI when other treatments have failed.

Prognosis

If the underlying problem is functional incontinence, constipation, inflammatory bowel disease, or other resolvable bowel disturbance problems, then most patients will be helped by medical therapy. Patients with sphincter disruption or neurological problems and severe FI are less likely to improve sufficiently with simple measures and will benefit from an early referral to a specialist centre.

How to handle uncertainty with this symptom

Patients are afraid to socialize or leave the house for fear of embarrassing incontinence. They are reticent to talk about their problem even to their partner. They lose self-confidence and self-esteem. They need and welcome the opportunity to discuss their problem with a sensitive healthcare professional, if only to 'fine-tune' their coping strategies.

61 Vaginal discharge

Jackie Sherrard and Graz Luzzi

Definition of the symptom

Vaginal discharge may be a normal feature (physiological discharge). However, as a symptom, the term is used to denote vaginal discharge which is excessive in quantity or abnormal in appearance, consistency, or odour. Causes of vaginal discharge are given in Table 61.1.

Context

Vaginal discharge is the result of secretions produced from glands in the vaginal and the cervical mucosae. It is a common presenting symptom and may be caused by a range of physiological and pathological conditions. All women have physiological discharge starting a year or two before puberty and ending after the menopause. During the menstrual cycle, concentrations of oestrogen and progesterone vary, leading to alterations in the quantity and type of cervical mucus. Prior to ovulation, oestrogen concentration increases, altering cervical mucus from non-fertile to fertile (clearer, wetter, stretchy, and slippery). After ovulation, oestrogen concentration decreases and progesterone concentration increases; cervical mucus becomes thick and sticky and hostile to sperm. The amount of discharge varies from woman to woman, as do perceptions of what is normal. However, there are also a number of conditions, both infective and non-infective, that may give rise to pathological vaginal discharge. Many of the

symptoms and signs are non-specific, and a number of women may have other conditions such as vulvar dermatoses or allergic reactions as a cause of their symptoms.

A normal physiological discharge is a white or clear, non-offensive discharge that varies with the menstrual cycle. Sexual arousal, pregnancy, and using the oral contraceptive pill are typically associated with an increase in 'normal' vaginal discharge.

Three common infections are associated with vaginal discharge—bacterial vaginosis, candidiasis, and trichomoniasis. Infections with other organisms such as *Chlamydia trachomatis* and *Neisseria gonorrhoeae* may cause vaginal discharge due to cervicitis.

Approach to diagnosis

A full sexual history (to assess STI risk) and clinical history should be sought, with a particular note of the nature of the discharge (what has changed, odour, onset, duration, colour, consistency) and associated symptoms (may include itch, superficial dyspareunia, or dysuria), or symptoms suggestive of upper reproductive tract infection (e.g. abdominal pain, deep dyspareunia, abnormal bleeding, dysuria, pyrexia). Also consider concurrent medications (e.g. recently starting, changing, or stopping hormonal contraceptives, antibiotics, corticosteroids), and medical conditions (e.g. diabetes, immunocompromised state).

Specific clues to the diagnosis

Symptoms suggesting that discharge is abnormal include:

- a discharge that is heavier or thicker than usual
- greyish, greenish, yellowish, or blood-tinged discharge
- offensive smelling discharge

Vaginal infections are suggested by a discharge accompanied by vulval or vaginal itching, burning, rash, or soreness, the presence of genital sores or ulcers, abdominal pain or pain on intercourse, and a recent change in sexual partner, a new partner, or concurrent symptoms in a sexual partner.

Infective, non-sexually transmitted causes of vaginal discharge

There are two infective, non-sexually transmitted causes of vaginal discharge:

Bacterial vaginosis: Bacterial vaginosis is due an overgrowth of anaerobic bacteria and occurs and remits spontaneously. It typically presents as a thin, profuse, and fishy-smelling discharge without itch or soreness, and may cause dyspareunia.

Candidiasis: Candidiasis is more common in pregnant women and those with diabetes mellitus, recent antibiotic treatment, or immunosuppression. The characteristic symptoms are thick, white, non-offensive discharge associated with vulval itch and soreness. It may cause mild dyspareunia and external dysuria, and on examination there may be vulval and/or vaginal erythema, oedema, and fissuring.

Infective, sexually transmitted causes of vaginal discharge

Chlamydia trachomatis, *Neisseria gonorrhoeae*, and *Trichomonas vaginalis* can all present with vaginal discharge:

Chlamydia trachomatis: This is asymptomatic in 80% of women but may cause a copious purulent vaginal discharge due to cervicitis. The woman may complain of post-coital and/or intermenstrual

Table 61.1 Causes of vaginal discharge, listed according to age and pregnancy status

Prepubertal	Physiological Allergic dermatitis Vulval dermatitis
Reproductive age	Non-sexually transmitted infection: <ul style="list-style-type: none"> • bacterial vaginosis • <i>Candida</i> infections Sexually transmitted infection: <ul style="list-style-type: none"> • <i>Chlamydia trachomatis</i> • <i>Neisseria gonorrhoeae</i> • <i>Trichomonas vaginalis</i> Cervical polyps and ectopy Vulval dermatitis Physiological Foreign bodies, e.g. retained tampon Erosive lichen planus Genital tract malignancy (cancer of cervix, cancer of uterus, ovarian cancer) Fistulae
Pregnancy	Physiological Non-sexually transmitted infection: <ul style="list-style-type: none"> • <i>Candida</i> infections common in pregnancy (30%–40%) • bacterial vaginosis Sexually transmitted infection: <ul style="list-style-type: none"> • <i>Chlamydia trachomatis</i> • <i>Neisseria gonorrhoeae</i> • <i>Trichomonas vaginalis</i>
Postmenopausal	Atrophic vaginitis Cervical polyps and ectopy Desquamative inflammatory vaginitis Vulval dermatitis Genital tract malignancy (cancer of cervix, cancer of uterus, ovarian cancer) Fistulae

bleeding. Chlamydia infection may be complicated by pelvic inflammatory disease.

Neisseria gonorrhoeae: This is asymptomatic in up to 50% of women but may present with a purulent vaginal discharge due to cervicitis. Other symptoms include dysuria and intermenstrual bleeding. Gonorrhoea may be complicated by pelvic inflammatory disease.

Trichomonas vaginalis: This may cause an offensive yellow vaginal discharge, which is often profuse and frothy, and may be associated with vulval itch and soreness, dysuria, abdominal pain, and superficial dyspareunia.

Non-infective causes of vaginal discharge

The following are non-infective causes of vaginal discharge:

Allergic reactions: Diagnosis is suspected on taking the history (e.g. use of irritant chemicals in douching, contact with latex and semen).

Retained foreign bodies: These are usually tampons or condoms and result in a foul-smelling serosanguinous discharge. The diagnosis is confirmed on examination.

Cervical polyps and ectopy: These tend to be asymptomatic but there may be increased discharge and intermenstrual bleeding. The diagnosis is made on speculum examination.

Genital tract malignancy: The presentation varies and, in some cases, a persistent vaginal discharge not responding to conventional treatment may be the first clue. The diagnosis is made on examination and biopsy.

Fistulae: A history of trauma or surgery is suggestive. There may be a foul or feculent discharge in association with recurrent urinary tract infections.

Key diagnostic tests

Exclusion of infective and other causes can help confirm that a vaginal discharge is physiological. Patients complaining of discharge should have an examination of the external genitalia for evidence of vulvitis or ulcers, and a speculum examination to allow inspection of the vagina and cervix and to undertake appropriate investigations.

A woman presenting with symptoms suggestive of bacterial vaginosis or vulvovaginal candidiasis can be treated without taking swabs at first presentation, if she is at low risk for STIs and without symptoms indicative of upper reproductive tract infection. However, a woman complaining of vaginal discharge should be investigated if she requests investigation; is deemed to be at increased risk of STIs; has symptoms indicative of upper genital tract infection; is postnatal, post-miscarriage, post-abortion, or within 3 weeks of intrauterine contraceptive device insertion; or if previous treatment has failed.

Initial investigations outside a GUM clinic include:

- a high vaginal swab to identify bacterial vaginosis, candida infections, and *Trichomonas vaginalis*
- endocervical or vulvovaginal swab for DNA amplification test to diagnose gonorrhoea
- endocervical or vulvovaginal swab for a chlamydial DNA amplification test to diagnose *Chlamydia trachomatis*
- vaginal pH testing (using narrow range pH paper) is a quick, cheap, and simple test that can help discriminate between bacterial vaginosis (pH 4.5 or above) and vulvovaginal candidiasis (pH <4.5)

Other diagnostic tests

In a woman at risk of STIs, it is prudent to offer a full screen, including testing for blood borne viruses and syphilis serology. Further tests will depend upon the findings on examination, and may include patch testing for allergies, or biopsy of suspicious lesions.

Introduction to therapy

General principles include good basic personal hygiene (cleanliness without the use of douches and perfumed chemical agents), with

avoidance of tight synthetic clothing. Where it is decided that the discharge is physiological, the woman may need careful explanation of this, and reassurance regarding the absence of pathology.

Infective, non-sexually transmitted vaginal discharge

The following are therapies for infective, non-sexually transmitted causes of vaginal discharge:

Bacterial vaginosis: The recommended treatment is oral metronidazole (400–500 mg twice daily for 5–7 days).

Candidiasis: Vaginal imidazole preparations (e.g. clotrimazole, econazole, miconazole) or fluconazole 150 mg orally are equally effective in the treatment of vulvovaginal candidiasis. Avoid oral azole regimens in pregnancy, due to potential teratogenicity. Vulval antifungals (in addition to oral or vaginal regimens) can be used if women have vulval symptoms. Latex condoms, cervical caps, and diaphragms may be damaged by azole-containing local preparations.

Infective, sexually transmitted vaginal discharge

Patients with infective, sexually transmitted vaginal discharge should be referred to the GUM clinic (unless your practice has the appropriate expertise and access to local treatment protocols and partner notification). Patients need to be fully screened for concurrent STIs and treated as is appropriate, and partners will need to be identified, screened, and treated too:

Chlamydia trachomatis: First-line therapy includes doxycycline 100 mg twice daily for 7 days (contraindicated in pregnancy) and azithromycin 1 g orally in a single dose.

Gonorrhoea: Therapy includes ceftriaxone intra-muscularly as a single dose.

Trichomonas vaginalis: Metronidazole 2 g orally in a single dose or metronidazole 400–500 mg twice daily for 5–7 days.

Non-infective causes of vaginal discharge

The following are therapies for non-infective causes of vaginal discharge:

Allergic reactions: Treatment includes identifying and removing the cause.

Retained foreign bodies: These can usually be removed with a sponge forceps or similar instrument. A short course of antibiotics may be needed if the object was there long enough to cause secondary infection.

Cervical polyps and ectopy: In this case, excision of larger symptomatic or suspicious looking polyps may be necessary.

Prognosis

The prognosis is as follows:

- Bacterial vaginosis has a 70%–80% cure rate after one course of treatment (but commonly recurs).
- Candida has a cure rate of 80%–95%.
- Trichomoniasis has a 95% cure rate.
- The finding of an STI should prompt patient education, screening for other infections, and sexual contact tracing for testing and appropriate management to prevent reinfection.

How to handle uncertainty in the diagnosis of this symptom

In women who experience intermittent symptoms, it may be necessary to see them acutely when they are symptomatic to establish the diagnosis. Where no cause is found for discharge, and examination is normal, a woman often needs careful explanation of the nature of physiological discharge and reassurance regarding the absence of pathology.

Some women suffer with recurrent discharge and, in general, the advice is the same as for the initial presentation, although it is prudent to go through the symptoms, signs, and examination process

rigorously to ensure coexistent pathology hasn't been missed (e.g. an STI in the case of a patient being treated for bacterial vaginosis) and explore personal hygiene habits that may contribute to the disruption of normal vaginal flora (such as douches). Finally, be alert to possible underlying associated problems such as diabetes, immunosuppression, or concurrent antibiotic administration and for psychosexual problems and depression that can be associated with recurrent episodes of vaginal discharge.

62 Joint pain

Pippa Watson

Definition of the symptom

When a patient complains of pain confined to a joint or joints, they are said to have **arthralgia**. If, in addition, there is swelling of the joint, tenderness of the joint line to palpation, and limitation of movement, the patient is said to have an **arthritis**. It is important to establish if an arthritis is **inflammatory** or **non-inflammatory**, as this affects the differential diagnosis. Soft tissue swelling of the joint, the presence of a joint effusion, increased temperature of the joint, erythema of overlying skin, and early morning stiffness of at least 30 minutes duration are signs of an inflammatory arthritis.

Differential diagnosis

Joint pain (arthralgia) may reflect trauma, degenerative and inflammatory arthritis, inflammation of extra-articular tissues, systemic infection, or an allergic reaction to medication. The causes of acute arthralgia in primary and secondary care are shown in Table 62.1

Context

A history of trauma should prompt consideration of diagnoses such as fracture or ligament damage. Other conditions which can mimic monoarthritis include bursitis or tendonitis. It is always vital to consider the diagnosis of septic arthritis because of the serious consequence of late or missed diagnosis. Systemic upset, fever, severe pain, and grossly restricted range of movement of the joint raise the possibility of this diagnosis, and should trigger urgent referral to a specialist.

It is useful to make the distinction between septic arthritis, where there is infection in a joint, and reactive arthritis, where a joint becomes inflamed in response to infection elsewhere. Septic arthritis is usually the result of haematogenous spread, but may result from adjacent osteomyelitis. Reactive arthritis can occur in response to sexually transmitted infections, when it may result in the classical triad of arthritis, conjunctivitis, and non-specific urethritis. It may also be triggered by a range of viral or bacterial infections.

Approach to diagnosis

Pattern recognition is important in determining the cause of a hot joint. A thorough history and examination will often provide the necessary information to make a diagnosis.

Table 62.1 Causes of acute arthralgia in primary and secondary care

	Primary care (% of cases)	Secondary care (% of cases)
Gout/pseudogout	77	66
Monoarticular presentation of inflammatory arthritis	15	20
Reactive arthritis	5	10
Haemarthrosis	2	3
Septic arthritis	1	1
Monoarticular presentation of connective tissue disease or vasculitis	<1	1

Key factors in the history

Key factors in the history are as follows:

Demographics: Premenopausal women are extremely unlikely to suffer from gout, while conditions such as pseudogout and septic arthritis are more common in the elderly.

The time course of symptom onset: Symptom onset may be acute, chronic, relapsing, flitting, migrating, or additive. Attacks of gout typically develop over a matter of hours. The onset of septic arthritis is usually fairly rapid but can have a more insidious onset in elderly or immunosuppressed patients.

The number of joints involved and the pattern of involvement: Determining the number of joints involved (monoarticular, oligoarticular, polyarticular, spinal involvement) and the pattern of involvement (symmetrical vs non-symmetrical; small joints, large joints, or mixed; upper limb vs lower limb predominant) is important because, although the knee is frequently affected by all conditions, some conditions have a predilection for certain joints (e.g. gout and the first metatarsophalangeal joint). Screen for involvement of other joints, past or present. Patients with gout or pseudogout will often have a previous history of similar attacks. Morning stiffness lasting for longer than an hour is a classical feature of inflammatory arthritis. Patients with rheumatoid arthritis will often have pain involving the hands. Those with ankylosing spondylitis may report lower back or buttock pain (suggestive of sacroiliitis). It is, however, important to remember that crystal arthritis and infection can occur as a secondary problem in preexisting inflammatory and degenerative arthritis.

The presence of systemic upset: Fever and malaise makes the diagnosis of septic arthritis more likely. Other risk factors for infection should also be screened for, notably, diabetes, immunodeficiency/immunosuppression, previous joint replacement, and underlying inflammatory arthritis.

A history of current or recent infection: This is important, as it may indicate a septic or reactive arthritis. Care must be taken to screen for common infections (urinary, respiratory tract), and particularly sexually transmitted diseases, which are frequently associated with reactive arthritis. This should include asking about recent unprotected sexual intercourse and vaginal or urethral discharge. Age should not be a discriminating factor for taking a sexual history.

Systemic enquiry: It is always worth performing a screen for involvement of other systems: skin, cardiovascular, respiratory, gastrointestinal, and neurological. Connective tissue disorders and vasculitis may present with a hot joint.

Past medical history: Psoriasis or inflammatory bowel disease can be pointers towards seronegative inflammatory arthritis. A history of haemophilia, von Willebrand's disease, or anticoagulation raises the possibility of haemarthrosis. Although relatively rare, a past history of TB should prompt consideration of this as a cause of septic arthritis.

Key features on examination

Key features on examination are as follows:

Fever: Fever is usually present in septic arthritis.

Severely restricted movement of a joint: This indicates serious pathology, and should prompt urgent referral to a rheumatologist.

Involvement of other joints: Conditions such as pseudogout invariably develop on a background of osteoarthritis.

Involvement of other systems: A careful examination may pick up further clues as to the likely diagnosis. Expose the patient fully and look for psoriatic plaques, tophi, and rheumatoid nodules or pustules (gonococcus).

Specific clues to the diagnosis

Table 62.2 outlines specific clues which can aid diagnosis.

Key diagnostic tests

Further investigation is not always indicated. For example, a patient with previous gout who develops acute pain and swelling of his ankle and is systemically well could sensibly be treated with a course of NSAIDs, and advice to rest the affected joint.

Joint aspiration and synovial fluid analysis are extremely useful, and comprise the key investigation when the problem is a single hot joint. Joint aspiration is mandatory if septic arthritis is suspected, and is desirable in cases of suspected gout, pseudogout, or haemarthrosis. As well as being a key diagnostic test, aspiration often provides symptomatic benefit. Wherever possible, drain the joint to dryness, as this will reduce pain and improve function.

Large joint aspiration, especially of the knee, is relatively safe. However, when undertaking joint aspiration, it is important to first consider a couple of factors. Look carefully for the presence of cellulitis, or psoriasis, which may affect the skin overlying a joint. It is

never desirable to enter a joint through abnormal skin and, whenever possible, an alternate route should be taken. Similarly, if a patient is taking an oral anticoagulant, or is suspected of having coagulopathy, check a clotting screen before proceeding. If in doubt, seek advice from a specialist. Fluid should be aspirated and sent to microbiology for an urgent Gram stain, microscopy, and sensitivity. Fluid should also be sent to cytology for polarized light microscopy, looking for crystals of gout or pseudogout.

In cases in which further investigation is felt to be necessary, blood tests provide a useful adjunct to synovial fluid analysis. Consider performing the tests outlined in Table 62.3.

A plain radiograph must always be performed if there is a history of trauma, and may also yield diagnostic clues to the presence of other conditions (see Table 62.4).

Other diagnostic tests

Further investigations will be guided by the history and examination, and likely diagnosis (see Chapter 264). Other tests which may be helpful include X-rays of the hands and feet if involvement of these joints is revealed by the history or examination. A full sexually

Condition	Common sites	Features in history	Features on examination
Osteoarthritis	Weight-bearing joints; hips, knees; first CMC/MTP joints and DIP joints in hands; neck/lumbar spine	Insidious onset; lack of morning stiffness; pain worse after activity; previous trauma; weight gain	May be bony swelling, e.g. Bouchard's or Heberden's nodes; pain and crepitus on movement of a joint
Rheumatoid arthritis	Hands; involvement tends to be symmetrical; MCP joints, PIP joints, and wrists	Morning stiffness >1 hour; joint pain and swelling	May be rheumatoid nodules, typically at elbows/pressure points; 'boggy swelling'; joint effusions
Seronegative inflammatory arthritis: <ul style="list-style-type: none"> ● psoriatic ● enteropathic ● reactive ● ankylosing spondylitis 	Hands (including DIP joints) and large joints; spine and sacroiliac joints may be affected	Recent infection; psoriasis; inflammatory bowel disease; alternating buttock pain; morning stiffness >1 hour	Asymmetrical arthritis; psoriatic plaques/nail changes; limited spinal movement; sacroiliitis; dactylitis; enthesitis; conjunctivitis/uveitis
Polyarticular/chronic tophaceous gout	Hands, large joints, first MTP joint	Family history; high alcohol/protein intake; diuretic use	Gouty tophi, particularly on ears, elbows, hands, or feet
Connective tissue diseases: <ul style="list-style-type: none"> ● SLE ● scleroderma 	Hands, arthralgia more common than arthritis, may be tenosynovitis	Female gender; Raynaud's disease; skin rash; skin thickening; difficulty swallowing	Malar or photosensitive rash; sclerodactyly; correctable ulnar deviation (Jaccoud's arthropathy)
Vasculitis: <ul style="list-style-type: none"> ● Henoch–Schonlein purpura ● Wegener's granulomatosis ● Churg–Strauss syndrome 	Any	Systemic features, e.g. fever, malaise, weight loss	Rash; lung/abdominal/renal/neurological signs; blood/protein on urine dipstick
Septic arthritis	Any, most commonly knee or hip	Fever and systemic upset; marked pain and inability to move the affected joint	High temperature; haemodynamic compromise; single hot and swollen joint with grossly restricted movement
Gout	First MTP joint, knee, ankle, wrist, elbow	Previous attacks; family history; high alcohol intake or high purine diet; diuretic use; typically sudden onset (hours)	Joint typically erythematous and exquisitely tender; gouty tophi on affected joint, ears, elbows, or hands (in chronic gout)
Pseudogout	Knee, ankle, wrist, shoulder	Osteoarthritis; previous attacks; associated infective trigger, e.g. urinary infection or dehydration	Nodal osteoarthritis; nodal osteoarthritis; crepitus on joint examination
Monoarticular presentation of generalized arthritis (e.g. rheumatoid or psoriatic arthritis)	Any; frequently knee or hip	History of inflammatory arthritis; involvement of other joints; morning stiffness	Synovitis of other joints; rheumatoid nodules; psoriatic plaques or nail changes; dactylitis
Reactive arthritis	Any; frequently knee or hip	History of recent infection; vaginal/urethral discharge or diarrhoea; eye involvement	Conjunctivitis/uveitis; fever; vaginal/urethral discharge; sacroiliitis
Haemarthrosis	Any	Haemophilia/von Willebrand's disease or anticoagulant use; history of bleeding after minor procedures, e.g. tooth extraction	Bruising around the affected joint

Abbreviations: CMC, carpometacarpal; DIP, distal interphalangeal; MCP, metacarpophalangeal; MTP, metatarsophalangeal; PIP, proximal interphalangeal; SLE, systemic lupus erythematosus.

Table 62.3 Investigations ordered for the diagnosis of acute joint pain, with their justifications

Blood test	Reason for performing test
Blood cultures	Diagnosis of bacteraemia in suspected septic or reactive arthritis
FBC	Raised WCC in infection; reduced Hb in chronic disease, e.g. rheumatoid arthritis
Clotting screen; PT/APTT	May be prolonged in patients on warfarin or with bleeding disorders
ESR and CRP	Raised in systemic inflammation
Plasma urate	Raised in cases of gout (although caution required, as it may not be elevated during acute attack)
Plasma creatinine	Screen for renal involvement in systemic disease; also important to consider renal function before prescribing NSAIDs
Liver function tests	Screen for hepatic involvement
Rheumatoid factor/anti-CCP antibody	May be positive in patients with rheumatoid arthritis
ANA, ANCA	Only indicated if features in the history/examination suggest the possibility of underlying connective tissue disease or vasculitis

Abbreviations: ANA, antinuclear antibody; ANCA, antineutrophil cytoplasmic antibody; APTT, activated partial thromboplastin time; CCP, cyclic citrullinated peptide; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; FBC, full blood count; Hb, haemoglobin; NSAIDs, non-steroidal anti-inflammatory drugs; PT, partial thromboplastin time; WCC, white-cell count.

transmitted disease screen, including throat and genital swabs, is essential where reactive arthritis is suspected or there is a history of high-risk behaviour. If there are features to suggest the presence of connective tissue disease or vasculitis, a chest radiograph and urinalysis/urine microscopy must also be performed. More detailed imaging of a particular joint using CT or MRI may be useful if there is uncertainty about the diagnosis. CT scans are particularly good for looking at bone, while MRI is the modality of choice for soft tissue.

Introduction to therapy

Septic arthritis

Patients with septic arthritis should be referred to the on-call orthopaedic team for urgent review and admission. Management usually involves urgent washout of the affected joint and prolonged treatment with IV and subsequently oral antibiotics.

Iidiopathic peripheral inflammatory arthritis (seropositive or seronegative rheumatoid arthritis)

Once a diagnosis of inflammatory arthritis has been given, disease-modifying anti-rheumatic drugs (DMARDs) should be started with minimal delay. These include methotrexate, sulfasalazine, leflunomide, hydroxychloroquine, and azathioprine. Many authorities now advocate early aggressive combination therapy with monitoring for

Table 62.4 Radiographic features of diseases leading to acute joint pain

Condition	Features on radiographs
Septic arthritis	Likely to be normal on presentation or may show osteopenia in surrounding bone; late changes include rapid joint destruction
Gout	Soft tissue swelling and juxta-articular erosions (areas of punched-out bone)
Pseudogout	Features of underlying osteoarthritis (joint space narrowing, osteophytes, subchondral cysts, and sclerosis); chondrocalcinosis
Rheumatoid arthritis	Erosions (areas of punched-out bone)

potential side effects such as bone marrow suppression and drug-induced hepatitis. In the appropriate clinical setting, the treatment can be stepped up to include the use of biological agents such as anti-tumour necrosis factor (anti-TNF) therapy (etanercept, adalimumab, infliximab, certolizumab, golimumab), B-cell depletion therapy (rituximab), and IL-6 blockade (tocilizumab).

Connective tissue disorders and vasculitis

There are a variety of connective tissue disorders and vasculitic syndromes, each of which require a tailored approach to treatment, depending on organ involvement. Careful and frequent follow-up allows the clinician to react appropriately to any changes in disease expression. These diseases require early specialist input to direct management. Aggressive immunosuppression may be required, as well as a range of supportive measures in the event of threat to vital organs.

Crystal arthropathies

Treatment of crystal arthropathies can be divided into two sections: the acute flare and chronic prophylaxis. The acute flare is conventionally treated with NSAIDs, colchicine, or steroids. The exact choice depends on patient-related factors such as renal function, cardiovascular disease, gastrointestinal disease, and diabetes. Chronic prophylaxis is only available to treat gout. Uric-acid-lowering therapy with allopurinol (or febuxostat, if the patient is allergic to allopurinol), a xanthine oxidase inhibitor, is the treatment of choice. It is necessary to titrate the dose of allopurinol to achieve a serum uric acid level in the lower half of the normal range. Uricosuric drugs such as sulfinpyrazone and probenecid drugs, which increase renal uric acid excretion, are generally less safe and less effective and therefore used less often. Other forms of crystal arthritis are managed by symptom control of recurrent acute flares.

Spondyloarthropathies

In the presence of purely axial disease, NSAIDs and physiotherapy have been found to be of marked benefit. DMARDs only have an impact if there is accompanying peripheral joint involvement. Where there is inadequate response to full conservative drug and non-drug measures, it is possible to escalate treatment to use anti-TNF therapy.

Prognosis

Outcomes are very variable, depending on the cause of the inflammation. Most cases will settle after a period of time with appropriate treatment. Even cases of septic arthritis can, if managed well, have good outcomes, with return to normal function. Once movement returns to an affected joint, if there has been a prolonged period of reduced activity, patients often benefit from a course of physiotherapy to help build up affected muscles.

How to handle uncertainty in the diagnosis of this symptom

Proper assessment of a patient with a hot joint requires a good history and examination. The key is not to miss a septic arthritis. Any patient suspected of having this condition must be referred urgently for further evaluation in hospital.

Removal of synovial fluid is extremely useful and should be undertaken whenever possible as it is useful therapeutically, and diagnostically.

Make sure that the patient is aware of the likely diagnosis and the anticipated duration of symptoms, and encourage them to seek further review if things don't settle as expected.

63 Muscle pain

Parthajit Das and Rachel Jeffery

Definition of the symptom

Muscle diseases constitute a large group of hereditary and acquired disorders, collectively referred to as **myopathy**. Symptoms of myopathy are muscle pain, muscle cramps or spasms, stiff or rigid muscles, and muscle weakness.

Muscle pain, or **myalgia**, is by far the most common presentation. Although most myalgia will be benign and self-limiting, it can be a reflection of underlying serious illnesses which may lead to significant morbidity. It is important to differentiate myalgia from **myopathy** (muscle disease) and **myositis** (inflammatory myopathy).

A muscle is said to be in **spasm** when it contracts involuntarily. When the spasm is forceful and sustained, it becomes a **cramp**. Muscle cramps commonly occur with dehydration, with electrolyte abnormalities (hypokalaemia, hypocalcaemia, or hypomagnesaemia) and in neurological conditions such as Parkinson's disease, motor neuron disease, radiculopathies, and polyneuropathies. They are not usually associated with primary muscle diseases.

A successful clinical approach to a patient with a muscle pain is based on a thorough medical history and clinical examination to establish the pattern and nature of the muscle symptoms.

Approach to diagnosis

What is the time course of symptoms?

The time course of the onset of myalgia can be indicative:

Acute-onset myalgia: With prominent constitutional symptoms, acute-onset myalgia suggests viral or bacterial infections or inflammatory disease, (inflammatory arthritis, connective tissue disease, vasculitis). In the older patient (>50 years), myalgia involving the neck, shoulders, and upper arms (+/- buttocks, hips, thighs) raises the possibility of polymyalgia rheumatica.

Subacute-onset myalgia: This is usually seen in drug-induced myalgia (e.g. from statins) and can occur weeks to months after initiating therapy.

Chronic-onset myalgia: This is seen in endocrine myopathies, nutritional deficiency (vitamin deficiency), and chronic widespread musculoskeletal pain syndrome (fibromyalgia).

What is the distribution of muscle pain?

The distribution of muscle pain can be indicative:

Localized myalgia: Common causes are strenuous exercise or overuse.

Other causes include soft tissue disease (local trauma, tendonitis, bursitis), compartment syndrome, and complex regional pain syndrome.

Generalized myalgia: This is most commonly seen in viral illnesses.

When prolonged, it may suggest metabolic myopathy, inflammatory myopathy, nutritional deficiency related muscle disease (e.g. vitamin D deficiency), other autoimmune rheumatic diseases (SLE, systemic sclerosis) or chronic pain syndrome (fibromyalgia).

Referred pain: Pain can be referred to the upper limb from the neck and shoulder joint, and to the lower limb and thigh from the spine and hip joints.

Proximal muscle pain: This is a feature of inflammatory muscle disease (especially dermatomyositis), endocrine myopathy, and vitamin D deficiency.

Is there associated muscle weakness?

Associated muscle weakness can be indicative of a number of conditions:

- Muscle weakness can occur with chronic disuse, neurological disorder, and muscle disease and it can be difficult to distinguish between these on examination alone.

- Neuropathies, inflammatory myopathies, toxic myopathies, and endocrine myopathies may present with pain and weakness.
- Patients with 'true' muscle weakness will struggle to perform specific tasks such as rising from sitting without support, raising their head off the pillow, walking upstairs, lifting their arm above the shoulder, combing their hair, or holding a glass of water.
- Muscle wasting can occur with muscle weakness (an exception is Duchenne muscular dystrophy with calf hypertrophy), disuse, and lower motor neuron lesions.
- Involvement of pharyngeal, thoracic, diaphragmatic, or sphincteric muscles indicates systemic disease and can be life-threatening.

Is there associated muscle stiffness?

Associated muscle stiffness can be indicative of a number of conditions:

- Muscle pain along with stiffness is usually associated with inflammatory muscle disease.
- There is muscle stiffness with weakness in myositis (as seen in polymyositis and dermatomyositis).
- There is muscle stiffness without weakness in polymyalgia rheumatica and fibromyalgia (non-inflammatory chronic pain syndrome).
- Parkinson's disease can also present with muscle pain and stiffness.

Does the clinical picture suggest an inflammatory or non-inflammatory myopathy?

Features suggestive of inflammatory muscle disease are:

- symmetrical proximal muscle weakness
- stiffness

Features suggestive of non-inflammatory muscle disease are:

- a family history of myopathy (storage diseases, genetic myopathies and neuropathies)
- muscle weakness/cramps worsened by exercise or dietary change, for example, fasting or excess carbohydrate intake (metabolic myopathies)
- drug history (statins, zidovudine, alcohol, steroid, vincristine, colchicines, etc.)
- muscle atrophy, hypertrophy, or myotonia (e.g. Duchenne and Becker's muscular dystrophy, myotonic dystrophy)
- fasciculation and other neurological signs

Are there clinical signs pointing to a specific aetiology of myopathy?

A thorough examination may reveal important clues as to the aetiology of myopathy, such as:

- cushingoid habitus, steroid purpura (exogenous steroids or Cushing's disease)
- myxoedema changes (thyroid disease); hyperpigmentation (Addison's disease)
- malar rash (SLE); sclerodactyly, digital infarcts, telangiectasia, (systemic sclerosis); heliotrope rash, Gottron's papules, mechanic's hands, calcinosis (dermatomyositis); livedo reticularis, purpura, digital infarcts (vasculitis)
- joint involvement (degenerative or inflammatory joint disease)
- absent peripheral pulses (peripheral vascular disease, arteritis, compartment syndrome)

Box 63.1 Causes of a raised creatine kinase level**Traumatic causes**

- hypothyroidism
- neuroleptic malignant syndrome
- malignant hyperthermia
- drowning
- prolonged strenuous exercise

- lymphadenopathy/hepatosplenomegaly (infectious disease: EBV, HIV; autoimmune rheumatic disease: SLE, sarcoidosis)
- evidence of malignancy (which can be associated with inflammatory muscle disease)

Key diagnostic tests

All patients with muscle pain should have the following tests:

- full blood count, which may show the anaemia of chronic inflammatory disease, leucopenia (SLE, HIV), or thrombocytopenia (SLE)
- erythrocyte sedimentation rate and C-reactive protein
- biochemical profile
- plasma creatine kinase level (see Box 63.1)
- thyroid function tests
- urinalysis and urine microscopy (to screen for myoglobinuria and evidence of vasculitis)
- chest radiography (consolidation, malignancy, interstitial lung disease, pleural or pericardial effusions, hilar lymphadenopathy, pseudofractures)

Further investigation

Further investigation will be directed by the clinical features and findings on key diagnostic tests:

- spirometry, if there is systemic involvement or respiratory symptoms (reduced forced vital capacity with diaphragmatic weakness; requires close monitoring and ventilatory support if compromise results)
- infection screen (blood cultures, HIV, hepatitis serology, borrelia)
- cortisol level, dexamethasone suppression test (Cushing's disease), tetracosactide test (Addison's), parathyroid hormone level
- autoantibodies (antinuclear antibody (ANA), extractable nuclear antigen antibody (ENA), anti-double-stranded DNA antibody (dsDNA), rheumatoid factor, anti-citrullinated protein antibody (anti-CCP); antineutrophil cytoplasmic antibody (ANCA), if vasculitis suspected)
- echocardiography (assess myocardial function re possible cardiac involvement, ischaemic, cardiomyopathy, pericardial effusion, valvular abnormality)
- MRI scan brain and/or spine (exclude central neurological cause)
- electromyography and nerve conduction studies (helpful to distinguish primary muscle disease, neuropathy, or inflammatory myopathy)
- MRI muscles, T2-weighted/fat-suppressed STIR sequence (can show muscle inflammation, atrophy, or fat infiltration and guide best site for muscle biopsy)
- muscle biopsy; open sample is best (for diagnosis of primary muscle disease and inflammatory myositis)

See Parts 10 and 12 for disease-specific information.

64 Low back pain

Elaine Buchanan and Chris Lavy

Definition of the symptom

Low back pain (LBP) is pain arising from the structures of the lumbar spine, including joints, discs, connective tissue, and nerves. Symptoms include pain and muscle tightness or stiffness, with or without referral of pain to the legs.

Differential diagnosis

Most (95%) of LBP is managed in primary care; the rest is managed in secondary care (see Table 64.1).

Context

LBP affects nearly everyone at some point in their life and has an annual prevalence of around 40%. It is less common in children but from age 16 onwards the point prevalence for all age groups is around 25%. Many experience milder persisting symptoms interspersed with exacerbations, and 7% of adults have persisting LBP, which restricts function. With an aging and less fit population, this situation is unlikely to improve.

LBP is one of the most prevalent musculoskeletal conditions presenting to healthcare. It accounts for 4% of all GP consultations and 5% of all NHS specialist referrals. The main reasons for seeking healthcare are to gain an understanding of the problem, to obtain a prognosis, and for symptom relief.

LBP is the leading cause of occupational disability and missed work-days. Although not more prevalent, it is most bothersome in the working age population and accounts for 13.5% of UK incapacity benefit.

Degenerative changes of lumbar spinal structures are commonly found in both asymptomatic and symptomatic populations. The relationship between radiological findings and specific diagnoses is weak.

The key to management is to identify and refer onwards the minority with serious and surgical presentations and to reassure, advise to remain active, and provide symptomatic relief for the others.

Approach to diagnosis

The approach to diagnosis includes the following:

- history, and examination of back, neurology in legs, and abdomen
- exclude non-spinal causes of back pain (e.g. disease of the kidneys or abdominal aorta, gynaecological disease)
- categorize spinal back pain into:
 - serious spinal pathology (e.g. fracture, neoplasm, inflammatory disease, cauda equina syndrome, infection)
 - non-specific LBP (NSLBP)
 - radicular pain
 - neurogenic claudication

Table 64.1 Low back pain diagnosis in primary and secondary care, in order of frequency

Diagnosis in primary care	Frequency (%)	Diagnosis in secondary care	Frequency (%)
Non-specific low back pain	80	Neurogenic claudication	35
Radicular pain	10	Radicular pain	30
Neurogenic claudication	7	Non-specific low back pain	25
Serious spine pathology	3	Serious spine pathology	10

The information needed to categorize patients is mainly found in the subjective history.

Serious spinal pathology

It is important to first identify or rule out the possibility of serious spinal pathology. Delayed or misdiagnosis has a major impact on patient survival, quality of life, and clinical outcome and may result in medical negligence litigation. Red flags (Box 64.1) are recommended internationally as a system for screening for serious spinal pathology. It is important to remember that the presence of one red flag is common but the incidence of serious spinal pathologies is rare. Independently, some red flags are more predictive than others and should always result in further investigation. The predictive utility of other red flags is individually low but significantly increases when used in combination.

Inflammatory back pain

Inflammatory back pain is worse after prolonged rest and relieved by exercise. It is therefore worse in the morning and is associated with prolonged morning stiffness of the back of greater than 30 minutes (often several hours). Occasionally, there is an associated peripheral inflammatory arthritis, which helps to clarify the underlying inflammatory pathophysiology. Inflammatory arthritis of the spine is referred to as spondyloarthritis or spondylitis. The commonest cause of spondyloarthritis is ankylosing spondylitis—a condition typically causing chronic inflammation of both sacroiliac joints (sacroiliitis) and associated with progressive calcification of the spinal ligaments, resulting in

Box 64.1 Red flags in screening for serious spinal pathology

Strong red flags (always investigate)

- past history of cancer
- unexplained weight loss >10% of body weight
- widespread neurology
- known osteoporosis
- erythrocyte sedimentation rate >50, packed cell volume <30
- under age 16
- recent significant trauma
- penetrating wound near spine
- recent bacterial infection

Weak red flags (but which in combination raise suspicion)

- age 16–20
- age >50
- non-mechanical pain
- thoracic pain
- local pain or tenderness
- past history of steroids
- past history of substance abuse
- immunosuppression
- clinician judgment
- >1/12 duration, no response to treatment

Cauda equina syndrome (emergency referral)

A combination of:

- saddle anaesthesia
- recent onset of bladder dysfunction
- recent onset of faecal disturbance
- reduced anal tone

Note: MRI is the investigation of choice.

Box 64.2 Yellow, blue, and black flags for identifying people at increased risk of non-specific low back pain*Yellow flags (personal risk factors)***Thoughts**

- negative thinking
- dysfunctional belief about pain, prognosis and cure
- health anxiety

Feelings

- emotional distress (anxiety, depression)
- fear of movement or damage

Behaviours

- passive coping strategies
- healthcare shopping without effect

*Blue flags (occupational risk factors)***Employee**

- high physical job demands
- low expectation of return to work
- low job satisfaction
- belief that work is harmful

Workplace

- lack of employer support
- lack of work modification

Black flags (social risk factors)

- financial and compensation issues
- interpretation of media reports
- reaction of friends and family
- social dysfunction
- national/workplace policies

progressive spinal fusion. Inflammatory spinal pain should be referred for evaluation by a specialist multidisciplinary rheumatology team. Several other diseases associated with HLA-B27 can also present with spinal or sacroiliac inflammation:

- psoriatic arthritis (spondylitis type)
- reactive arthritis
- arthritis related to inflammatory bowel disease (associated with Crohn's disease and ulcerative colitis)
- undifferentiated spondyloarthritis (may have several features of the conditions in this list)

In addition to articular symptoms, these patients often have enthesitis at multiple sites (e.g. Achilles tendon insertion, plantar fascia).

NSLBP

The largest diagnostic group is NSLBP, where it is back pain that dominates. Symptoms may or may not be referred to the leg, but are not associated with any neurological abnormality. Currently there is no reliable system for subclassification of NSLBP. Psychosocial factors are more predictive of long-term LBP related disability than biomedical factors. The use of yellow, blue, and black flags to classify factors (Box 64.2) is an internationally recognized method of identifying people at increased risk. The most effective psychosocial screening employs a battery of questionnaires (self-reported disability, health beliefs, and emotional distress) used in combination with a thorough consultation. Early identification of those at risk, at 6–8 weeks from onset, is fundamental, to prevent disability becoming established. Spinal imaging may exclude other pathology but does not influence the diagnosis, management, or outcome in NSLBP.

Radicular pain

Leg-dominant pain referring in a dermatomal distribution is categorized as radicular pain and there may also be neurological deficits of sensation, power, or reflexes, correlating with the symptomatic dermatome. It is important to look for signs of cauda equina syndrome, saddle anaesthesia, bladder/bowel disturbance, and anal tone. A positive straight leg raise is suggestive of disc protrusion but low specificity limits its usefulness. Early spinal imaging (around 6 weeks) is helpful in patients who wish to proceed to invasive management. The commonest cause of radicular pain is disc herniation.

Neurogenic claudication

Neurogenic claudication secondary to spinal stenosis results in leg-dominant symptoms which severely restrict walking but are eased by sitting. The leg symptoms are commonly non-dermatomal and described as cramp, heaviness, or generalized lower-limb weakness. Many patients have a good range of spinal flexion, normal straight leg raise, and intact neurology. Spinal imaging is clinically helpful in patients with concerning neurological deficits and in those having had symptoms for greater than 6 months and who wish to consider invasive management.

Specific clues to the diagnosis

See Table 64.2 for specific clues to the diagnosis.

Table 64.2 Specific clues to the diagnosis of non-specific low back pain, radicular pain, neurogenic claudication, and serious pathologies

	Non-specific low back pain	Radicular pain	Neurogenic claudication	Serious pathology
Age	>16 years	>18 years	Developmental stenosis at >30 years; acquired stenosis at >50 years	Any age, but especially at <16 and >55 years
Onset	Variable	Variable	Gradual	Variable
Back pain	Yes	Leg pain dominates	Leg pain dominates	Yes
Leg pain	Back pain dominates	Unilateral, dermatomal; most commonly L5 or S1	Foraminal stenosis: unilateral and dermatomal; canal stenosis: bilateral and non-dermatomal	Dependant on location of pathology
Activity	Mechanical pattern	Mechanical pattern	Worse with walking and standing; eases with sitting	Variable
Lumbar range of movement	Global restriction	Restricted forward flexion	Restricted extension	Variable
Neurological deficit	No	Correlating with the affected nerve root	Neurological signs at or below the stenotic level	Dependant on location of pathology
Straight leg raise	Normal	Reduced	Normal	Variable
Saddle anaesthesia	Nil	Possible in cauda equina syndrome	Rare	Dependant on location of pathology
Bladder/bowel dysfunction	Nil	Possible in cauda equina syndrome	20% report bladder dysfunction	Dependant on location of pathology

Table 64.3 Imaging of choice compared with diagnostic categories duration of pain

Diagnostic category	Duration	Imaging of choice
Past history of cancer	Any	Limited MRI whole spine
Leg-dominant pain (moderate or severe)	>6 weeks	Full MRI lumbar spine
Under age 16	Any	Limited MRI thoracolumbar spine
Acute deformity in older people	Any	Limited MRI thoracolumbar spine
Neurogenic claudication (moderate or severe)	>6 months	Full MRI lumbar spine
Inflammatory spinal disease	Any	Limited MRI; thoracolumbar and sacrum
Non-specific low back pain	Only after optimal conservative management	Limited MRI lumbar spine
Infection	Any	Limited MRI thoracolumbar
Painful osteoporotic collapse	Any	Limited MRI thoracolumbar with axial views through level of collapse

Key diagnostic tests

Diagnostic tests are only useful if they change the diagnosis, management, or outcome of LBP (Table 64.3). It is the correlation between symptoms, clinical findings, and diagnostic tests that is important. This is especially relevant because of the prevalence of abnormal imaging findings in the asymptomatic population.

When diagnostic tests are clinically indicated, MRI is the gold standard for investigating most pathologies. It is superior at demonstrating soft tissue, more sensitive at differentiating between neoplastic disease, infection, and osteoporotic spinal pathologies, and images more planes, compared to other radiology tests. CT is the best for investigation of bony pathologies and in patients where MRI is contraindicated.

Limited MRI (sagittal T1 and STIR images) is a highly sensitive and cost-effective investigation for suspected serious spinal pathologies and potential surgical candidates with back dominant pain. Full MRI (sagittal and axial T1 and T2 images) is indicated for patients with clinical signs of cauda equina or radicular involvement, who are potential candidates for surgery or therapeutic spinal injection.

A warning: in patients with lower limb weakness, with a past history of cancer or upper motor neuron lesions, it is important to scan the whole spine. We have seen too many patients with paraplegia who have only had lumbar spine imaging.

In contrast, the clinical value of diagnostic tests for NSLBP is limited by the high prevalence of spinal degenerative radiological findings in asymptomatic individuals. Imaging does not change the diagnosis, management, or outcome for patients with NSLBP but is associated with higher healthcare costs. There is a morbidity associated with the communication of radiological findings, which may result in increased anxiety or delay return to normal activities. Surgical rates have been shown to be higher when imaging rates are higher, but no better clinical outcomes are achieved.

Other diagnostic tests

In a small number of patients, diagnostic tests, in addition to imaging, help with differential diagnosis. Nerve conduction studies are useful where a neurological weakness is found on examination, but not explained by spinal imaging. Nerve root blocks are informative for surgical planning where potentially significant nerve root pathology exists at more than one level on MRI. Although occasionally used, the popularity of discography has reduced because of low specificity and because it may hasten disc degeneration.

In addition to imaging, laboratory tests can be useful where cancer, infection, or inflammatory disease is suspected.

Introduction to treatment

UK, European, and American guidelines clearly outline evidence-based management of acute and chronic non-specific LBP with or without radicular pain or neurogenic claudication.

The only surgical emergencies are cauda equina syndrome and pathologies resulting in cord compression.

In the absence of concerning red flags, acute LBP with or without leg pain is usually self-limiting. Early management includes reassurance and medication. Return to normal activities is actively encouraged. Patient information, such as *The Back Book*, should reinforce self management.

Persisting non-specific LBP is a condition we can treat but not cure. Modern management emphasizes self-care. Evidence-based patient information and pain relief are key. For those who continue to seek healthcare, exercise and manual therapy, are recommended. These interventions have evidence of small-to-moderate benefit. In patients with persisting disability and/or distress, who have not responded to the initial core therapies, referral to an intensive combined physical and psychological programme (CPPP) is recommended. CPPP optimizes quality of life and the potential to return to some form of meaningful work. A small number of those who have severe pain post CPPP may be considered for spinal fusion. Fusion offers small-to-moderate benefit in some patients who have not been helped by CPPP, but the complication rate is high (16%). NICE NG59 recommend that fusion should only be offered as part of a randomised controlled trial.

In radicular pain due to disc herniation and persisting beyond 6 weeks, surgery offers quick relief of leg pain and return to function. Early surgery is also recommended for those with progressive neurological deficit. Therapeutic injections, including nerve root blocks and epidurals, are useful in patients with severe leg pain but who are not suitable for surgery. The success rate of injection is only around 50%. Decisions regarding invasive treatment should take account both the fact that benefits may be relatively short term and the tendency for patients to improve either with or without intervention.

Although evidence is limited, conservative treatment for neurogenic claudication have been shown to be beneficial. When severe symptoms persist beyond 6 months, surgical decompression can be helpful in improving quality of life. The benefits of surgery however tend to tail off after 2 years.

Prognosis

In general, the clinical course of acute NSLBP and radicular pain is favourable: 80% of patients who present for healthcare during an acute attack improve sufficiently to return to normal activities within the first 6 weeks, and stop consulting healthcare within 3 months. Further improvement beyond 6 weeks is slower, and 62% continue to have symptoms at 1 year. Back pain symptoms commonly fluctuate over time, and recurrences of variable severity are common.

Around 7% of those with NSLBP are at risk of long-term pain-related disability. Without CPPP, people who have established LBP-related disability have a very bleak long-term prognosis.

Neurogenic claudication has an unfortunate long-term prognosis in that 70% will have persisting symptoms of a similar severity, 15% will improve, and 15% will worsen over time.

How to handle uncertainty in the diagnosis of this symptom

The only certainty with back pain is that most of us will get it. First, it is essential to minimize risk by identifying the small number with serious pathology, through:

- use of red flags to raise diagnostic suspicion of serious spinal pathology
- early referral or investigation of those concerning red flags
- remembering that most of those with red flags will not have serious spinal pathology
- keeping diagnosis under review for those who continue to seek healthcare

Thereafter, we can be confident that the risk of overlooking serious spinal pathology is highly unlikely. For the remainder, diagnostic uncertainty is the norm; thus, symptom-based classifications are used. It is the symptomology that drives management decisions. It is good management that optimizes outcome. Note that:

- conservative management is appropriate for most LBP
- the presence of leg-dominant pain with or without neurological deficits will more likely be suitable for an invasive procedure
- in leg-dominant pain, a strong correlation between the clinical presentation and diagnostic imaging improves diagnostic certainty
- non-specific LBP is a diagnosis by exclusion; despite extensive research, correlations between diagnostic imaging and symptomology remain weak and, while diagnostic theories have been proposed, no gold-standard test exists

65 Painful leg

Benjamin Bloch and David Sprigings

Definition of the symptom

The leg (more accurately called the lower limb) extends from the gluteal region to the foot. Pain in the leg may reflect disease of its constituent bones, joints, soft tissues, or neurovascular supply, or be referred from diseases of the spine.

Differential diagnosis

The differential diagnosis of leg pain is given in Table 65.1.

Table 65.1 Differential diagnosis of leg pain		
Tissue/structure	Acute leg pain	Chronic leg pain
Skin and subcutaneous tissues	Erysipelas Cellulitis Necrotizing fasciitis Hypersensitivity reaction to insect sting or bite Contact dermatitis	Ulceration (venous, arterial, or mixed aetiology) Post-phlebotic syndrome
Arteries	Acute ischaemia	Chronic ischaemia Popliteal artery entrapment syndrome
Veins	Superficial thrombophlebitis Deep vein thrombosis Phlegmasia cerulea dolens	Post-phlebotic syndrome
Nerves	Acute neuropathies, including Guillain-Barre syndrome Acute radiculopathies Herpes zoster	Chronic neuropathies Peroneal nerve entrapment Neurospinal claudication
Muscles	Localized <ul style="list-style-type: none"> ● strain injury (partial tear) ● contusion injury (direct impact) ● intramuscular haematoma ● intramuscular abscess ● tendon rupture ● compartment syndrome Generalized <ul style="list-style-type: none"> ● systemic infection ● acute myositis ● acute vasculitis 	Localized <ul style="list-style-type: none"> ● chronic exertional compartment syndrome Generalized <ul style="list-style-type: none"> ● metabolic, inflammatory, or nutritional-deficiency myopathies ● autoimmune rheumatic diseases (e.g. SLE) ● polymyalgia rheumatica ● fibromyalgia
Joints	Fracture Meniscal or ligamentous injury Acute arthritis Acute bursitis Ruptured Baker (popliteal) cyst (may complicate rheumatoid arthritis or osteoarthritis of the knee)	Osteoarthritis Chronic inflammatory arthritis
Bones	Subperiosteal haematoma Fracture Osteomyelitis	Primary or metastatic cancer Infection Stress fracture Medial tibial stress syndrome Loosened hip or knee replacement Osteomyelitis

Context

Acute leg pain (symptoms present for <2 weeks) is a medical emergency, as it may signify disease (e.g. acute ischaemia, necrotizing fasciitis, deep vein thrombosis) which is a threat to life or the viability of the limb.

Approach to diagnosis

Diagnosis begins with determining whether pain is felt in one leg or both, its principal site and radiation, and the time course of symptoms. Establish if there has been preceding trauma or fall and if the patient is known to have arterial disease, diabetes, or other systemic disease. Are there risk factors for venous thrombosis (see Chapter 101)? Has the patient had previous surgery to the leg? Is there associated weakness, sensory impairment, back pain, or sphincter disturbance?

General examination should include standard physiological observations. Is the patient febrile? Is there evidence of haemodynamic instability (which may reflect sepsis or pulmonary embolism)? Does the patient look well, acutely ill, or chronically unwell? The legs should be examined systematically (Table 65.2), front and back, comparing one side with the other.

Specific clues to diagnosis

Skin and subcutaneous tissues

Cellulitis

Cellulitis is an acute, spreading, bacterial infection of the dermis and subcutaneous tissue, usually complicating a wound, ulcer, or primary skin disorder. Other predisposing factors include previous episodes of cellulitis, lymphoedema, and vein harvest for coronary artery bypass grafting. Involved skin is erythematous, tender, warm, and swollen, without sharp demarcation from surrounding areas.

Erysipelas

Erysipelas is a more superficial infection of the dermis and epidermis. It is clinically distinguished from cellulitis by a more clearly demarcated border.

Table 65.2 Examination of the leg

Tissue/structure	Diagnostic features
Skin and subcutaneous tissues	Swelling; oedema; discolouration; rash; blister, ulcer or abscess formation; tenderness; induration; crepitus; temperature difference; lymphangitis
Arteries	Arterial pulses normal, reduced, or absent; femoral bruit; prolonged capillary refill; ischaemic lesions of the feet
Veins	Superficial thrombophlebitis; localized tenderness over the deep veins
Nerves	Muscle power; tendon reflexes; light touch and pinprick sensation
Muscles	Localized or diffuse swelling or tenderness
Joints	Swelling around the joint; presence of effusion; increased temperature of the joint; reduced range of movement; instability; tenderness
Bones	Alignment (normal, angled, or rotated); localized swelling; localized tenderness

Necrotizing fasciitis

Necrotizing fasciitis, a rapidly progressive infection of the deep fascia and muscle, is rare but should be suspected in an ill patient with severe leg pain disproportionate to the physical signs. The skin may be very tender, with blue-black discolouration and blistering.

Arteries

Acute ischaemia

Acute ischaemia is recognized by leg pain and paraesthesiae, with absent arterial pulses. The skin distal to the occlusion is cool and may be pale or mottled. Causes of acute limb ischemia include acute thrombosis of a limb artery or bypass graft; embolism from the heart or a proximal arterial aneurysm; aortic dissection with involvement of the limb artery; and trauma (e.g. arterial puncture or cannulation). Findings on neurological examination (sensory loss/muscle weakness) and Doppler assessment of arterial and venous flow stratify the degree of ischaemia and guide further management. If acute limb

ischaemia is suspected, give heparin 5000 units intravenously over 5 minutes, followed by an IV infusion, and seek urgent advice from a vascular surgeon.

Chronic ischaemia

Chronic ischaemia may be asymptomatic or may present with intermittent claudication: pain, aching, muscle stiffness, or fatigue of the affected areas on exercise and relieved by a few minutes' rest. In aortoiliac disease, symptoms typically occur in the buttocks, thighs, and calves. In superficial femoral artery disease, the calves only are affected. Features distinguishing intermittent claudication from other causes of chronic leg pain associated with exercise are shown in Table 65.3.

Veins

Deep vein thrombosis

Deep vein thrombosis (DVT) should be considered in every patient with leg pain, and may complicate other disorders such as cellulitis.

Table 65.3 Differential diagnosis of intermittent claudication

Condition	Location	Prevalence	Characteristic	Effect of exercise	Effect of rest	Effect of position	Other characteristic
Calf IC	Calf muscles	3% of adult population	Cramping, aching discomfort	Reproducible onset	Quickly relieved	None	May have atypical limb symptoms on exercise
Thigh and buttock IC	Buttocks, hip, thigh	Rare	Cramping, aching, discomfort	Reproducible onset	Quickly relieved	None	Impotence. May have normal pedal pulses with isolated iliac artery disease
Foot IC	Foot arch	Rare	Severe pain on exercise	Reproducible onset	Quickly relieved	None	Also may present as numbness
Chronic compartment syndrome	Calf muscles	Rare	Right, bursting pain	After much exercise (jogging)	Subsides very slowly	Relief with elevation	Typically heavy muscled athletes
Venous claudication	Entire leg, worse in calf	Rare	Tight, bursting pain	After walking	Subsides slowly	Relief speeded by elevation	History of iliofemoral deep vein thrombosis, signs of venous congestion, edema
Nerve root compression	Radiates down leg	Common	Sharp lancinating pain	Induced by sitting, standing, or walking	Often present at rest	Improved by change in position	History of back problems. Worse with sitting. Relief when supine or sitting. Not intermittent
Symptomatic Baker cyst	Behind knee, down calf	Rare	Swelling, tenderness	With exercise	Present at rest	None	Not intermittent
Hip arthritis	Lateral hip, thigh	Common	Aching discomfort	After variable degree of exercise	Not quickly relieved	Improved when not weight bearing	Symptoms variable. History of degenerative arthritis
Spinal stenosis	Often bilateral buttocks, posterior leg	Common	Pain and weakness	May mimic IC	Variable relief but can take a long time to recover	Relief by lumbar spine flexion	Worse with standing and extending spine
Foot/ankle arthritis	Ankle, foot, arch	Common	Aching pain	After variable degree of exercise	Not quickly relieved	May be relieved by not bearing weight	Variable, may relate to activity level and present at rest

Abbreviations: IC, intermittent claudication.

Table 65.4 Wells score to determine the clinical probability of deep vein thrombosis

Variable	Points
History	
Active cancer (treatment on-going, or within previous 6 months, or palliative)	1
Paralysis, paresis or recent plaster immobilization of the legs	1
Recently bed-ridden for more than 3 days, or major surgery within 4 weeks	1
Examination	
Entire leg swollen	1
Calf swelling by >3 cm when compared with asymptomatic leg (measured 10 cm below tibial tuberosity)	1
Pitting edema (greater in the symptomatic leg)	1
Localized tenderness along the distribution of the deep venous system	1
Collateral superficial veins (non-varicose)	1
Alternative diagnosis	
Alternative diagnosis as likely or more likely than DVT?	-2
Clinical probability (prevalence of DVT)	Score
Low (<5%)	0 or less
Intermediate	1-2
High (>60%)	>3

Abbreviations: DVT, deep-vein thrombosis.

Reprinted from The Lancet, Volume 350, issue 9094, Philip S Wells, David R Anderson, Janis Bormanis, Fred Guy, Michael Mitchell, Lisa Gray, Cathy Clement, K Sue Robinson, Bernard Lewandowski, Value of assessment of pretest probability of deep-vein thrombosis in clinical management, pp. 1795-1798, Copyright (1997), with permission from Elsevier.

The Wells score (Table 65.4), based on specific features in the clinical assessment, is a validated method of determining the probability of DVT. This guides investigation (see Chapter 101).

Phlegmasia cerulea dolens

Phlegmasia cerulea dolens is a syndrome due to extensive iliofemoral DVT with occlusion of collateral veins. This results in a marked increase in capillary pressure in the leg, with resultant fluid extravasation. The leg is painful, grossly swollen, and cyanotic. Venous gangrene may develop.

Nerves

Peripheral neuropathy

Pain may be a feature of many peripheral neuropathies (see Chapter 234), notably those due to diabetes and alcohol.

Spinal disorders with referred pain

Spinal disorders with referred pain should be considered if no pathology is evident in the leg: these include isolated nerve root compression with radiculopathy, and spinal stenosis with neurospinal claudication (see Chapter 233).

Muscles

The assessment of muscle pain is discussed in Chapter 63.

Acute generalized muscle pain

Acute generalized muscle pain with prominent constitutional symptoms is most commonly due to systemic infection.

Chronic generalized muscle pain

Chronic generalized muscle pain is seen in metabolic, inflammatory, and nutritional-deficiency myopathies, autoimmune rheumatic diseases (e.g. systemic lupus erythematosus), and patients with chronic pain syndromes such as fibromyalgia.

Polymyalgia rheumatica

Polymyalgia rheumatica typically presents in a person aged over 50 (peak incidence between 70 and 80) with bilateral aching and morning stiffness in the neck, shoulders, upper arms, hips, and thighs. The pain is exacerbated by activity, and is often associated with systemic

features including fever, malaise, and weight loss. The erythrocyte sedimentation rate is typically at least 40 mm per hour.

Compartment syndrome

Compartment syndrome is defined as increased pressure within a myofascial space (most often tibial), compromising the circulation and function of tissues within that space. It typically follows trauma, particularly fractures, crush injuries, and burns, but can also follow IV drug administration or arterial puncture. Unrelieved, it causes acute ischaemia and thus threatens the viability of the limb. In a patient at risk, if there is pain which is worse on stretching the muscles within the affected compartment, there should be a high clinical suspicion of compartment syndrome and immediate orthopaedic review should be sought. The diagnosis can be confirmed with compartment pressure monitoring, and the treatment is emergent decompression of the affected compartment by fasciotomy.

Bones and joints

The assessment of acute joint pain is discussed in Chapter 62.

Septic arthritis

Septic arthritis is usually the result of haematogenous spread, but may result from adjacent osteomyelitis. Systemic upset, fever, severe pain, and grossly restricted range of movement of the joint raise the possibility of this diagnosis, and should trigger urgent referral to an orthopaedic surgeon. Diagnosis should be made by prompt aspiration of the joint (before antibiotic treatment is commenced).

Reactive arthritis

Reactive arthritis may be triggered by a range of viral or bacterial infections, and can occur in response to sexually transmitted infection, giving the triad of arthritis, conjunctivitis, and non-specific urethritis.

Hip pain

Pain arising from the hip joint typically gives rise to groin pain, which can radiate to the knee, but may be felt only around the knee. Hip pain is usually due to osteo- or inflammatory arthritis, but can result from bony metastases or stress fractures in athletes. The hip is a deep joint and is difficult to palpate. The greater trochanter is felt laterally, and tenderness here may indicate trochanteric bursitis. Movement should be assessed in flexion, extension, abduction, adduction, and internal and external rotation. If there is a significant effusion, such as in septic arthritis, then the hip is held flexed, abducted, and externally rotated, as this position maximizes capsular volume, and any movement is extremely painful. In fractured neck of femur, the typical presentation is with a shortened, externally rotated leg, but this is not always seen.

Knee pain

Pain arising from the knee joint generally localizes to the joint lines around the knee, or more anteriorly in patellofemoral problems. It may be associated with an effusion. Knee pain in younger patients is usually due to injury to the menisci and ligaments, but may also result from patella dislocation, osteochondral fracture, or avulsion fracture. In older patients (>50 years), arthritis is the major cause of knee pain. Look for the presence of an effusion or for a boggy swelling of the pre- or infrapatellar areas; the latter may be consistent with a bursitis. Feel for warmth compared with the other side. Tenderness may be felt over the joint lines. Move the knee and compare it with the other side, particularly with respect to extension; when the unaffected knee can hyperextend but the affected knee does not, this represents a loss of extension. There may be audible or palpable crepitus on movement.

Ankle pain

Pain arising from the ankle joint is generally felt as a band over the anterior surface of the ankle. The ankle has stabilizing ligamentous structures—the medial deltoid ligament and the lateral ligament complex. Both of these may be damaged as a result of trauma and can give rise to pain in the chronic situation.

Foot pain

The foot is a complex structure consisting of the hindfoot (calcaneus and talus), midfoot (tarsal bones), and forefoot (metatarsals and

phalanges). In cases of foot pain, careful clinical examination should give you clues as to where the pain is arising, with maximal tenderness over the affected area. Morton's neuroma may be associated with a 'Mulder's click' sign on compression of the metatarsal heads.

Long bone pain

Pain arising from the long bones—the femur and tibia—is uncommon, and may be caused by primary or metastatic tumours, infection, stress fractures, and loosened hip or knee replacements.

Key diagnostic tests

Diagnostic tests are determined by the likely pathology (Table 65.5). Additional tests needed for management may include measurement of a full blood count, C-reactive protein, erythrocyte sedimentation rate, biochemical profile, creatine kinase, and blood glucose. Blood culture should be done if systemic sepsis is suspected.

Introduction to therapy

Therapy is determined by the working diagnosis.

Prognosis

The prognosis for viability of the leg and survival depend on the causative disease, the speed with which the diagnosis is made, and the response to treatment. Many causes of acute leg pain need multidisciplinary management to achieve a good outcome, and the appropriate surgical opinion should be promptly sought.

How to handle uncertainty

Uncertainty most commonly arises from leg pain without characteristic clinical features. In patients with no abnormal signs evident, consider DVT, small-fibre neuropathies, bone disease, and referred pain from the spine.

Table 65.5 Diagnostic tests in leg pain

Suspected site of disease	Key diagnostic tests
Skin and subcutaneous tissues	Microscopy and culture of samples from areas of ulceration Plain radiography if suspected gas in tissue or underlying fracture, osteomyelitis or foreign body Ultrasonography, CT, or MRI if suspected necrotizing fasciitis
Arteries	Duplex scan Angiography (CT or direct)
Veins	Duplex scan Measurement of plasma D-dimer (to rule out low-probability deep vein thrombosis)
Nerves	Nerve conduction studies MRI of lumbosacral spine
Muscles	Ultrasonography MRI Measurement of plasma creatine kinase
Joints	Plain radiography (in anteroposterior and lateral views) Joint aspiration if effusion present CT or MRI if suspected fracture not revealed by plain radiographs
Bones	Plain radiography (in anteroposterior and lateral views) CT or MRI if suspected pathology not revealed by plain radiographs

66 Leg ulcers

Emily Davies and Susan Cooper

Definition of the symptom

Leg ulcers are defined as open wounds, usually below the knee, persisting for more than 6 weeks.

Differential diagnosis

Over 80% of leg ulcers are managed in primary care, and the majority of these are due to venous disease. The causes are outlined in Table 66.1.

Context

Leg ulcers are a common and costly problem. Treatment of leg ulcers places a significant financial burden on healthcare providers and uses a substantial amount of medical resources. Estimated costs to the NHS are £300–600 million per annum. Studies have found that venous ulcers affect 2% of the population in Western countries. The prevalence of leg ulcers is increasing as the population ages, with an estimated 3.6% of the population over the age of 65 affected.

Approach to diagnosis

The key to making an accurate diagnosis is taking a detailed medical history, examination of the ulcer and surrounding skin, and measurement of the ankle–brachial pressure index (ABPI). It is also important to remember that many ulcers are of mixed origin.

History

The incidence of venous ulcers increases with age. Patients with arterial ulcers are often men over the age of 40 with a sedentary lifestyle. It is important to enquire about previous deep-vein thrombosis, varicose veins, knee or hip surgery, trauma, smoking history, diabetes mellitus, hypertension, and hyperlipidaemia. The clinician should ask about symptoms of intermittent claudication or rest pain.

Site of the ulcer

The site of the ulcer can be a pointer towards venous, arterial, or neuropathic disease. Venous ulcers are typically on the medial gaiter region of the lower leg. Arterial ulcers are typically seen on the toes, foot, and ankle. Neuropathic ulcers classically present at pressure

sites. Other key features of the different types of ulcer are outlined in 'Specific clues to the diagnosis'.

Surrounding skin

There are numerous signs in the surrounding skin which can provide useful clues towards the different types of ulcers, including haemosiderin pigmentation, varicose eczema, atrophie blanche, venous flare, lipodermatosclerosis, calluses, shiny atrophic skin and loss of hair. The temperature of the skin should be noted.

ABPI

Measurement of the ABPI is useful to assess for arterial disease. An index >0.8 is considered normal, but one <0.8 would imply a degree of arterial disease. Results should be interpreted in conjunction with the examination findings, as falsely high readings may be obtained if the arteries are calcified.

Specific clues to the diagnosis

As outlined in 'Approach to diagnosis', there are many clues in the history and examination to help with the diagnosis; these are outlined in Table 66.2. Pain is not usually a helpful diagnostic indicator, as both arterial and venous ulcers can be extremely painful.

Key diagnostic tests

Arterial and venous duplex ultrasound is the preferred method of investigation for assessing vascular structure and function. This will highlight any abnormalities of the vascular anatomy and blood flow which might be amenable to surgical intervention.

Other diagnostic tests

Other diagnostic tests are as follows:

Skin biopsy: This should be a deep incisional biopsy to include both the ulcer margin and the bed; it should be taken if the ulcer is not healing, is in an atypical site, or has any suspicious features of neoplasia (e.g. rolled edge, overgranulation). It should be sent for histological evaluation and also for fungal and mycobacterial culture if the ulcer has not started to heal after 3 months of treatment.

Swabs for bacterial microscopy and culture: These should be taken if infection is suspected. All open wounds will be colonized, so it is important only to treat if there are clinical (increased temperature, pain, fever) and/or laboratory (raised white-cell count and C-reactive protein) signs of infection.

Full blood count: A full blood count should be taken to investigate for factors that might be contributing to the ulceration, such as anaemia, polycythaemia, and infection (elevated white-cell count).

Urine dipstick: This should be taken to screen for diabetes mellitus.

Coagulopathy screen: This should be done particularly in young patients and should include Protein C, Protein S, Factor V Leiden, Antithrombin III, and lupus anticoagulant.

Additional laboratory tests: Additional laboratory tests that might be considered would include serum albumin, ferritin, erythrocyte sedimentation rate, antinuclear antibodies, rheumatoid factor, hepatitis B and C, cryoglobulins, and cryofibrinogen.

Patch testing: Patients with chronic leg ulcers often develop an allergic contact dermatitis, commonly to an antibacterial agent, preservative, or rubber chemicals. Patients in whom a contact allergy is suspected should be referred for patch testing.

Table 66.1 The causes of leg ulcers

Causes of leg ulcers	%

Table 66.2 The clinical features of venous, arterial, and neuropathic ulcers

	Venous	Arterial	Neuropathic
History	DVT Phlebitis Varicose veins Previous leg injury Knee/hip/major abdominal surgery	Smoking Diabetes mellitus Hypertension Hyperlipidaemia Hyperhomocystinaemia Intermittent claudication Rest pain	Diabetes mellitus Other rarer causes include drugs, alcohol, spinal cord lesions, hereditary sensory and motor neuropathy, and leprosy
Site	Medial gaiter region of the lower leg	Toes, foot, and ankle	Pressure sites
Ulcer	Irregular borders Sloping edge Slough in wound bed	'Punched out' Necrotic base Deep, pale base	'Punched out'
Exudate	Often high volume	Often low volume	Usually low volume
Surrounding skin	Haemosiderin pigmentation Varicose eczema Atrophie blanche Venous flare Lipodermatosclerosis	Shiny Atrophic Loss of hair Cool	Calluses
Other findings	Leg oedema often present Varicose veins Obesity Lymphoedema in long-standing cases	Weak/absent peripheral pulses Prolonged capillary refill time (>3–4 seconds)	Peripheral neuropathy with decreased sensation

Introduction to therapy

Treatment depends on the underlying cause of the ulcer as well as some common principles, such as treating any infection, controlling pain, and correcting factors such as anaemia, which may contribute to poor wound healing. It is also important that any problems in the surrounding skin are treated. For example, varicose eczema should be treated with emollients and topical steroid.

The choice of dressing depends on the nature of the wound; the degree of exudate; odour; and ulceration. The ideal dressing should provide a moist wound environment to accelerate healing and there are many alternatives with different properties available. Sterile maggots are sometimes used to debride slough and necrotic tissue from wounds.

The management strategy for venous ulceration is elevation, exercise, and graduated sustained compression (usually aim for 30–40 mm Hg at the ankle). **Weight loss is important in overweight patients.** Pentoxifylline is sometimes used to accelerate healing. Sclerotherapy is a useful non-surgical procedure. Vascular surgery (to superficial veins and perforators) and skin grafts are also suitable treatments for some patients. A sympathectomy is occasionally used for intractable arterial ulcers, especially those due to small vessel disease.

Patients with arterial leg ulcers should be assessed by a vascular surgeon, as the main aim of treatment is to re-establish an adequate arterial supply. Risk factors such as smoking, weight loss, control of hypertension, and reducing cholesterol should be addressed.

The management of diabetic neuropathic ulcers involves optimizing diabetic control, treating associated arterial disease, aggressive debridement, off-loading pressure with a non-weight bearing regime, and prompt treatment of any infections.

Other, rarer causes of leg ulcers have specific treatments, such as topical and systemic steroids or ciclosporin for pyoderma gangrenosum.

Prognosis

The recurrence rate for venous ulceration can be greater than 70%. There is a higher recurrence rate in patients with ulcers for more than 1 year. A large wound area, ABPI < 0.8, and history of venous ligation or stripping are also associated with a poorer prognosis.

Wearing support stockings by day, keeping active, and elevation of the legs are all important strategies to reduce the risk of recurrence. It is also important to keep the skin well hydrated with emollients to help maintain good barrier function.

Between 16% and 37% of patients with arterial ulcers require an amputation. The higher rate reflects those who did not undergo revascularization. The risk of amputation is also higher in patients with diabetes and a larger ulcer size; 14%–24% of patients with diabetic neuropathic ulcers will require amputation. Poor glycaemic control, diabetes for more than 10 years, male gender, and associated cardiovascular, renal, or retinal complications are all risk factors. Addressing these risk factors and taking great care to avoid injury (e.g. use of good-fitting shoes) will help reduce the need for amputation.

How to handle uncertainty in the diagnosis of this symptom

If a leg ulcer is not responding to usual treatments, is in an unusual site, or has atypical features, always consider other causes such as neoplasia, vasculitis, pyoderma gangrenosum, infection, and hypercoagulable states. A skin biopsy for histology and culture and more focused blood tests may help with diagnosis.

67 Limb ischaemia

David Ratliff

Definition

Acute limb ischaemia is defined as a decrease in the arterial blood flow, over a period of minutes to days, which threatens the viability of the limb. Presentation is within 2 weeks of the onset of symptoms. **Chronic limb ischaemia** (presentation >2 weeks after the onset of symptoms) can be divided into **critical ischaemia**—a potential threat to limb viability, with ischaemic rest pain, ischaemic ulcers, or gangrene—and **non-critical ischaemia**, which may be symptomatic (typically with claudication) or asymptomatic.

Differential diagnosis

See Box 67.1 for a list of the different causes of limb ischaemia.

Context

Acute limb ischaemia

Acute limb ischaemia is usually caused by embolic occlusion or in situ thrombosis of a native vessel or arterial bypass graft. The leg is affected in >80% cases. Over the past 20 years, embolic occlusion has become rarer, owing to the increased use of anticoagulation for thromboprophylaxis in atrial fibrillation, while in situ thrombosis is now more common, as the prevalence of peripheral arterial disease has increased. In contrast, acute arm ischaemia is usually due to embolism from the heart. Cardiac sources of embolism include left atrial thrombus as a consequence of atrial fibrillation, left ventricular mural thrombus following myocardial infarction or in dilated cardiomyopathy, valve vegetations due to infective endocarditis, and left atrial myxoma.

Chronic limb ischaemia

Chronic limb ischaemia is most commonly due to atherosclerotic arterial disease. Segmental lesions causing stenosis or occlusion are usually localized in the large and medium-sized vessels. The leg is much more often affected than the arm.

Approach to diagnosis

History

Sudden onset of severe pain in the leg or arm, with evidence of impaired circulation, is typical of acute ischaemia. The insidious progression of intermittent claudication of the buttocks, thighs, or calves over several months or years indicates chronic lower limb ischaemia. The symptoms of limb ischaemia in a heavy smoker (typically male) under 40 years of age raise the possibility of Buerger's disease, thromboangiitis obliterans. Other causes to consider are given in Box 67.1.

Examination

Assess the limb for reduced sensation and movement, the cardinal features of acute ischaemia. An acutely painful cold limb with reduced or absent sensation is due to acute ischaemia until proven otherwise. Assess the limb muscles for tenderness or rigidity.

Inspect the lower legs and feet. Marked pallor, hair loss in the pretibial area, tissue loss, ulceration, or gangrene occurs in chronic lower limb ischaemia. Critical lower limb ischaemia is indicated by a positive Buerger's sign (elevation pallor with venous guttering, followed by dependency rubor).

Assess the capillary refill time (return of capillary circulation after blanching produced by pressure). This is a useful assessment of the peripheral circulation and is normally <4 seconds.

Assess the skin temperature with the dorsum of the hand. A clearly marked change of temperature may reveal the site of arterial occlusion.

Box 67.1 Causes of limb ischaemia

Acute ischaemia

- embolic occlusion
- thrombosis of a diseased artery or arterial bypass graft
- trauma (including arterial cannulation)
- aortic or arterial dissection

Chronic ischaemia

- atherosclerotic arterial disease
- Buerger's disease (thromboangiitis obliterans), and other types of arterial disease (e.g. polyarteritis nodosa, Takayasu's arteritis)
- popliteal artery aneurysm with secondary thromboembolism
- popliteal artery entrapment
- arterial thoracic outlet syndrome
- embolic occlusion
- congenital or acquired coarctation of the aorta

Assess the pulses in the limbs, grading them as normal, reduced, or absent. In the arm, palpate the subclavian, axillary, brachial, radial, and ulnar pulses and, in the leg, the femoral, popliteal, posterior tibial, and dorsalis pedis pulses. A reduced or absent pulse indicates severe stenosis or occlusion of the proximal artery.

Listen for a bruit over the subclavian artery in the supraclavicular fossa, over the iliac artery in the iliac fossa, over the femoral artery in the groin, and over the superficial femoral artery in the thigh.

Measure the blood pressure in both arms, and examine the heart.

Specific clues to the diagnosis

The symptoms of acute limb ischaemia are pain and paraesthesiae, followed rapidly by reduced sensation and movement and subsequent muscle swelling and rigidity. Tissue necrosis typically occurs after 6 to 12 hours of acute ischaemia, although this is influenced by the location of the occlusion and the degree of collateral circulation.

Patients with chronic lower limb ischaemia usually have long-standing symptoms and will describe intermittent claudication (from the Latin *claudicare*, to limp or be lame), the equivalent of angina of the leg. Patients complain of pain, aching, muscle stiffness, or fatigue of the affected areas during exercise but which is relieved quickly by rest. In aortoiliac disease, symptoms typically occur in the buttocks, thighs, and calves. In superficial femoral artery disease, the calves only are affected. The differential diagnosis of intermittent claudication is given in Chapter 104.

In critical lower limb ischaemia, rest pain occurs. It usually involves the toes or foot in a stocking distribution and is relieved by dependency of the limb (hanging the foot out of bed at night), which increases perfusion pressure.

Key diagnostic tests

Non-invasive tests

Non-invasive tests provide an accurate vascular assessment and objective evidence of the severity of the disease, and are the initial investigations of first choice:

- ankle-brachial pressure index at rest and after exercise (walk test on a treadmill) (Figure 67.1).
- arterial duplex scan (ultrasonography with colour-flow imaging)

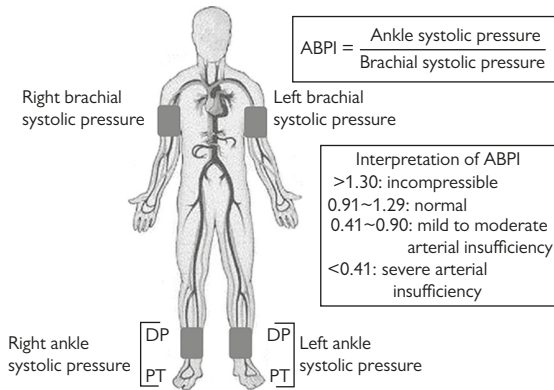

Figure 67.1 Measurement of ankle–brachial pressure indices; ABPI, ankle–brachial pressure index; DP, dorsalis pedis artery; PT, posterior tibial artery.

Xiaoyun Li, Ling Wang, Chi Zhang, et al., “Why Is ABI Effective in Detecting Vascular Stenosis? Investigation Based on Multibranch Hemodynamic Model,” *The Scientific World Journal*, vol. 2013, Article ID 185691, 10 pages, 2013. doi:10.1155/2013/185691

Angiography

The following angiographic techniques show the site and extent of the arterial disease, and provide a road map for treatment:

- CT angiogram
- MR angiogram
- catheter-based angiogram (potentially therapeutic as well as diagnostic)

Other diagnostic tests

Other diagnostic tests are:

Electrocardiography: This defines the cardiac rhythm and is a screen for structural heart disease.

Echocardiography: This should be done if embolic occlusion is suspected from the history or if abnormalities are found on cardiac examination or electrocardiography.

Introduction to therapy

Acute limb ischaemia

As soon as the diagnosis of acute ischaemia is made, the patient should be given 5000 IU heparin intravenously (to prevent propagation of thrombus) and referred for a vascular specialist opinion as

an emergency. Balloon embolectomy under local anaesthesia is the standard treatment for emboli. Patients with preexisting vascular disease will often require emergency angiography and treatment by percutaneous thrombolysis, angioplasty, or reconstructive surgery.

Chronic limb ischaemia

Patients with atherosclerotic peripheral arterial disease should be treated with aspirin 75 mg daily and a statin, even if their cholesterol level is within the normal range. Vascular risk factors should be managed, with advice on smoking cessation and optimal control of hypertension and diabetes. Regular foot care is very important for patients with diabetes; such patients should be referred promptly for treatment in a multidisciplinary diabetic foot clinic should any problem develop.

A graduated exercise programme is the initial treatment for mild to moderate leg claudication. Angioplasty is offered to patients with disabling symptoms. It is carried out under local anaesthesia and is effective, with a low risk of serious complications (1%–2%). Lower limb reconstructive vascular surgery is indicated for patients with severe restrictive claudication or critical ischaemia not suitable for treatment by angioplasty.

Prognosis

In acute limb ischaemia, limb loss and mortality are high. Acute arm ischaemia carries less risk to life and limb than acute leg ischaemia. Prompt recognition and treatment of the cause is the key to reducing mortality.

Claudication is a relatively benign symptom and carries a very low rate of limb loss in patients with good control of vascular risk factors, but a high mortality from cardiovascular disease.

How to handle uncertainty in the diagnosis of this symptom

Most patients can be diagnosed by careful history taking and clinical examination, and there is no substitute for this. Non-invasive tests are valuable adjuncts to the clinical assessment.

68 Rashes

Christine Soon

Definition of the symptom

Rash is a term used to describe the appearance of discolouration of areas of the skin. It can be due to any factor and can be different colours. It is a generic term and by itself does not confer any true meaning without further elaboration.

Differential diagnosis

There are numerous causes for rashes to appear. A useful way to think about rashes is to start with the description. Common terms used to describe rashes are:

Macule: a flat area of discolouration of the skin; ≤ 5 mm wide

Papule: a raised area of discolouration of the skin; a palpable, raised lump ≤ 5 mm wide

Patch: a flat area of skin, >5 mm in diameter

Plaque: a raised area of skin, ≥ 5 mm in diameter

Purpura: discolouration due to extravasation of red blood cells; found in the skin or mucous membranes, 2 mm–1 cm in diameter

Petechia: a small purpuric lesion <2 mm in diameter

Ecchymosis: a large area of extravasation of blood, >1 cm in diameter; more commonly called a bruise

Nodule: a lump >5 mm in diameter

Vesicle: a fluid-filled lesion which can come out in crops (e.g. in chicken pox); generally, 1–3 mm in diameter

Bulla: a large, fluid-filled lesion

Context

Rashes are very common and most people will have had a few episodes of rashes in their life. It is one of the most common presentations to a GP practice. The key to correctly diagnosing and identifying a rash lies in the ability to describe it correctly and recognizing the context in which it occurs.

Most rashes are transient and will clear on their own accord. Many are linked with concurrent viral or bacterial infections. The most common rashes seen, especially in childhood, include chicken pox, impetigo, hand, foot and mouth, glandular fever, and viral exanthem.

More persistent and troublesome rashes include eczema and psoriasis; they are common, and their severity ranges from mild to serious.

Drug eruptions, for example, rashes occurring as a result of exposure to certain medications (e.g. from an allergy to penicillin), are also very commonly seen.

Approach to diagnosis

Description, distribution, and duration of the eruption are key to the diagnosis of rashes. Family history medication history, concurrent illnesses, and past medical history are also very relevant.

Demographics

Children are very prone to viral infections and atopic eczema. Older patients are more likely to have a drug-related rash.

Family history

Often patients with eczema or psoriasis have a family history of similar conditions. A history of atopy such as asthma or hay fever is also very relevant in eczema.

Concurrent illnesses

The presence of a concurrent illness, such as an upper respiratory tract infection, can be very helpful in the diagnosis of a rash. Guttate psoriasis can be triggered by a concurrent upper respiratory tract infection. Hay fever and asthma indicate an atopic tendency. Individuals with atopic tendencies are more likely to have eczema. Headaches, photophobia, and meningeal stiffness in association with a rash could mean meningitis.

Past medical history

Patients may have previously experienced a similar rash, which has recurred; for example, psoriasis tends to recur with intercurrent periods of stress, whether physical or mental. Past history of a drug allergy is very important.

Drug history

The drug history is a crucial part of the diagnosis of a rash. Many rashes are linked with medications. Angiotensin-converting-enzyme (ACE) inhibitors are known causes of angioedema, and NSAIDs can cause urticaria. Minocycline and amiodarone can cause grey pigmentation of the skin. Calcium channel antagonists can cause a photosensitive rash.

Social history

The patient's occupation and hobbies can give very important clues towards their diagnosis. A rash that gets better when the patient is off work or on holiday may be linked to the individual's occupation. Hobbies may lead to exposure to allergens, which could trigger a contact dermatitis response. Social contacts may be relevant, especially in infectious conditions, such as a chicken pox outbreak in a playgroup.

Having taken a careful, thorough history, it is time to examine the patient. Ask the patient to remove clothing and check the distribution of the rash. The next step is to try to describe the rash and try to see if it fits a pattern. The mucous membrane should not be forgotten.

Specific clues to the diagnosis

Symptoms (e.g. the rash being pruritic, painful, asymptomatic) are crucial to the diagnosis of the rash. Signs such as dryness, scaliness, or flakiness are also important, as is the exact distribution of the rash (see Table 68.1).

Key diagnostic tests

Usually, no diagnostic test is necessary to diagnose a rash. However, a skin biopsy can be helpful when the diagnosis is uncertain. Depending on the differential diagnosis, a bacterial or viral swab of the skin, skin scraping, hair plucking, or nail clipping may be carried out.

Introduction to therapy

Therapy is as follows:

- For short-term, transient rashes (e.g. secondary to viral infections), no treatment is usually necessary other than treatment for the underlying infection.
- Moisturizers are the mainstay of treatment for eczema and most dry skin conditions; topical steroid therapy is helpful for

Table 68.1 Common diagnoses and their distribution

Common diagnoses	Distribution	Description
Atopic eczema	Flexures of the limbs	Dry, red, itchy patches
Psoriasis	Extensors of the limbs, scalp, umbilicus, behind ears, nails, genital areas	Scaly, red plaques, often very thick, nail pitting, onycholysis
Lichen planus	Extensor surfaces of wrists, mucous membranes, nails, trunk	Violaceous papules with whitish streaks called Wickham's striae
Chicken pox	Trunk and limbs, mucous membranes	Erythematous patches with vesicles; intensely itchy; crusts at later stages
Urticaria	All over body	Very itchy; each individual lesion tends to come and go over 24 hours; can be associated with angioedema
Meningococcal septicaemia	Anywhere over body; usually starts with lower limbs	Purpura and petechiae, spreads rapidly
Mycosis fungoides	Trunk	Scaly, atrophic patches
Vasculitis	Usually lower legs first	Purpura and petechiae
Drug eruption	Several different presentations; a common presentation to hospital is widespread on trunk and limbs	Can be maculopapular, urticaria, lichen planus-like, vasculitic
Erythema multiforme	Palms, soles, trunk; mucous membranes may be involved	Target lesions, patches, and plaques
Bullous pemphigoid	Trunk and limbs	Bullae and erythematous patches

inflammatory dermatoses such as eczema and lichen planus; vitamin D₃ analogues, coal-tar-based treatments, and topical steroid therapies are all helpful in psoriasis.

- Conditions such as severe bullous pemphigoid may require systemic immunosuppressants such as prednisolone at the initial stages and then azathioprine; tetracycline antibiotics and nicotinamide have also been shown to be helpful.
- In vasculitis, treatment would depend on the type and underlying cause.
- Phototherapy can be helpful for widespread psoriasis, eczema, and mycosis fungoides.
- Biologics are used for severe psoriasis not responsive to disease-modifying antirheumatic drugs (DMARDs).

Prognosis

The prognosis for most rashes is very good. The majority of rashes will clear within a few weeks. Chronic skin conditions such as eczema and psoriasis tend to persist, although their severity tends to vary and some patients do have clear periods. Atopic eczema often clears in childhood but may recur under the correct conditions. Although rare, serious rashes such as toxic epidermal necrolysis and meningococcal septicaemia are associated with fatality.

How to handle uncertainty in the diagnosis of this symptom

Uncertainty in the diagnosis of this symptom can be handled as follows:

- Retake the history and ensure that a comprehensive history has been obtained: for example, a patient with multiple, itchy, red ring-shaped patches could have tinea; does the patient have a pet or had other contact with animals?
- Look for other hidden signs; check nails, scalp, behind the ears, and other often-overlooked areas.
- Ask about recent travel and contacts.
- A sexual history might be helpful.
- A systemic examination may be crucial in giving further clues.
- A skin biopsy can be sent, not just for histology but also for immunofluorescence if immunobullous conditions such as bullous pemphigoid or pemphigus are suspected.

69 Blistering rashes

Emily Davies

Definition of the symptom

A blister is a fluid-filled, circumscribed elevation of the skin. By convention, blisters are divided by size; blisters less than 0.5 cm wide are called vesicles, and those greater than 0.5 cm wide are called bullae. A blistering rash is used to describe any skin condition which morphologically consists of vesicles or bullae. Vesicles more than 48 hours old may evolve into pustules (pus-filled lesions). Pustular eruptions have not been included in this chapter.

Secondary lesions include erosions (partial loss of epidermis), which may occur when a superficial blister ruptures or is scratched, and ulcers (loss of epidermis and superficial papillary dermis), which may occur either as part of the blistering process or secondary to infection.

Differential diagnosis

Eczema, infections, and oedema are the commonest causes of blistering seen in primary care (see Table 69.1).

Context

Blisters can be caused by a number of different mechanisms: it can be due to friction, skin fragility, or oedema; it can be secondary to infectious agents or drugs; it can be toxin mediated; or it can occur via autoimmune attack. Bullous pemphigoid is the commonest

immunobullous disease in Western Europe and will be covered in detail in Chapter 252.

Approach to diagnosis

A detailed medical history is important. Preceding symptoms such as itch (sometimes can precede blistering by several months in bullous pemphigoid), systemic upset (fever, malaise), atopic history, and allergies should be recorded. A detailed drug history should be taken and other factors such as recent sunburn, injuries (portal of entry for cellulitis), or insect bites should be noted.

All of the skin should be examined, including the hair, nails, and mucous membranes. It should be noted if the blistering is localized or generalized, and the size of the blisters. The presence of pustules, erosions, ulcers, and any evidence of infection (crusting, weeping, increased heat) should be documented.

The skin should be palpated for tenderness, and Nikolsky's sign checked (positive when gentle rubbing of the skin at the edge of a blister results in extension of the blister). This is almost always positive in toxic epidermal necrolysis and pemphigus and is used to distinguish pemphigus vulgaris from bullous pemphigoid. Any changes in the surrounding skin such as oedema or eczema should also be looked for. In addition, baseline observations, that is, temperature, pulse, and blood pressure, should be assessed. Investigations can then be targeted, depending on these initial findings.

Table 69.1 The differential diagnosis of blistering rashes in primary and secondary care

Diagnosis in primary care	%	Diagnosis in secondary care	%

Specific clues to the diagnosis

Table 69.2 outlines diagnostic features which may help to differentiate the different conditions.

It is important to remember that any blistering disorder can be complicated by secondary bacterial infection, which may confuse the clinical picture.

Key diagnostic tests

These will depend on the differential diagnosis formed after initial history and examination, but the following would be recommended on most patients:

- skin biopsy for histology (fresh blister)
- skin swabs for bacterial and viral microscopy and culture

- full blood count
- C-reactive protein

The key to diagnosing immunobullous disorders such as Bullous pemphigoid and pemphigus is direct and indirect immunofluorescence. Direct immunofluorescence is performed on a sample of perilesional skin and demonstrates deposition of immunoglobulins and complement. Indirect immunofluorescence is performed on serum and detects circulating immunoglobulins.

Other diagnostic tests

Other tests may be warranted, depending on the provisional diagnosis, such as patch testing if an allergic contact dermatitis is suspected. Fungal microscopy and culture should be carried out in cases

Table 69.2 Diagnostic features which may help to differentiate the different conditions

Diagnosis	Age	Site	Examination findings	Symptoms	Other information
Acute eczema	Any	Any	Acutely inflamed skin with vesicles	Itch /pain	Background of eczema; often recurrent; there may be a history of contact with an irritant or allergen; often there is secondary staphylococcus infection
Impetigo	Children	Frequently face	Large bullae, become cloudy and then rupture to form honeycrusts; healing from the centre gives rise to circinate lesions	None	Contagious; only some impetigo is bullous; often localized
Staphylococcal scalded skin syndrome	Children	Widespread	Skin tenderness, fever and widespread superficial blistering erythema which evolves into large painful areas where the superficial epidermis has stripped off	Pain	Toxin mediated; mucous membranes not affected
Cellulitis	Adults	Any, but often leg (usually unilateral)	Hot, red, and tender	Pain	Portal of entry
Varicella (chicken pox)	Any age, usually children	Widespread	Malaise and upper respiratory tract symptoms followed by a widespread papulovesicular eruption	Itch	Scalp involvement characteristic
Herpes zoster	Older adults	Dermatomal	Erythema and grouped vesicles (may be haemorrhagic)	Preceding burning pain	
Herpes simplex	Any	Face, lips, and genitals	Occurs in roughly the same place each time	Preceding tingling or burning pain	Recurrent
Hand, foot, and mouth	Children	Hands, feet, and mouth	Small grey vesicles, with a halo of erythema on the hands and feet with small erosions of the buccal mucosa	Oral lesions may be painful	
Oedema	Older adults	Legs bilateral	Pitting oedema with blisters and weeping	Discomfort	Often associated with congestive cardiac failure, low albumin, or other medical causes
Tinea pedis	Adults	Feet, often unilateral	Scale, erythema, and a vesiculopustular eruption	Itch	Nails may be affected
Insect bite reaction	Any	Usually lower legs	Bullae on an erythematous base; often linear configuration	Itch	Inflammatory papules may also be present
Erythema multiforme	Any	Usually acral; may be mucous membrane involvement	Erythematous macules/plaques with a central bulla and marginal ring of vesicles	None	Recurrent attacks are often secondary to herpes simplex
Stevens–Johnson syndrome/ toxic epidermal necrolysis	Any	Widespread	Tender, erythematous skin which develops widespread erosions	Pain	Marked mucous membrane involvement Spectrum of severity Usually due to a drug
Porphyria cutanea tarda	Older adults	Sun-exposed sites—dorsa of hands	Presents with skin fragility, blisters, and milia	Pain	Often associated with high alcohol intake in men or oestrogen-containing tablets in women
Bullous pemphigoid	Elderly	Usually widespread	Tense bullae and sometimes urticated plaques	Itch/pain	Often prodrome of pruritus for several months before the onset of blisters
Cold/heat injury	Any	Any	Acute erythema and blisters	Pain	Usually clear history, e.g. sunburn

of possible tinea pedis. Patients with possible porphyria cutanea tarda should have blood and urine porphyrins measured.

Introduction to therapy

Treatment depends on the underlying cause of the blistering, as well as some common principles, such as treating any secondary infection and controlling any pain or pruritus with appropriate analgesia and sedating antihistamines (at night) if required:

- Acute eczemas should be treated by removing any possible allergen or irritant and then topical therapy with emollients, soap substitutes, and an appropriate strength topical steroid.
- Bacterial infections, including toxin-mediated staphylococcal scalded skin syndrome (SSSS), require appropriate antibacterial treatment, topically, orally, or intravenously, depending on the extent of involvement and any systemic upset; it is important that family members do not share towels with the patient, as SSSS is highly contagious.
- Varicella, in most immunocompetent individuals, does not require active treatment, but soothing emollients can help with the itch. Herpes zoster and simplex may be treated with oral or intravenous acyclovir.
- The offending drug should be removed in all cases of drug reactions, although it may take several weeks or even months for the rash to resolve.
- Treatment for oedema blisters needs to be targeted at managing the cause of the oedema.
- Clinicians should be alert for signs of secondary bacterial infection in all blistering rashes; patients should be advised to keep their nails short to limit damage from scratching the skin.

Prognosis

Once treated, most causes of blisters, such as acute vesicular eczemas and infections, usually resolve over a couple of weeks. More persistent causes of blistering are the immunobullous disorders, which have a remitting and relapsing course.

How to handle uncertainty in the diagnosis of this symptom

If a blistering eruption is not responding to an initial treatment (e.g. antibiotics for suspected bullous impetigo), always consider a biopsy through an intact blister, for histology, and of perilesional skin, for direct immunofluorescence, in case the patient has an immunobullous disorder. In addition, always retake a drug history, including over-the-counter and herbal remedies, as well as medications which are just taken occasionally, in case a drug reaction is the cause.

Most blistering reactions, although dramatic in appearance, are localized and short-lived. It is important not to miss the rarer, more persistent blistering conditions which need specific targeted treatment.

70 Photosensitive rashes

Jane McGregor

Definition of the symptom

Clinical photosensitivity is an abnormal reaction of the skin to sun exposure. This can present in many ways, including sunburn, urticaria, itching, pain, and the development of skin rashes as diverse as skin necrosis and eczema.

Differential diagnosis

The majority of the common reactions to sun exposure, including sunburn, polymorphic light eruption, and solar urticaria are managed in general practice (Table 70.1). The rare photodermatoses require specialist investigation and are usually managed in the specialist centres.

Context

Sunburn is the commonest form of photosensitivity. When this is seen in the context of overexposure, then symptomatic relief with emollients and hydration, sometimes with oral or topical steroids, is all that is required. When the degree of sunburn seems disproportionate to the exposure, then drug phototoxicity should be considered (many drugs are potentially phototoxic). Easy sunburn in children should raise the possibility of the very rare condition known as xeroderma pigmentosum (a DNA-repair-deficient condition which results in premature development of skin cancer and early death). This is not an easy diagnosis to make and children with suspected sunburn after minimal exposure should be referred to a specialist.

Polymorphic light eruption (PLE) is the second most common form of photosensitivity. It affects about 10% of the population, predominantly women. The history is usually clear, namely, the patient develops an itchy papular eruption a few hours after sun exposure, and only on sun-exposed sites. It can occur in the context of systemic lupus erythematosus, and this should be considered and investigated.

Other forms of photosensitivity are very rare, but any patient presenting with pain (erythropoietic protoporphyria), itching (polymorphic light eruption, urticaria, chronic actinic dermatitis), or a skin rash of any other type following sun exposure should be referred to a specialist for investigation.

Table 70.1 The causes of photosensitive rashes in primary and secondary care

Diagnosis in primary care	%	Diagnosis in secondary care	%
Sunburn		Sunburn	
• overexposure	75%	• overexposure	10%
• drug phototoxicity	25%	• drug phototoxicity	80%
		• xeroderma pigmentosum	10%
Polymorphic light eruption	70%	Polymorphic light eruption	30%
Solar urticaria	80%	Solar urticaria	20%
Other photodermatoses (rare)			
Managed in the specialist centres			

Approach to diagnosis

The key to making a diagnosis of photosensitivity is to take a very careful history. This should include any seasonal variation in the symptoms, the time after exposure that the reaction occurs (minutes, hours, days), the nature of the reaction (pain, itching, rash), and the duration of symptoms (minutes, hours, weeks or months). Since many forms of photosensitivity are acute and transient, there may be no rash to examine at the time of the consultation.

If a skin rash is present, then either the consultation has occurred soon after the episode of photosensitivity, or the eruption is chronic. Careful observation should include details of cut-off, that is, sparing of non-exposed sites, and the nature of the rash (urticaria, papules, nodules, excoriation, blistering, skin thickening, eczema, etc.).

Specific clues to the diagnosis

Specific clues to the diagnosis are shown in Table 70.2.

Key diagnostic tests

The diagnosis is a clinical one in many cases, so the history and clinical examination are paramount. First, there should be an accurate assessment of photosensitivity, and then there are tests (see 'Other diagnostic tests') which can be used to confirm a diagnosis in some specific cases.

Other diagnostic tests

Photosensitivity can be objectively demonstrated in selected cases by using a monochromator light testing procedure—this is time consuming, expensive, and only available in specialist centres. It is useful in confirming a diagnosis of chronic actinic dermatitis and in defining the causal wavelengths in solar urticaria.

Patch testing is required in patients with chronic actinic dermatitis, as concomitant contact allergies are common.

Lupus serology (antinuclear antibody (ANA), anti-double-stranded DNA (ds DNA), and extractable nuclear antigen antibody tests) is mandatory in patients suspected of having photosensitivity associated with both cutaneous and systemic lupus erythematosus. It should also be undertaken in any patient presenting with classical features of polymorphic light eruption, before undertaking phototherapy.

Porphyrin analysis (blood, urine, faeces) is required to confirm a diagnosis of the cutaneous porphyrias, including in erythropoietic protoporphyria.

Human leukocyte antigen (HLA) testing can be helpful in supporting a diagnosis of the rare condition known as actinic prurigo. HLA DRB1 is present in 90% of patients (compared with 30% of the general population), and 60% of these will have the rare HLA BRB1 0407 haplotype.

DNA repair can be estimated in ex vivo fibroblasts (requires a skin biopsy)—a defect confirms a diagnosis of the very rare xeroderma pigmentosum—but this requires a specialist opinion first.

Introduction to therapy

Therapy depends on the diagnosis (see Table 70.3).

Prognosis

Prognosis depends on diagnosis (see Table 70.4).

Table 70.2 Clues to the diagnosis of photosensitive dermatoses

Symptoms	Investigation	Diagnosis	Recommendations
Itching and whealing	Routine bloods (usually normal); porphyrin analysis (EPP can present with urticaria); history and examination	Wheals indicate solar urticaria	If sun avoidance and antihistamines are insufficient, will require referral to specialist
Itching and papules	Lupus serology to exclude lupus	Polymorphic light eruption	If sun avoidance and antihistamines are insufficient, will require referral to specialist
Itching, papules, nodules, and excoriations	HLA testing	Actinic prurigo (rare)	Refer to specialist
Pain and/or scarring	Exclude porphyria	Hydroa vacciniforme	Refer to specialist
Eczema at sun exposed sites	Patch test to exclude airborne or other contact allergies	Chronic actinic dermatitis	Refer to specialist
Sunburn	Consider drug phototoxicity; consider XP in child	–	Withdraw drug and review; refer to specialist for opinion and further investigation
Blistering and skin fragility	Porphyrin analysis, liver function tests, ferritin and alpha feto protein	Cutaneous porphyria (porphyria cutanea tarda or variegate porphyria)	Refer to specialist
Erythema (redness) or scaling, annular eruption	Lupus serology: ANA, anti-dsDNA, ENA	Cutaneous lupus or photosensitivity in systemic lupus erythematosus	Refer to specialist

Abbreviations: ANA, antinuclear antibody; anti-dsDNA, anti-double-stranded DNA antibody; ENA, extractable nuclear antigen antibody; EPP, erythropoietic protoporphyria; HLA, human leukocyte antigen; XP, xeroderma pigmentosum.

Table 70.3 Therapy in the different diseases causing photosensitive dermatoses

Diagnosis	Investigations	Therapy	Other recommendations
Sunburn	Consider drug phototoxicity (withdraw drug if relevant); consider XP in child with easy sunburn (rare)	Emollients, topical or oral steroids for a few days, hydration	Advise on sun protection; refer to specialist
Polymorphic light eruption	Lupus serology to exclude lupus as a cause	Sunblock and sun avoidance measures; phototherapy (desensitization programme)	Refer to specialist if simple measures are insufficient
Actinic prurigo	HLA testing	Sun block and sun avoidance; phototherapy desensitization; thalidomide	Refer to specialist
Hydroa vacciniforme	Clinical diagnosis of exclusion	Sunblock and sun avoidance; phototherapy desensitization; immunosuppression	Refer to specialist
Solar urticaria	Clinical diagnosis may be supported (if necessary) by phototesting in specialist centres to define precipitating wavelengths	Antihistamines and sun avoidance; phototherapy desensitization; photophoresis; immunosuppression	Refer to specialist if simple measures are insufficient
Chronic actinic dermatitis	Clinical diagnosis supported by monochromator phototesting	Sun avoidance; topical steroids; oral immunosuppression	Refer to specialist
Cutaneous porphyrias	Clinical diagnosis supported by porphyrin analysis; look for haemochromatosis (in PCT)	Sun avoidance; avoidance of precipitating factors (e.g. alcohol, oestrogens, etc.); venesection (if ferritin raised); low-dose hydroxychloroquine	Refer to specialist

Abbreviations: HLA, human leukocyte antigen; PCT, porphyria cutanea tarda; XP, xeroderma pigmentosum.

Table 70.4 Prognosis of different photosensitive dermatoses

Diagnosis	Prognosis
Sunburn	Good outlook if infrequent; long-term consequences include increased risk of melanoma and non-melanoma skin cancer
Drug phototoxicity (sunburn)	Good outcome if drug identified and withdrawn; usually no further sequelae
Xeroderma pigmentosum	Patients at 1000x risk for melanoma and non-melanoma skin cancer; some xeroderma pigmentosum complements develop neurological complications; patients need specialist care and continued, lifelong vigilance; death from metastatic skin cancer common
Polymorphic light eruption	Usually self-limiting; patients may remit after several years but some are photosensitive for life; with desensitization, they can live a reasonable life outside during summer
Solar urticaria	Often self-limiting; can be very disabling if symptoms not adequately controlled
Actinic prurigo	Usually well controlled with therapy; most children grow out of this condition but it occasionally persists into adulthood
Hydroa vacciniforme	May self-limit; some cases persist into adulthood; lifelong scarring
Chronic actinic dermatitis	Can be very disabling, and severity may limit exposure outside, even with therapy; rarely remits
Porphyrias	Depends on type; risk of liver damage and hepatoma

How to handle uncertainty in the diagnosis

Photosensitivity can be a surprisingly difficult symptom to elicit, especially in the chronically photosensitive patient who may not be aware of the relationship with sun exposure. If in doubt, even if you have elicited a good history for photosensitivity, refer to a specialist—making a specific diagnosis and subsequent management can be challenging.

71 Itching

Christine Soon

Definition of the symptom

Itching, also known as pruritus, is an unpleasant sensation on the skin that leads to an urge to scratch the skin in order to obtain some relief from the symptom.

Differential diagnosis in primary care and secondary care

There are many causes of itching. More common ones are listed in Table 71.1.

Context

Itching is a very common symptom and nearly everyone will have experienced it in his or her lifetime. Most itching is temporary and resolves quickly. It can be a response to a physical stimulus, such as an insect bite. However, chronic itching can be debilitating and it is often helpful to find the cause and treat it accordingly. Most patients with eczema will have experienced itching that requires treatment of their condition. It is the most common symptom of an inflammatory skin condition.

Approach to diagnosis

An accurate and detailed history is crucial to diagnose the cause. History should include age of onset, duration of symptom, distribution of symptom, family history, drug history, contact history, any associated systemic symptoms, and social history.

Examination is crucial, and care must be taken to document any rash on the skin and its distribution. Areas that may give clues to the diagnosis include the scalp, genital areas, mucosal surfaces, and nails.

Specific clues to the diagnosis

Babies, toddlers, and young children are more likely to have seborrhoeic dermatitis and atopic eczema. A detailed family history of

atopy should be sought. History of age of onset of symptom and any accompanying rash is important. The distribution of the rash is also important. Seborrhoeic dermatitis commonly occurs on the scalp, in the skin folds, and in the nappy area. It may be accompanied by crusting on the scalp.

Atopic dermatitis tends to occur on flexor surfaces of the limbs. There may be a history of sleep disturbance caused by the itching. Widespread eczema occurring at weaning age may indicate intolerance to certain foods. In adults who present with eczema, but without a previous history of atopic eczema, a careful contact history should be sought to elicit any possible underlying allergen; for example, a cashier presenting with hand eczema may have an allergy to nickel present in coins. It is also common to see irritant eczema secondary to occupational causes such as frequent handwashing in medical and nursing staff, use of harsh detergents in pot washers and hairdressers, and constant wet work in bar staff. Asteatotic eczema tends to present in older individuals, especially on the lower limbs. This is associated with very dry skin leading to a crackled egg appearance.

Psoriasis tends to have two peak ages of presentation: in the late teens and in the 50s. Patients often have a family history, and typical erythematous scaly well-demarcated plaques distributed on the extensor aspects of the limbs, lower back, scalp, behind the ears, and umbilicus. Nails and genital areas can also be involved. Nails may be brittle and demonstrate onycholysis, pitting, thickening, and discoloration. There may be associated arthropathy.

There are many causes of urticaria. Acute urticaria can be caused by a reaction to medications, foods, and plants, and viral, bacterial, and helminth infections. There may also be associated angioedema. Urticaria is often intensely itchy. Dermographism may be present. Each urticated lesion resembles an erythematous raised papule or plaque, which typically lasts for less than 24 hours. Physical stimuli such as heat, cold, water, pressure, sun, and exercise can also be implicated. It is often hard to find a cause for chronic urticaria. Occasionally, a systemic cause such as thyroid disease may be implicated.

Lichen planus tends to present as violaceous, flat-topped polygonal papules. White streaks, known as Wickham's striae, may be seen on the papules and on the oral mucosa. There may be nail pitting.

In infestations, such as with scabies, lice, fleas, or bedbugs, the culprit may be detectable with the naked eye. Scabies is intensely itchy and tends to occur in outbreaks in institutions such as residential and nursing homes for the elderly, and hospitals. Patients may have a widespread rash with lots of excoriations. Burrows may be seen.

Lice and their eggs may be seen in hair-bearing areas. Fleas may also be present in the patient's pets. In infestations, there may be other close contacts who are affected.

Varicella, also known as chickenpox, can cause intense itching in the acute phase. A history of contact with affected people or of outbreaks in the school or nursery will help to point towards the diagnosis. In UK, varicella is a common childhood illness. It is self-limiting. It typically occurs centripetally before spreading to the limbs. Lesions ranging from vesicles, papules, and pustules may be seen. Mucosal surfaces are often affected. The lesions then crust over.

Folliculitis appears as inflamed hair follicles often with pustules. Infection, occlusion, irritation, and certain drugs can cause it. It is common and can be seen often in women who shave their legs, and in beard areas of men.

Dermatitis herpetiformis presents as intensely itchy vesicles and papules on the limbs and the buttocks. It is associated with coeliac disease. It is important to take a gastrointestinal history if this diagnosis is suspected.

Table 71.1 Common causes of itching

Directly related to skin	Systemic causes of itching
Dry skin	Chronic renal failure
Eczema, including atopic eczema, seborrhoeic dermatitis, pompholyx, contact dermatitis, asteatotic eczema, gravitational eczema, irritant eczema	Biliary obstruction
Psoriasis	Haematological malignancies such as lymphomas and leukaemias
Urticaria	Iron deficiency anaemia
Lichen planus	Polycythaemia
Lichen simplex	Thyroid dysfunction
Tinea	Medications
Scabies	
Varicella	
Bullous pemphigoid	
Pityriasis rosea	
Folliculitis	
Lichen sclerosus	
Dermatitis herpetiformis	
Fleas	
Lice	
Insects such as mosquitoes	

Bullous pemphigoid presents as blisters in older patients. There is often underlying erythema and itching.

Lichen sclerosus commonly affects the genital areas and presents as a white, crinkled patches. It can be intensely itchy. Ecchymoses may be present. In about 10% of cases, extra-genital areas may be affected, although these do not appear to be as itchy.

Lichen simplex is used to describe an area of lichenified skin caused by repeated rubbing or scratching. It is often seen on the nape of the neck, the upper shoulders, lateral aspect lower limbs, and wrists. It can be linked with stress.

If the patient's skin appears normal with no obvious signs of dryness or inflammation, a pruritus screen should be conducted to look for underlying causes. A systemic examination including checking for hepatosplenomegaly, and lymphadenopathy should be performed. A careful drug history should also be taken. Pregnancy and postmenopause are times associated with a higher incidence of itching in women.

Key diagnostic tests

In inflammatory skin conditions, a skin biopsy will usually confirm the diagnosis. However, this is often unnecessary as the diagnosis may be obvious from the clinical appearance. If allergic contact dermatitis is suspected, patch tests should be carried out.

In pruritus of unknown cause, blood tests, including full blood count, urea and electrolytes, liver function tests, immunoglobulins, iron levels, thyroid function tests, lactate dehydrogenase, and serum electrophoresis, should be carried out.

Other diagnostic tests

Depending on the findings of the pruritus screen, a chest X-ray, renal ultrasound, hepatic ultrasound, gastroscopy, colonoscopy, bone marrow biopsy, and CT of the chest, abdomen, and pelvis may be necessary. A blood film may be useful. Prick tests may be carried out to confirm the suspected trigger of acute urticaria.

Introduction to therapy

Treatment of itching will depend on the underlying cause. In conditions associated with dry skin, such as eczema and psoriasis, emollients are the mainstay of treatment. These need to be applied regularly and frequently. It is useful to stop soap and replace it with an emollient bath oil or shower cream. Avoidance of placing irritants such as lamb's wool next to the skin of affected individuals can be very helpful. In allergic contact dermatitis, patch tests should be carried out and the relevant allergens avoided. Education and counselling will be very important here.

Topical steroids of varying strengths are usually used in inflammatory skin conditions. Coal-tar-based treatments and vitamin D analogues can be helpful in psoriasis. Occlusion can be helpful for lichen simplex. Immunomodulators such as tacrolimus and pimecrolimus are often used in place of topical steroids, especially on the face.

Sedating antihistamines are often used in individuals whose itching wakes them from sleep. Care should be taken to ensure that they do not interact with other medications the patient may already be on.

Non-sedating antihistamines such as fexofenadine are useful in the treatment of urticaria. In acute urticaria and angioedema with a known trigger, avoidance of the trigger is recommended. If systemic symptoms such as wheeze and hypotension are present, nebulizers, systemic steroids, and even adrenaline may have to be administered.

Phototherapy can be useful in intractable itchy conditions associated with renal failure. It is also often used for itching linked with other causes. It is an established treatment for eczema and psoriasis.

Systemic medications such as oral prednisolone are used in severe cases of skin inflammation. Immunosuppressants such as methotrexate and ciclosporin are also used.

In psoriasis, biologics such as anti-tumour necrosis factor inhibitors are increasingly used.

Infestations can be treated with insecticides. Often, close contacts of the affected individual will need to be treated as well. In cases of bedbugs, the premises may also need to be treated. Pets may also

need to be treated if they have fleas. Education about infestations is important to prevent recurrence. Head lice and scabies can spread particularly easily if close contacts are not treated.

Varicella can be treated with aciclovir, which can be helpful if given within 24 hours of the rash appearing.

Treatment of the underlying condition is important in systemic illnesses. It can, however, be very difficult as the underlying condition may be very hard to treat. This is the case in chronic renal failure.

Prognosis

Itching associated with infestations is relatively easy to cure. The aim would be to eradicate the responsible organism and ensure adequate measures are taken to prevent recurrence. Patients should be warned that they might itch for a few weeks even after successful eradication, especially post scabies.

Itching associated with viral infections such as varicella tends to resolve once the acute infection is over. There is now a vaccine for varicella.

Most urticarias tend to resolve within 6 weeks. Chronic urticaria, however, may take months or years to resolve. If there is a known trigger, avoiding it will generally treat the condition.

There is no cure for eczema or psoriasis. Treatment is aimed at controlling the disease and reducing the symptoms. However, in allergic contact dermatitis, avoidance of the allergen may cure the condition. Although patch tests are exceedingly helpful, allergens are not always easy to identify.

The prognosis for itching associated with systemic illnesses is harder to predict. Treating the underlying cause will hopefully help with the itching, but this is not always possible and, occasionally, itching persists despite treatment of the cause.

How to handle uncertainty in the diagnosis of this symptom

Diagnosing an itch is usually very straightforward, as patients will generally give a very good description of this symptom. Excoriations and scratch marks may be seen on physical examination.

Diagnosing the cause of the itch can be very challenging, especially if there is no obvious skin inflammation. It is crucial to take a detailed history. It is very easy to miss important clues such as medication started around the first onset of the itch. A systemic examination may be helpful, and blood tests to rule out common causes should be performed. If there is an associated rash, a skin biopsy could be carried out. In some cases, no cause can be found.

Although psychogenic itching should only be diagnosed after other causes have been ruled out, it can occasionally be very obvious from the history. In delusions of parasitosis, sufferers complain of parasites infesting their skin. They may present with numerous excoriations and may bring along samples of crusts, scabs, and hair, which they have removed from their skin. The skin may be dry from overuse of antiseptics and other cleaning agents that have been applied in attempts to eradicate the parasites. There may be a history of psychiatric illness. Treatment is not easy, and antipsychotics are often necessary.

Itching can be more common during pregnancy and menopause. It is also more common in the elderly, as dry skin is more common in this age group. It is, however, important to bear in mind other causes and to take steps to rule them out, if appropriate. AIDS and anorexia nervosa are also linked with itching.

In a patient with widespread intractable itching for which no cause can be found, it may be prudent to continue follow-up, as itching has been reported to precede haematological malignancies by a number of years.

72 Lumps and bumps

Rubeta Matin, Jane McGregor, and Catherine Harwood

Definition of the symptom

A skin 'lump or bump' is taken here to refer to a lesion on the skin that an individual recognizes as something new or unusual. It comprises a heterogeneous group and presents in many guises, usually to primary care. Common causes of 'lumps and bumps' include warts, moles, skin tags, dermatofibromas, lipomas, epidermoid cysts, and, of course, melanoma and non-melanoma skin cancers. Distinguishing malignant from non-malignant is not always straightforward. Maintaining a low threshold for referral into secondary care is wise, especially for pigmented lesions, but also for those lesions where there is no obvious diagnosis. Occasionally, a lump in the skin may have arisen from an internal source, such as a metastasis or lymph node. In this section, we describe only primary cutaneous lesions and classify them according to their origin.

Differential diagnosis

The differential diagnosis in primary care and secondary care, ordered by probability, is outlined in Table 72.1.

Context

Approximately 25% of all consultations in primary care are skin related, and a significant proportion of these are 'lumps and bumps'.

Table 72.1 Two tables, side by side, outlining the differential diagnosis in primary care and secondary care, ordered by probability

	Diagnosis in primary care	Diagnosis in secondary care
Infective (most common)	Viral wart Molluscum contagiosum Skin abscess (bacterial)	Skin abscess (bacterial, deep fungal, mycobacterial)
Benign (common)	Fibroepithelial polyps (skin tag) Seborrhoeic keratosis (basal cell papilloma) Dermatofibroma Epidermoid ('sebaceous') or acne cyst Lipoma Melanocytic naevus Pyogenic granuloma Haemangioma (e.g. Campbell de Morgan spot) Sebaceous gland hyperplasia Keloid/hypertrophic scar	Fibroepithelial polyps (skin tag) Seborrhoeic keratosis (basal cell papilloma) Dermatofibroma Epidermoid ('sebaceous') or acne cyst Lipoma Melanocytic naevus Pyogenic granuloma Haemangioma (e.g. Campbell de Morgan spot) Sebaceous gland hyperplasia Keloid/hypertrophic scar
Malignant (less frequent)	Precancerous lesion (e.g. actinic keratosis, Bowen's disease) Non-melanoma skin cancer (e.g. basal cell carcinoma, squamous cell carcinoma) Melanoma Cutaneous metastasis	Non-melanoma skin cancer (e.g. complex or facial basal cell carcinoma, squamous cell carcinoma, keratoacanthoma, Kaposi's sarcoma, appendageal tumours, sarcomas (e.g. dermatofibrosarcoma protuberans), Merkel cell carcinoma, cutaneous lymphoma) Melanoma

The majority of these will be benign, but skin cancer is common and should always be considered in the differential of any new or changing lump, particularly in an adult and presenting on sun-exposed skin. Melanoma in particular is an aggressive skin cancer but, in its early stages, when it is curable, the signs indicating malignancy, such as irregular outline, irregular pigmentation, or growth, can be subtle. It is important to take a careful history and not to dismiss concerns about changing moles, as early detection is essential to improved survival outcomes.

Occasionally, patients are troubled by the cosmetic appearance of a lump, or by itching or bleeding from trauma, and may request removal of the lesion.

Approach to diagnosis

History

A detailed history of the lesion should be taken, including:

- when the lesion was first noticed, how long it has been there, and whether or not it is changing with time
- the site of the lesion—whether it is on sun-exposed or non-exposed sites, and whether it is single or multiple (multiple lesions are less likely to be malignant)
- the nature of the lesion if it is changing (e.g. changing in colour, contour, or elevation)
- any associated symptoms, such as itch or ulceration; be wary of patients attributing skin lesions to an injury which is slow to heal—this is a cardinal sign of skin malignancy
- previous treatment, if any
- risk factors (e.g. previous history of precancerous or cancerous lesions; see Chapter 259, Table 259.2)
- recreational or occupational exposure to UV
- family history of skin cancer
- immunosuppression

Examination

Inspection

The following features should be assessed and documented:

- site (where on the body—sun exposed or non-exposed skin—and where in the skin—e.g. is it epidermal, dermal, subcutaneous, or vascular?)
- size (a visual estimate)
- border (regular, irregular)
- colour (pigmented or non-pigmented; erythematous; flesh-coloured)

Palpation

Assess for:

- tenderness
- consistency (e.g. is it soft, firm, hard, translucent, pulsatile, or compressible?)
- relationship to other structures (e.g. origin and attachment)

Examination of other sites

Examine other sites as necessary. Examine regional lymph nodes, if skin cancer is suspected. In addition, examine the rest of the body for similar lesions.

Specific clues to the diagnosis

See Box 72.1 for specific clues to the diagnosis of lumps and bumps.

Box 72.1 Specific clues to the diagnosis of lumps and bumps**Non-pigmented lesions****Cyst (e.g. epidermoid, pilar, and acne type)**

- well-circumscribed, deep nodule within dermis on trunk/scalp
- fluctuant, mobile, cystic lesion
- central punctum may be visible (epidermoid cysts)
- similar cysts may occur in individuals with acne after damage to hair follicles

Actinic keratosis

- scaly, red lesion on chronically sun-exposed sites (e.g. face, hands)
- often multiple

Non-melanoma skin cancer

1. Basal cell carcinoma
 - slowly growing erythematous patch (superficial subtype), papule, or nodule (nodular or morphoeic subtypes) on sun-exposed areas
 - can ulcerate
 - may also be pigmented (see 'Pigmented lesions')
2. Squamous cell cancer
 - hyperkeratotic and/or ulcerated lesion on chronically exposed skin
 - often tender and with relatively rapid growth

Lipoma

- soft, mobile, subcutaneous nodule
- usually long-standing and asymptomatic

Dermatofibroma

- firm, hard papule situated in the dermis
- 'like a button'
- commonly on legs
- usually history of insect bite/minor trauma
- may also be pigmented (see 'Pigmented lesions')

Neurofibroma

- skin-coloured, pink, or red papule or nodule appearing anywhere on the skin after puberty
- if multiple, check for clinical signs of neurofibromatosis (e.g. axillary freckling; see Chapter 224)

Infective lesions

1. Viral wart
 - human papillomavirus infection of the epidermis
 - a small, papilliferous nodule, often multiple, on fingers or toes
 - a filiform lesion has finger-like projections and is commonly seen on the face
 - a plane wart is flat-topped and may koebnerize
 - may also be pigmented (see 'Pigmented lesions')
2. Molluscum contagiosum
 - pox virus infection of the skin
 - usually affects children
 - small, 1–5 mm white or pink umbilicated papule
 - may koebnerize
 - in adults, suggestive of immunosuppression

Pigmented lesions**Seborrhoeic keratosis**

- warty-looking lesion with 'stuck-on' appearance
- may have grey/yellow, greasy appearance which may be mistaken for pigment
- solitary or multiple, on face and trunk
- common in late adulthood

Dermatosis papulosa nigra

- found in Asian/black skin
- histologically identical to a seborrhoeic wart
- may present on cheeks
- inherited as an autosomal dominant trait

Melanocytic naevus and atypical naevus

- a mole can be pigmented or skin-coloured
- a mole with variable colour/abnormal features is atypical
- multiple atypical naevi comprise a risk factor for melanoma

Basal cell carcinoma (nodular subtype)

- occasionally, a basal cell carcinoma is heavily pigmented and can be confused with a melanoma
- a typical rolled edge should suggest the diagnosis

Kaposi's sarcoma

- small, red-brown/purple macule or papule which grows to form nodules and plaques
- mainly observed in patients with HIV/AIDS and iatrogenically immunosuppressed individuals (see Chapter 296)

Melanoma

- a changing or new mole with irregular contours or pigment*
- may occur at any site
- a low index for referral should be maintained

Dermatofibroma

- pink-brown nodule, often with darker circumference
- can be mistaken for compound naevus but firmer on palpation, and squeezing lesion from the side results in puckering of the surface
- may also be unpigmented (see 'Non-pigmented lesions')

Vascular lesion

1. Pyogenic granuloma
 - rapidly growing
 - often at site of injury, particularly digits, lips
 - bleeds profusely if traumatized
2. Campbell de Morgan spots (cherry angiomas)
 - multiple small bright red/purple papules on trunk and proximal limbs in >35-year-olds

Viral wart

- common warts are firm, rough, skin-coloured, or brown papules with black pinpoint dots on the surface
- plane warts may often be pigmented
- may also be unpigmented (see 'Non-pigmented lesions')

*ABCDE criteria (**A**symmetry, **B**order irregularity, **C**olour variation, **D**iameter > 6 mm, **E**levation) are used to identify early melanomas.

Key diagnostic tests

For the majority of common skin lumps and bumps, a diagnosis can be made after a careful history and examination, and no further investigations are required. Where malignancy is suspected, or the diagnosis is not certain, then referral to a dermatologist in secondary care is recommended. Dermoscopy (epiluminescence microscopy) is used as an adjunct by trained specialists, especially when assessing pigmented lesions.

In cases of diagnostic uncertainty or suspected skin malignancy, histological examination is mandatory. Sometimes a diagnostic biopsy is indicated, with a view to obtaining histological diagnosis before making definitive management decisions. In other cases, such as small tumours or suspected melanoma, a primary excision is recommended, with narrow excision margins taken in the first instance. Shave biopsies should be avoided in these circumstances, as it may not be possible to assess excision margins or stage the lesion. In addition, an incorrect diagnosis can occur due to sampling error. Incisional or punch biopsy (a core of skin tissue up to 6 mm in diameter) is occasionally acceptable, for example, in the differential diagnosis of lentigo maligna of the face, of acral melanoma, or of a very large tumour where primary excision and closure would not be possible. Table 72.2 details the different biopsy techniques and their applications.

Other diagnostic tests

Clinical photography of individual lesions can be helpful for monitoring lesions where there is uncertainty regarding change. Total body mole mapping is used for individuals with a large number of moles, as they may have an increased risk of malignant change. The images created can then be used as part of an individual's skin cancer surveillance programme. As the incidence of melanoma is increasing

Table 72.2 Different biopsy techniques and their applications

Biopsy technique	Use
Incisional biopsy (small part of lesion removed)	To establish a diagnosis before definitive treatment is instigated
Punch biopsy (up to 6 mm core diameter of skin lesion is removed)	To remove very small lesions
Curettage	To removing superficial (epidermal) lesions such as seborrhoeic keratoses, viral warts, and actinic keratoses
Excision	To remove a lesion in its entirety (usually a malignancy); allows the pathologist to examine the periphery and adequacy of removal

and individuals are becoming more aware of the need to detect skin cancer early, mole mapping is an expanding field. Mole mapping can be undertaken using conventional photographic mapping or digital dermoscopic imaging. In the former, a series of standardized photographic images (taken by qualified medical photographers) of body regions are taken to generate a complete map of the skin. Images are printed on photographic paper, or stored on a computer/CD-ROM. Dermoscopic images allow recording of a more detailed image of the mole. Digital devices standardize images for magnification and illumination and can accurately record moles. Most digital dermoscopic systems have integrated computer software which can provide a risk analysis of how suspicious a mole is. Independent published research has repeatedly shown limitations in the diagnostic ability of these systems, and the interpretation of any changes seen is best performed by a trained specialist.

For infective lesions, swabs can be taken to identify any causative bacteria by Gram stain and culture. Viruses can be identified by electron microscopy, culture, or PCR. Occasionally, blood testing is indicated; for example, multiple infected boils may raise the possibility of diabetes, whereas resistant viral warts/mollusca in adults may alert the clinician to immunosuppression. Radiological imaging (e.g. ultrasound scans) may be used to assist the diagnosis of subcutaneous lumps, especially if diagnostic fine-needle aspiration is planned. CT and MRI may be used in selected cases to delineate structures prior to surgery.

Introduction to therapy

Treatment of lumps and bumps depends on their cause. In many cases, skin lesions are benign or self-limiting (e.g. molluscum), and no treatment is required. Request for removal by the patient may be made because of the cosmetic appearance (intradermal naevi, skin tags, Campbell de Morgan spots, seborrhoeic warts, etc.). Histological examination of any lesion removed is mandatory.

Benign lesions

Seborrhoeic keratoses

Seborrhoeic keratoses do not require any treatment. If they are repeatedly traumatized, treatment options include cryotherapy, curettage and cautery, and excision.

Epidermoid cysts

Epidermoid cysts, which are well-defined, keratin-containing cysts, are subject to recurrent infection and can rupture, resulting in subsequent fibrosis and scarring. Cysts may be surgically excised in their entirety, with the sac lining intact to prevent future recurrence. Active infection should be treated prior to surgical intervention.

Actinic keratoses

Spontaneous regression is reported in 15%–25% of cases of actinic keratosis over a 1-year period. Common treatment modalities for individual lesions include cryotherapy, curettage, and cautery. Surgical intervention includes excision or shave excision/curettage.

It has the benefit of providing histological diagnosis and is useful in the management of larger, tender indurated lesions when distinction from a non-melanoma skin cancer is required. For multiple lesions, fluorouracil cream, 5% imiquimod cream and ingenol mebutate are useful, but result in transient inflammation. Diclofenac 3% gel (Solaraze®) is also useful in milder cases or when fluorouracil/imiquimod is not tolerated. When there are multiple actinic keratoses or they are confluent at sites of poor healing or exhibit poor response to standard therapies, photodynamic therapy (combination of dedicated light source and photosensitizing cream with active agent 5-aminolaevulinic acid) may be helpful.

Infective lesions

Viral warts

Treatment of warts depends on the age of the patient and the number of lesions present. In young children, the best treatment is conservative management, as lesions generally resolve spontaneously. In older children and adults, topical keratolytics, 5% imiquimod cream, cryotherapy, and curettage and cautery are some of the treatment options available.

Molluscum contagiosum

Trauma to individual lesions can result in resolution. In children these eventually resolve spontaneously over 6–24 months.

Vascular lesions

Pyogenic granuloma

These vascular lesions grow very rapidly and can arise at the site of trauma. Distinction from amelanotic melanoma is important and therefore, where possible, surgical excision is the best management. Other options include deep shave excision with cautery to the base.

Suspected skin cancers

For skin cancers, the treatment of choice is usually surgical, so that excision margins can be assessed and documented. In the majority of cases, this procedure will be curative. In the UK, basal cell carcinomas with low-risk features (depending on anatomical site, size, and histological subtype) can be excised in primary care by trained surgeons who are members of the local skin cancer multidisciplinary team (LSMDT). Basal cell carcinomas with high-risk features should be referred into secondary care for further management, usually surgery. In selected cases, radiotherapy may be used, either as primary or adjunct therapy. All suspected squamous cell carcinomas should be referred into secondary care for surgery.

All suspected melanomas should be referred into secondary care (LSMDT) for further management. After primary excision, a further wide local excision is undertaken which reduces the risk of local recurrence, although it does not alter eventual outcome. Management of skin cancers is detailed further in Chapter 259.

Prognosis

Benign lesions

Most benign skin lesions cause no health hazard but may cause significant morbidity in terms of anxiety or cosmesis. Diagnosis of some skin lesions can alert the clinician to systemic or inherited disease (e.g. boils and diabetes; multiple epidermoid cysts before puberty, and polyposis coli (Gardner's syndrome) or Gorlin syndrome; adult mollusca/viral warts, and immunosuppression/HIV infection; adenoma sebaceous and tuberous sclerosis; and neurofibromas and neurofibromatosis).

Malignant and premalignant lesions

Actinic keratoses

Actinic keratoses are low-risk lesions, 25% of which will remit spontaneously without treatment. They have potential to progress to squamous cell cancers (estimated risk <1% per annum, latent period 10 years). Actinic keratoses are a biological marker of UV damage and, in the UK, an estimated 25% of Caucasians over 65 years old

will develop at least one actinic keratosis. The presence of multiple actinic keratoses is a risk factor for both non-melanoma and melanoma skin cancer (Madan et al., 2010).

Skin cancers

The prognosis of skin cancers is discussed in Chapter 259.

How to handle uncertainty in the diagnosis of this symptom

When there is diagnostic uncertainty, referral to a specialist dermatologist, trained in the diagnosis and management of skin lesions, is

recommended. Lesions suspected to be squamous cell carcinoma or melanoma should be referred urgently and, in the UK, this is governed by the 2-week wait rule for assessment by local screening services, which are usually run by dermatologists.

73 Falls

Adam Darowski

Definition of the symptom

A fall is an involuntary event that results in coming to rest at a lower level. Most falls occur while standing or walking. Some people fall off a chair or out of bed, particularly in hospitals and care homes, when transferring is a time of particular risk.

A side-by-side comparison outlining the differential diagnosis in primary care and secondary care, ordered by probability, is given in Table 73.1.

Context

Adults fall at a rate of about 35% each year. This rate increases in later life, so that about 50% of people aged 80 years fall each year. It is not just the number of falls that changes with increasing age, but the unexpected circumstances in which they occur and their more severe consequences. With ageing, the body become more frail, fragile, osteoporotic, and weaker. The damage may be physical, but also psychological, with fear of falling (and family anxiety) limiting activities and causing increased dependency.

Fall-related injuries (particularly head injuries and hip fractures) consume a large fraction of the health budget. They are more common, and result in more occupied hospital bed days than do any of stroke, heart disease, or cancer. They are the most common cause of moving into a care home: 25% of all social care in the UK is due to the consequences of hip fracture. The 58 244 hip fractures that occurred in England in 2005–6 would have cost £1.4 billion pounds in health and social care in their first year, and resulted in about 17 000 deaths. The cost of fall-related injuries in the US in 2000 was estimated to be \$19 billion.

Falls can be classified into four main groups:

- accidents—slips and trips—as occur at any age; if such accidents recur, an underlying cause should be sought

- illness: falling can be the presentation of almost any illness in the elderly; commonly, infections present with falls
- an intrinsic tendency to fall because of impairments of gait, balance, or vision; this may be because of neurological or musculoskeletal degeneration, or due to disability caused by illness (most commonly stroke, Parkinson's disease) or the effects of medicines or alcohol
- paroxysmal events:
 - syncope and presyncope
 - seizures
 - vascular events (stroke, myocardial infarction, pulmonary embolus)
 - vertigo
 - rarities (e.g. cataplexy)

In general, falls are multifactorial. Most falls are simple accidents, as occur throughout life. When falls occur in people who are physically sprightly, an accident or some paroxysmal event is the probable cause.

Most recurrent falls occur in people with some degree of impaired balance, poor gait, and poor vision. It is thought probable that an age-related degeneration of proprioceptive function is the main cause of the unsteadiness seen in later life. This combines with muscular weakness due to lack of exercise, to the muscle loss of ageing, and to weight loss from any cause. In addition, pathological changes in the white matter in the brain cause disruption of cerebral pathways, slowing reaction times. The patient may have other neurological diseases—stroke and Parkinson's disease are common causes of falling, together with a wide variety of other neurological problems. Movements are made around joints that may be arthritic and painful, which may give way; prosthetic joints do not provide proprioceptive inputs to the brain. The whole system becomes deprived of adequate sensory input, weaker, slower, and less accurate. What might have been a stumble or a moment of imbalance becomes a fall.

One reason that falls are important is that they lead to fractures. Patients who fall require an osteoporosis assessment.

The nonsense term 'mechanical fall' provides closure through pseudodiagnosis and should be avoided.

Table 73.1 A side-by-side comparison outlining the differential diagnosis in primary care and secondary care, ordered by probability

Falls occurring in the community	Falls in hospital or care homes
Most falls have multiple causes, with an event occurring in a susceptible individual.	
Accidents	Illness
Poor gait and balance: <ul style="list-style-type: none"> • sedative or hypotensive medications • neurological disability • weight loss and weakness 	Syncope and presyncope
Syncope and presyncope: <ul style="list-style-type: none"> • hypotension and orthostatic hypotension, carotid sinus hypersensitivity, vasovagal syndrome, medication effects • bradycardias or tachycardias 	Impaired balance
Seizures	
Other paroxysmal events	
Illness	Accidents
	About 40% are confused due to delirium or dementia
	About 40% occur trying to get to the toilet

Approach to diagnosis

The diagnosis is usually with a thorough history and a practised ear. A falls history can be very time consuming, and may involve extensive detective work to establish all the facts. The history is in three parts: the narrative, direct questioning, and corroboration.

The narrative

The narrative is the patient's account, elicited by an open question: what happened to you? It is likely to give you the patient's interpretation of events, and should not be the end of your enquiries.

Direct questioning

Direct questioning aims to establish several things:

- The scale of the problem: how long have unexpected falls been happening, and how many falls have here been? Are falls becoming more frequent? Has something happened to provoke them (new medication, illness, injury)?
- Is the story that of syncope, which is common, or of presyncope, which is extremely common? People seen to be unconscious deny it in about 30% of cases, so the history cannot always exclude syncope reliably. Was syncope followed by a secondary seizure?

- Are the falls stereotyped? What did the patient experience? Were there any symptoms beforehand or afterwards? Does the patient experience postural giddiness or vertigo?
- What was the patient doing just before the fall and at the time of the fall? Where were they? Were they sitting or standing? If standing, had they just stood up? Had they just got out of bed? Were they turning at the time? Was it unequivocally an accident?
- What were the consequences of the fall? Was there a fracture, head injury, or soft tissue damage? Has this resulted in loss of confidence in walking?
- A drug history and the indications for all the drugs: anything that acts on the CNS roughly doubles the chances of a fall. Any drug that affects the pulse or blood pressure may cause syncope or presyncope. Many people are taking antidepressants, antianginals, and antihypertensives that they no longer need, or in doses that are too big.

Corroboration

Corroboration from a witness to a fall, from a family member, or from GP or hospital records usually shows that the problem of falling is of longer duration and more frequent than the patient has volunteered. A witness may be able to confirm whether the patient lost consciousness, and for how long. Unconsciousness in syncope is brief—less than a minute—unless it is followed by a secondary seizure, which is common. More prolonged unconsciousness (as distinct from amnesia), or coming round confused or disorientated are suggestive of a seizure. Commonly, the patient remembers coming round in the ambulance or in hospital, but witnesses describe only a short period of unconsciousness.

Falls in hospital

Falls in hospitals are commonly due to delirium and agitation. They occur most frequently in the setting of someone trying to find a toilet in an unfamiliar environment, weakened by an illness. The use of hypotensive and sedating medications contributes to the falls risk. Orthostatic hypotension is common in patients who are dehydrated on multiple medications. Patients in hospital need an appropriate walking aid and proper footwear as soon as they are admitted and can try to walk. They need their glasses and hearing aids. They may need bed rails to keep them safe when unsupervised. Some falls risk has to be accepted during the process of rehabilitation.

Specific clues to the diagnosis

Specific clues to the diagnosis are as follows:

- In patients who are sprightly, the chances of syncope are greater. In frailer patients who have an obvious gait and balance problem, it cannot be assumed to be the cause of their fall, and syncope and presyncope need to be considered.
- Syncope in the elderly is most commonly due to a drop in blood pressure. The resting blood pressure may be low but, more commonly, the patient will have one of three syndromes of paroxysmal hypotension: orthostatic hypotension, vasovagal syndrome, or vasodepressor carotid sinus hypersensitivity. These are all very common. These conditions are usually due to the side effects of drugs, to autonomic dysfunction, or to both.
- Syncope may also be due to a rhythm disorder, such as heart block, cardioinhibitory carotid sinus hypersensitivity, fast atrial fibrillation, or any other bradycardia or tachycardia.
- Presyncope is caused by a brief reduction in cerebral blood flow and is due to the same causes that can cause a feeling of faintness or weakness, and loss of postural tone without loss of consciousness.
- Confusion on coming round or prolonged unconsciousness suggests a seizure.
- Any illness in an older person can cause falls. Most commonly, this is an infection.
- A history of neurological disease, and examination findings to confirm it, commonly reveal Parkinson's disease, a stroke that has gone undiagnosed, or a peripheral neuropathy. A large number of other neurological conditions present as falls.

- Any disease causing slow weight loss will result in falls due to muscular weakness. The first presentation of malignancy is commonly with falls.

Postural giddiness is a difficult symptom to interpret. Standing up causes a sudden reduction in sensory inputs to the brain—with proprioceptive input only from the feet telling the patient where the ground is, as well as sudden changes in visual fixation, and momentary changes in vestibular function. These combine to produce giddiness. Orthostatic hypotension also causes giddiness, but more commonly is asymptomatic. Less than half of postural giddiness is due to orthostatic hypotension.

Almost everyone who has giddiness will have it on standing. The key question with giddiness is whether it occurs when the patient is lying down (benign positional vertigo, cerebral white matter disease) or sitting (rhythm disturbance, vestibular disease).

Key diagnostic tests

Key diagnostic tests are as follows:

- Cardiovascular, musculoskeletal, and neurological examinations should be performed. Is the patient in sinus rhythm? Always check the lying and standing blood pressure, looking for a systolic drop of >20 mm Hg from lying to standing, using a manual sphygmomanometer. Are there signs of aortic stenosis?
- An assessment of mobility should be performed. This can be done on several levels of complexity.
- Most simply, an assessment of gait should be performed, looking at step length and regularity, and whether the patient looks stable. Perform a Romberg's test, with the patient having both feet together and then one foot in front of the other (tandem standing).
- Someone who can stand on their tip toes with their arms extended and their eyes closed for 5 seconds is unlikely to have any significant neurological abnormality causing falls.
- Tests should be done to look for infection (white-cell count, C-reactive protein, urine stick testing, chest X-ray), even if infection is not clinically apparent.

Other diagnostic tests

Patients with syncope should have an ECG, and Holter monitoring for at least a week. An echocardiogram is necessary if there are murmurs, to exclude aortic stenosis. Tilt-table testing adds less than might be expected (many false positives; elderly patients with syncope have multiple abnormalities on tilt testing of uncertain relevance). A good history often does away with the need for tilt testing.

A low level of vitamin B₁₂ (<250 ng/l) is an important, curable cause of orthostatic hypotension.

Further balance assessments include:

- timed get up and go: in this assessment, the patient gets up from a chair, walks 3 m, turns around, and then goes to sit down again; a normal time for this is less than 12 seconds
- the Berg balance score: this is a validated balance score (no gait component), with marks out of 56; it correlates well with risk of future falls

All patients who fall need an osteoporosis assessment. Use the FRAX score, a WHO-validated tool for the assessment of the risk of fracture over the next 10 years (<http://www.shef.ac.uk/FRAX/tool.jsp>).

Introduction to therapy

Treatment is aimed at the underlying cause:

- If syncope is the underlying cause, therapy may consist of a pacemaker, antiarrhythmic treatments, or may be withdrawal or dose reduction of culprit medication.
- Impaired gait and balance is treated with rehabilitation involving exercises that challenge balance and which need to continue for 6 months. The patient should be referred to the local falls service. Fear of falling is treated with group therapies through a day hospital.

- The provision of appropriate walking aids and exhortation to use them greatly improves safety, particularly in the hospital setting, where lack of such an aid is a major cause of falls.
- Drug hygiene involves an examination of all medication acting on the nervous and cardiovascular systems, and checking their indication and dosage. Commonly, patients are prescribed tablets they no longer need.
- Patients need an occupational therapy assessment, including a review of their home and their care arrangements.

Prognosis

When syncope is due to a rhythm disorder, it can usually be treated successfully. When it is due to hypotension, it may be possible to reduce the drug burden. Orthostatic hypotension responds poorly to treatment, but some patients improve with fluid expansion using fludrocortisone or slow sodium. A low B₁₂ level needs to be treated.

Falls due to balance disorders can be reduced in frequency by exercise programmes. Education aimed at heightening awareness of falls and improving safety improves confidence and function.

Falls assessments can reduce the number of falls by about a third and, in some patients, prevent them altogether.

How to handle uncertainty in the diagnosis of this symptom

Falls have multiple causes. It is rarely clear which of the many factors is the most important one in a given patient. What is treatable should be treated, and the patient should be referred on for further assessment by a falls service. It has to be accepted that a patient's life cannot always be made completely safe. The patient commonly has her own perception of her falls risk, and may not always agree to an assessment, let alone intervention.

74 Immobility ('Off legs')

Adam Darowski

Definition of the symptom

Immobility is a progressive or a sudden deterioration in the ability to walk. Table 74.1 gives a side-by-side comparison of the differential diagnoses in primary care and secondary care, ordered by probability.

Context

Immobility is one of the 'geriatric giants', and can be the presentation of any illness. Poor mobility during hospital stay is a marker of poor outcomes. Patients with poor mobility when in hospital have a much higher mortality and a prolonged length of stay, tend to have a decline in their functional status, and are more likely to require discharge to a care home. About 16% of people aged over 70 years in a medical take are immobile, with another 32% having impaired mobility. They require prompt treatment of their underlying medical conditions and help getting back on their feet as soon as possible to prevent the consequences of immobility.

Table 74.1 A side-by-side comparison of the differential diagnoses in primary care and secondary care, ordered by probability

Immobility presenting to hospital	Immobile at home
Immobility can be the presenting feature of virtually any illness in an elderly patient.	
Important to exclude diagnoses requiring urgent treatment:	
Cord compression: urgent MRI if there is any doubt	
Fracture: hip and pelvic fractures can be missed easily	
Acute polyneuropathy (Guillain-Barré syndrome)	
Stroke requiring thrombolysis	
Intracranial haemorrhage	
Usually not a single cause: predisposing factors with an intercurrent illness	Rapid onset: fall related injury, infection, vascular event
Infection is the proximate cause in >50% Usually chest, urine, gut, or skin, but occult infection common (biliary, cardiac, brain, diverticular)	Slow deterioration; multiple factors Chronic disability due to old injury or illness Arthritis: osteoarthritis, most commonly of the hip and knee Rheumatoid disease, gout, other arthritides
Recent fall with or without bony injury	Muscular weakness: • disuse atrophy • weight loss • 'sarcopaenia of ageing' • neuropathy, root lesions
Intracerebral lesion: • subdural haematoma, stroke • primary or secondary cerebral tumours	Obesity
Joint pain: • exclude septic arthritis, gout, pseudogout by joint aspiration • trauma, flare up of osteoarthritis, other joint disease	Dementia, depression, anxiety, fear of falling
Metabolic: • commonly dehydration, renal failure, diabetes, hyponatraemia • rarely hypercalcaemia, Addison's	Chronic neurological disease: • previous stroke • parkinsonism • neuropathies • cervical myelopathy

Immobility presenting to hospital	Immobile at home
Sedating medications: • tricyclic antidepressants • antipsychotics • benzodiazepines Drugs affecting circulation, causing bradycardia, hypotension, or orthostatic hypotension: • antihypertensives • antianginals • tricyclics • serotonin-norepinephrine reuptake inhibitors • phenothiazines	Infections: • difficult to diagnose in the patient's home
Disability from neurological disease: • previous stroke • parkinsonism • any other (multiple sclerosis, motor neuron disease, cervical myelopathy, neuropathies)	
Gait apraxia, painful neuropathy	
Lack of mental ability/will to walk • dementia, delirium • depression, personality disorder, conversion disorder	
Back pain: • degenerative disc disease • osteoporotic collapse • malignancy: secondaries usually from breast, bronchus, prostate, kidney, gut, thyroid	
Cardiovascular disease: • severe orthostatic hypotension • profound bradycardia or hypotension	
Obesity, deconditioning, muscular weakness	

Approach to diagnosis

Ensure this is not a disorder of consciousness (delirium, postictal, or drugged). Are they ill? Are they hypothermic? Are they hypoglycaemic, severely hyponatraemic, or uraemic? Is this the consequence of trauma? Can they understand instructions?

Do they have a cardiovascular problem—reasonably well while lying down, but unsteady on getting up? This is an uncommon cause for immobility (and the diagnosis is usually obvious) except for people who have such severe orthostatic hypotension that they cannot stand (or sometimes even sit) without severe symptoms.

The patient is usually old, frail, deaf, dysphasic, dysarthric, and often delirious or demented. It may not be possible to obtain a history from the patient. Such people are known to others; contact family, GP, district nurse, carers, and neighbours to get an assessment of the patient's normal function and recent history. A good history of how the patient came to be immobile and of the patient's usual level of function provides the framework for everything else in this case.

Satisfy yourself that the patient does not have cord compression (leg weakness, sensory loss, bowel, bladder, reflexes, sensory level—MRI spine), intracranial haemorrhage (are they hypertensive, do they take aspirin or warfarin, was there a head injury) or a fracture of the

hip or pelvis (history may not be available; X-rays may be normal initially; they may need MRI). These conditions are uncommon causes of immobility, but may require urgent treatment.

Infection is the most probable diagnosis, and no test excludes it. Fever (often missed—sublingual and tympanic measurements are insensitive tests for fever, measured using inadequate instruments—ignore a 'normal' temperature), raised white blood cell count (normal in 50% of febrile older people) and a raised C-reactive protein (not specific for infection; raised with any inflammation or tissue damage) are all markers of underlying infection. Ensure the urine has been tested, examine the chest, and obtain a chest X-ray. Remove any bandages on the legs to check for cellulitis.

Is the history of a sudden deterioration (consider stroke), or chronic? What is the normal level of function (Does the patient do their own shopping? Do they walk out of the house? Are they house-bound? Do they use the stairs? Are they mostly chairfast? Do they use a walking stick or a walking frame?) to assess how great is the change. What support do they have at home?

Are there symptoms of other diseases (cough, sputum, dysuria, frequency, chest pains, dyspnoea, diarrhoea)? Is there a history of neurological disease, or could this be a first presentation (Parkinson's, stroke, neuropathy, any other)?

Assess hydration status. If in doubt, consider supplementary IV fluids, if safe to do so.

Specific clues to the diagnosis

Do not expect there to be a single unifying diagnosis. There will be predisposing factors and possibly a proximate cause.

If the patient can cooperate, can they move their legs freely? If practical, try to get the patient to stand. This will exclude many musculoskeletal and neurological diagnoses, or make them more obvious.

Check for metabolic and cardiovascular causes, and for markers of infection. In an older person, pneumonia sufficient to cause immobility may produce no respiratory symptoms or signs (consolidation may not be visible behind the heart on a chest X-ray).

If leg movement is impaired, then a full neurological examination followed by appropriate imaging is required. Stroke is usually associated with neurological signs, but may present as immobility without obvious signs. Subdural haematoma commonly presents without any neurological signs. Have a low threshold for requesting a CT of the brain. Look for signs of Parkinson's disease.

Key diagnostic tests

Key diagnostic tests are as follows:

- pelvic X-rays and spinal MRI, if indicated, to exclude surgical causes
- CT of the brain, to look for intracranial lesions
- chest X-ray, to look for chest infection (and other pathologies)
- urea, electrolytes, glucose, and calcium; dehydration may be a cause of immobility or a consequence of poor access to fluids while immobile; if the patient is dehydrated, are renally excreted drugs (atenolol, angiotensin-converting enzyme (ACE) inhibitors) making things worse?
- stick testing of urine (if normal does not exclude infection), mid-stream specimen of urine, blood cultures
- blood count and C-reactive protein may point to an inflammatory cause; however, normal results do not exclude infection, and raised ones do not confirm it

- liver function tests; a raised bilirubin and alkaline phosphatase point to biliary disease
- prostate specific antigen in men, to exclude a significant prostatic carcinoma (weight loss, spinal metastases)

Other diagnostic tests

The use of other diagnostic tests is determined by the clinical findings and the results of initial tests. Other diagnostic tests are:

- X-rays of injured or painful areas, lateral of spine if vertebral collapse is suspected
- nerve conduction studies for neuropathies
- urine and plasma osmolality; urinary sodium; Synacthen test for hyponatraemia
- tests for weight loss: gastroscopy, CT colon

Introduction to therapy

Therapy is aimed at the underlying diagnoses, and at the immobility. Immobile patients require assessments by physiotherapists and occupational therapists as soon as possible. They will probably require additional support at home on discharge, which takes time to arrange and requires forward planning to prevent delays in hospital. Many patients wish to go home, but domiciliary rehabilitation, while desirable, is not readily available, and even then is rarely of adequate intensity.

Prognosis

The outcome depends upon the underlying diagnosis and the previous functional level. Where immobility is due to an infection (that has been treated successfully), walking improves over a week or two. Patients with fall-related trauma require several weeks to regain whatever function will recover.

For every day the patient is left immobile, they will require several days to recover their lost function. Vigorous rehabilitation prevents them becoming weaker, shortens length of hospital stay, and increases their chances of getting back to their own home.

How to handle uncertainty in the diagnosis of this symptom

It is important to establish there is no condition requiring urgent treatment. What is left is a mixture of metabolic, infective, neurological, musculoskeletal, and chronic diseases, and drug-side effects. Always bear in mind occult infection, and have a low threshold for giving antibiotics on empirical grounds. It is very easy to miss a significant infection in an older person.

Stop as many tablets as you can safely, and reconsider their need.

75 Suspected anaphylaxis

Siraj Misbah

Definition of the symptom

A type I IgE-mediated systemic allergic reaction is characterized by a constellation of symptoms which are due to widespread histamine release and which comprise acute-onset urticaria, angioedema, bronchospasm, and hypotension. While a mild reaction may be limited to localized urticaria and/or angioedema, a full-blown allergic reaction associated with systemic features is best described as anaphylaxis. The term 'anaphylactoid', previously used to denote non-IgE-mediated systemic allergic reactions, is no longer recommended for use.

Differential diagnosis

Other disorders which share some of the clinical features of anaphylaxis may occasionally cause diagnostic confusion. In most cases, a good history will help distinguish anaphylaxis from syncope, disorders associated with flushing (carcinoid), disorders associated with excessive endogenous histamine release (systemic mastocytosis), panic attacks, and angioedema due to C1-inhibitor deficiency or drug allergy.

Although no precise figures are available, the majority of allergic reactions are managed in primary care.

The differential diagnosis in primary and secondary care is given in Table 75.1.

Context

There has been a dramatic increase in the overall burden of allergic disease, including anaphylaxis, over the past two decades. The underlying explanation for this phenomenon, as enunciated in the hygiene hypothesis, has been attributed to the skewing of immune responses to the Th2 group of 'allergy-prone' lymphocytes due to poor infection-driven priming of Th1 lymphocytes. Although the hygiene hypothesis is unlikely to be the sole explanation for the upsurge in allergic disease, epidemiological trends over the past several decades clearly document an inverse relationship between the incidence of infectious diseases and the incidence of Th2-driven autoimmune disease.

The increasing incidence of anaphylaxis has prompted the introduction of evidence-based management guidelines by the UK Resuscitation Council and the Royal College of Physicians.

Approach to diagnosis

Anaphylaxis is a clinical diagnosis based primarily on the history and the recognition that one or more of the clinical features mentioned

in 'Definition of the symptom' has developed acutely (evolving over minutes to a few hours) following exposure to a potential triggering agent.

Specific clues to the diagnosis

Although there are no symptoms or signs that are specific for anaphylaxis, the occurrence of acute-onset bronchospasm and/or hypotension accompanied by cutaneous signs of histamine release in the form of angioedema and urticaria is highly suggestive of a systemic allergic reaction. Many patients who have experienced anaphylaxis describe a sense of impending doom as part of the clinical picture.

A clearly identifiable trigger (foods, drugs, insect venom stings) preceding the reaction by minutes provides a strong pointer to the diagnosis but this would not be apparent in the case of idiopathic anaphylaxis. The diagnosis of idiopathic anaphylaxis should only be made after careful consideration of known causes of anaphylaxis.

Key diagnostic tests

Mast cell activation and degranulation is a key event responsible for the clinical features of anaphylaxis. Of the many biomarkers of mast cell and basophil activation, the demonstration of elevated plasma or serum tryptase levels up to 3–4 hours after the event constitutes strong supportive evidence of anaphylaxis. Elevated tryptase levels are particularly associated with anaphylaxis associated with drugs or injection of insect venom. It is uncommon to find elevated tryptase levels in the case of food-induced anaphylaxis or in the absence of hypotension. Consequently, a normal tryptase level does not exclude a diagnosis of anaphylaxis.

Tryptase can also be measured in post-mortem blood samples and, if significantly elevated, points to anaphylaxis as being a possible cause of sudden, unexplained death. Although large amounts of histamine are also released during anaphylaxis, its short half-life of 10–15 minutes makes plasma histamine assays impractical in a routine laboratory. While elevated tryptase and histamine levels are strong clues suggestive of anaphylaxis, they are unable to pinpoint the cause of the reaction.

Other diagnostic tests

Based on the clues elicited in the history, potential triggers (drugs, foods, insect venom) should be selected for measurement of allergen-specific IgE and the performance of skin tests. The optimal time for performance of these tests is approximately 3–4 weeks after the episode, to avoid the possibility of false-negative results.

Introduction to therapy

The immediate injection of adrenaline (0.5 ml of a 1:1000 solution) is the single most important intervention in the treatment of anaphylaxis. In the vast majority of cases, the intramuscular route of administration should be used. Because of the risk of potentially lethal arrhythmias, intravenous adrenaline is reserved for the treatment of intractable anaphylaxis in an intensive-care setting. Attention to the airway, and the use of oxygen, fluid replacement, parenteral antihistamines, steroids, and bronchodilators are important additional measures that may be required in individual patients.

Lack of efficacy of adrenaline is usually due to either a delay in injection or use of suboptimal doses on a milligram per kilogram basis. Anaphylaxis in patients on long-term beta-blocker therapy may prove to be refractory to adrenaline due to its inability to interact with the

beta 1 and beta 2 adrenergic agonist receptors, which mediate (along with alpha 1 adrenergic vasoconstrictor effects) the beneficial effects of adrenaline. In such cases, glucagon should be considered in view of its cardiac inotropic effects.

Once patients are successfully rescued from anaphylaxis, it is essential that all patients undergo careful assessment by an allergist or immunologist to determine the trigger by testing for allergen-specific IgE antibodies and/or skin testing. Where a clear trigger is identified, long-term risk reduction is based on avoidance of the trigger.

For insect-venom-induced anaphylaxis, long-lasting protection can be achieved by desensitization immunotherapy, which involves the subcutaneous injection of the relevant purified venom over a period of 3–5 years. In cases where the trigger is unknown or where its avoidance is difficult, such as in severe nut allergy, patients should be provided with self-injectable adrenaline and trained in its use.

The recognition and management of anaphylaxis is summarized in Table 75.2

Prognosis

Where the trigger for anaphylaxis has been conclusively identified and appropriate avoidance measures instituted, recurrence of anaphylaxis is unusual. For patients with insect-venom allergy, desensitization offers a success rate of approximately 90% in reducing the risk of anaphylaxis with future stings. In contrast, the long-term prognosis for patients with idiopathic anaphylaxis is uncertain because the

underlying trigger(s) are unknown and, consequently, it is difficult to devise avoidance measures. In such patients, the possibility of underlying mastocytosis must be considered and investigated appropriately, using serum tryptase and bone marrow biopsy.

How to handle uncertainty in the diagnosis of anaphylaxis

Uncertainty in the diagnosis of anaphylaxis may occur in the absence of a clear history or where a patient has anaphylaxis-like symptoms due to another disorder (see Table 75.1). If a rise in serum tryptase has been documented, this would provide useful supportive evidence of mast cell degranulation suggestive of anaphylaxis.

Where uncertainty does exist, it is important to acknowledge it and undertake a thorough review of the history.

76 Fever

Emma Wall and Graham Cooke

Definition of the symptom

Fever is a rise in core body temperature, which is measured at the tympanic membrane, of greater than 37.8°C and which is one standard deviation beyond the upper limit of the normal range.

Common causes of fever

Common causes of fever are shown in Table 76.1.

Context

Febrile illness comprises approximately 1%–2% of Emergency Department presentations to UK hospitals. Fever has many causes, of which bacterial and viral infections are the most common (Table 76.1). Rare but important causes of fever include systemic fungal infections, tuberculosis, malaria, HIV (both seroconversion and chronic infection), autoimmune diseases (such as SLE and temporal arteritis), malignancies (such as lymphoma), parasitic infestations, and reactions to drug therapy or allergens.

Fever may be experienced for weeks to months without an identifiable cause. In one definition, fever of unknown origin (FUO), or pyrexia of unknown origin (PUO), is a recorded fever of greater than 38.0°C–38.5°C that has been present for more than 3 weeks or is still present after more than 1 week of investigation. Where a cause is identified, infection accounts for approximately one-third of causes of fever, with another third being due to collagen vascular diseases (commonly temporal arteritis), and the last third to malignancies (commonly lymphoma). A significant number of patients with PUO have no identifying diagnosis, but this group has an overall good prognosis.

Approach to diagnosis

The most important aspect of the approach to a patient with fever is to take a full and detailed history. This should include all current and preceding symptoms, but also a detailed travel, occupational, and sexual history, contacts with any known infection or febrile symptoms in close contacts, any illicit or non-prescribed drug use,

and unusual localizing symptoms. The importance of this cannot be overstressed, particularly for diseases associated with a specific risk factor. For example, the majority of deaths from malaria in the UK are due to delay or failure to suspect the diagnosis, which requires an adequate travel history and high index of suspicion.

A thorough and systematic physical examination of all the major organ systems is also essential; for example, subtle rashes, insect bites, masses, murmurs, respiratory crackles, and other physical signs may not have been noticed by the patient, and will lead towards a diagnosis in the majority of cases.

Specific clues to the diagnosis

Most clues towards the diagnosis of fever are obtained from the history. The following are particular diagnostic clues:

Travel: An enormous spectrum of diseases causing fever can be acquired through travel; the most important to recognize promptly is malaria. When necessary, advice from a tropical specialist should always be sought when investigating a febrile returning traveller.

Drug use: The use of all illicit drugs is associated with risks specific to the substance of abuse. Intravenous drug users particularly are at risk of deep-tissue, blood-borne infections which commonly present as a febrile illness.

Pattern of fever: Degree of fever can be divided into high grade (measured core body temperature >38.5°C) and low grade (measured core body temperature 37.6°C–38.5°C). Fever can also present as a relapsing or periodic symptom. Traditionally, there has been great emphasis on patterns of fever; however, while fever patterns can be helpful in suggesting a diagnosis, high-quality evidence in support of their use in diagnosis is lacking. Table 76.2 gives classical examples of diseases that have an associated fever pattern. However, this table is not comprehensive, and no pattern is sensitive or specific.

Weight loss: This is a particularly sinister symptom to accompany a complaint of fever. Malignancies, HIV infection, and tuberculosis are common in this scenario, along with amoebic liver abscesses and endocarditis, amongst others.

Key diagnostic tests

Where the source of fever is clinically apparent (e.g. pneumonia), then tests may be limited to screen for causes of that infection. FUO/PUO should only be used as a working diagnosis once initial common causes have been ruled out, and basic investigations as

Table 76.1 Common causes of fever in primary and secondary care

Primary care	Patients admitted to hospital	Hospital inpatients
Upper and lower respiratory tract infection, including otitis media and sinusitis	Lower respiratory tract infection including exacerbation of chronic obstructive pulmonary disease (COPD) and pneumonia	Hospital-acquired pneumonia Ventilator-associated pneumonia
Urinary tract infection	Urinary tract infection, including pyelonephritis	Catheter-associated urinary tract infection
Gastrointestinal infection	Severe gastrointestinal infection	Norovirus infection <i>Clostridium difficile</i> diarrhoea
Skin and soft tissue infection	Severe skin and soft tissue infection	Surgical-site infection
	Non-infectious causes of fever (e.g. inflammatory and neoplastic diseases)	Central-line-associated bloodstream infection Prosthetic-device-associated infection

Table 76.2 Classical patterns of fever and associated aetiology

Fever pattern	Associated aetiology
High grade	Bacterial sepsis, typhoid fever, <i>Plasmodium falciparum</i> malaria, systemic viral infections e.g. influenza, lymphoma
Low grade	Infective endocarditis, tuberculosis, bacterial abscesses/collections, malignancies other than lymphoma, HIV infection and associated opportunistic infections, collagen vascular diseases
Relapsing (every 1–3 days)	<i>Plasmodium vivax</i> malaria, rickettsial infections, autoimmune diseases, parasitic infections
Periodic	Inherited febrile tendencies (e.g. familial Mediterranean fever), juvenile rheumatoid arthritis, adult-onset Still's disease, Crohn's disease, and Behçet's syndrome

Box 76.1 Initial investigation of a patient with unexplained fever

- blood cultures:
 - two sets of 10 ml each where possible (three, if bacterial endocarditis is suspected)
- microbiological assessment of any body tissues where the source of the fever is suspected:
 - Gram and auramine staining
 - bacterial, tuberculosis, and fungal culture
 - 16S/18S ribosomal PCR
 - appropriate antibody screening, depending on the patient's history
- septic screen, for tissue culture and sensitivity:
 - throat swab
 - urine dip and culture
 - stool microscopy and culture
 - high vaginal swab
 - lumbar puncture
- a blood film examined for malarial parasites in any febrile patient with a history of travel to a relevant area, however brief or distant to the presenting complaint
- HIV serology plus p24 antigen testing
- basic imaging:
 - chest radiography
 - abdominal and pelvic ultrasonography
 - echocardiography
- inflammatory markers:
 - C-reactive protein
 - erythrocyte sedimentation rate
 - these tests are highly sensitive for the presence of inflammation, but have poor specificity
- autoimmune screen:
 - rheumatoid factor
 - antinuclear antibody
 - antineutrophil cytoplasmic antibody
 - complement
 - anti-streptolysin O test
 - lactate dehydrogenase
 - immunoglobulins
- serology following relevant exposure
 - e.g. *Borrelia burgdorferi* following a tick bite
 - consult with a specialist

detailed in Box 76.1 completed as deemed necessary by the thoughtful clinician. Fever in an immune-suppressed patient is a specialist area, and expert advice should be sought.

Other diagnostic tests

The tests outlined in 'Key diagnostic tests', when performed appropriately, will yield a diagnosis in the majority of patients. The following further investigations into the cause of a fever may be performed when indicated clinically or diagnostic uncertainty persists:

- contrast-enhanced CT or MRI scan of a relevant area (commonly brain/spinal cord/bone/joints/chest/abdomen/pelvis)
- bone-marrow aspirate and trephine
- liver biopsy
- lymph-node biopsy
- transoesophageal echocardiography
- radiolabelled white-cell scan
- radioisotope bone scan
- whole-body FDG-PET scan

Introduction to therapy

Empirical broad-spectrum antibiotic therapy should always be started when a patient presents with fever and signs of sepsis (see Chapter 152) or other serious infection, such as meningitis, where delay in initiating therapy may be harmful to the patient. The choice of drug should be made according to local guidelines or following advice from a medical microbiologist. When a source is found, this must be controlled with appropriate antibiotics or other treatment, such as surgical intervention, when necessary.

In a situation when the patient is not seriously unwell, and a clear, treatable cause is not immediately apparent, then empirical antibiotic therapy may be withheld pending the results of appropriate cultures, serology, or other tests, following close discussion with either a clinical infection specialist or a medical microbiologist. This is to allow time for a thoughtful diagnostic approach and directed therapy based on culture results.

Symptomatic fever may be relieved, if causing distress to the patient, with antipyretics during the diagnostic period, although there is no clear evidence to demonstrate noxious effects of fever per se, or of the clinical benefit of relieving symptoms on illness duration. Paracetamol may be used safely to reduce fever in most cases without significantly altering the inflammatory response, and may be superior to aspirin in endotoxaemia. However, equivalent effects have been seen in upper respiratory infections. In severe sepsis, there is some data to suggest that aggressive therapeutic management of the febrile response with paracetamol may be harmful, and alternative measures may be required to cool the patient. Ibuprofen is potentially more potent than paracetamol in reducing symptomatic fever in children and in adults with malaria, but data in other causes of fever is lacking. Ibuprofen is used in children, in whom the risk of Reye's syndrome outweighs any potential benefit of antipyretic treatment with aspirin.

Prognosis

The prognosis from most infectious causes of fever in the immunocompetent is excellent, with the exception of septicaemia associated with the systemic inflammatory response syndrome (see Chapter 152). It is otherwise impossible to give a prognosis for the entire range of the causes of fever, and much depends on the medical comorbidities of the individual patient. Conditions such as diabetes, chronic kidney disease, malignancies, and connective tissue diseases are associated with significantly higher risk of infection and a worse prognosis.

How to handle uncertainty in the diagnosis of this symptom

When the cause of fever is not immediately apparent, there are clear pathways for investigation, as previously outlined. The importance of regularly revisiting the history with the patient and relatives, and repeated detailed clinical examination, must be emphasized. Details from any previous medical notes and laboratory tests must be obtained, as these often contain highly relevant information. Consultation with an infection specialist may provide guidance and suggest alternative important investigations and management.

77 Hyperthermia

Matt Wise and Paul Frost

Definition of the symptom

As homeotherms, humans maintain their core temperature between 36°C–38°C, and this occurs despite variation in metabolic activity and environmental temperature. Elevation of core body temperature due to an increase in the thermoregulatory set point, but with intact thermoregulatory mechanisms, is called fever (see Chapter 76). By contrast, an elevation in core body temperature due to thermoregulatory failure with a normal thermoregulatory set point is called hyperthermia.

Differential diagnosis

Hyperthermia is a defining feature of a number of potentially life-threatening conditions (heat illnesses; Box 77.1).

Context

Hyperthermia occurs when heat production exceeds heat loss. Heat is primarily produced as a result of metabolic activity and this can be dramatically increased during exertion. Additionally, when ambient temperatures exceed 39°C, heat can be transferred from the environment. Thermoregulation is controlled by the preoptic nucleus in the anterior hypothalamus, principally by regulation of cutaneous blood flow and sweat production. Consequentially heat loss occurs mainly through the skin as a result of radiation, evaporation, conduction, and convection. Behavioural adaptation to heat, for example, removing clothing or seeking shade from the sun, is also very important. If these thermoregulatory mechanisms fail then hyperthermia ensues.

Although there is wide variation in individual tolerance to hyperthermia, in general, a core body temperature above 42°C for >8 hours is life-threatening, while death is virtually inevitable at temperatures above 45°C. Death occurs as a result of multiple organ failure due to the direct effects of the thermal injury and a massive inflammatory response to the heat stress. Therefore, hyperthermia should be viewed as a medical emergency requiring immediate intervention.

Globally, the most common heat illnesses are heat exhaustion and heat stroke, and these are major causes of morbidity and mortality. These illnesses represent a continuum of disease ranging from mild (heat exhaustion) to total (heat stroke) failure of thermoregulation. Heat exhaustion is characterized by sweating, muscle cramps, fatigue, vomiting, headaches, dizziness, and fainting. These symptoms may also occur in heat stroke but, in addition, neurological signs such as confusion, seizures, and coma predominate. Not surprisingly, the incidence of these illnesses increases in regions with a high ambient temperature. While the diagnosis of these conditions may be straightforward, hyperthermia may complicate a variety of rarer illnesses (Box 77.1). Knowledge of

these is essential, as successful management of hyperthermia is dependent on identification and treatment of the underlying cause.

Approach to diagnosis

Temperature, either taken orally or, more commonly, at the tympanic membrane, is one of the first measurements carried out on newly admitted patients. Therefore, patients with pyrexia are usually identified quite rapidly.

Clearly, definitive management of pyrexia requires identification of the underlying cause, but it is important to remember that patients with hyperpyrexia (>41.5°C) need immediate treatment, regardless of the aetiology.

As a general rule, hyperpyrexia is usually associated with a heat illness rather than a condition causing fever. Occasionally, the pattern of temperature elevation, for example, the intermittent fever seen in malaria, or the remittent fever observed in infectious endocarditis, will suggest an infectious aetiology. However, this is rare and, most often, there are no pathognomonic features (duration, extent, or pattern) of an elevated temperature per se that will reliably identify the underlying disease or distinguish hyperthermia from fever. As such, a meticulous history is required to differentiate the many causes of fever (infection, cancers, immunological causes, drugs, tissue infarction, pulmonary thromboembolism, etc.; see Chapter 76) from a heat illness.

Particular attention should be paid to the general circumstances around the admission, as this can frequently lead to the diagnosis; for example, the case of an athlete who collapses during an endurance event on a hot day, or of a witnessed overdose with the 'recreational' drug MDMA (3,4-methylenedioxy-N-methamphetamine).

Specific enquiry should be made about conditions known to cause heat illnesses, for example, endocrine or neuropsychiatric disease; culprit drugs such as neuroleptic agents or dopamine antagonists; a family history of malignant hyperthermia, or risk factors for heat exhaustion such as immobility, decreased fluid intake, or poor housing (lack of air-conditioning or ventilation).

Eliciting symptoms of 'heat illnesses' is frequently diagnostically unrewarding, as they are typically non-specific, often resembling those due to viral illness, such as, for example, myalgia, fatigue, nausea, vomiting, and irritability. However, CNS symptoms such as hallucinations, odd behaviour, delirium, or confusion are important because, in the context of recent heat exposure, the combination of CNS symptoms and hyperthermia is strongly suggestive of heat stroke. CNS examination is crucial, as a plethora of signs, including seizures, reduced level of consciousness, opisthotonus, pupillary abnormalities, and cerebellar dysfunction, can occur in heat stroke. Moreover, extrapyramidal effects, (choreiform movements, cogwheel rigidity, oculogyric crisis, dyskinesia, and festinating gait) are characteristic of neuroleptic malignant syndrome (NMS).

Signs of autonomic dysfunction (tachycardia, tachypnoea, diaphoresis, incontinence, and hypertension) may also be seen in NMS, and these should also be sought.

Specific clues to the diagnosis

In all cases, the core temperature is typically, but not invariably, elevated to 38°C–42°C.

Heat exhaustion/heat stroke

Specific clues to heat exhaustion/heat stroke are:

- high ambient temperature (heat wave)
- reduced ability for behavioural adaptation to heat (extremes of age, mental incapacity, physical immobility)

Box 77.1 Causes of hyperthermia

- heat exhaustion
- heat stroke
- malignant hyperthermia
- neuroleptic malignant syndrome
- drug-induced hyperthermia
- hormonal hyperthermia
- hypothalamic dysfunction
- neuropsychiatric hyperthermia

- limited acclimatization (tourist)
- recent vigorous exercise (athletes, military training)

Malignant hyperthermia

Specific clues to malignant hyperthermia are:

- anaesthesia with known trigger drugs (depolarizing muscle relaxants and inhalational agents)
- the following events occurring during the first 30 minutes of anaesthesia:
 - inexplicable increase in heart rate
 - inexplicable hypertension
 - inexplicable increase in end-tidal CO₂
 - inexplicable increase in oxygen consumption
 - generalized muscular rigidity

Neuroleptic malignant syndrome

Specific clues to neuroleptic malignant syndrome are:

- use of neuroleptic drugs (phenothiazines, butyrophenones, and thioxanthines)
- muscular rigidity
- autonomic instability
- altered mental status

Drug-induced hyperthermia

Specific clues to drug-induced hyperthermia are:

- history of overdose of salicylates
- history of drug abuse with:
 - cocaine
 - MDMA
 - amphetamines

Hormonal hyperthermia

Specific clues to hormonal hyperthermia are clinical and laboratory features of:

- thyrotoxicosis (thyroid storm)
- pheochromocytoma
- Addison's disease
- hypoglycaemia
- hyperparathyroidism

Hypothalamic dysfunction

Central (hypothalamic) thermoregulatory failure is rare. However, after exclusion of other causes of hyperthermia, hypothalamic dysfunction (via infection, cerebrovascular accident, tumour, granulomatous disease) should be considered.

Neuropsychiatric hyperthermia

Specific clues to neuropsychiatric hyperthermia are:

- clinical features suggestive of status epilepticus (known epilepsy, witnessed seizures, or post-ictal state)
- delirium tremens (history of drug or alcohol withdrawal)
- lethal catatonia (mutism, psychotic excitement, echolalia, muscular rigidity)

Key diagnostic tests

Key diagnostic tests are:

- core body temperature (tympenic, rectal, or oesophageal)
- tests providing evidence of organ damage and shock (which can occur in all heat illnesses):
 - creatine kinase (if elevated, suggests rhabdomyolysis)
 - liver enzymes (if elevated, suggests liver damage)
 - full blood count (will show haemoconcentration secondary to dehydration)
 - clotting screen (to exclude disseminated intravascular coagulopathy)
 - urea and electrolytes (to exclude acute kidney injury)
 - blood glucose (to exclude hypoglycaemia as a feature of acute liver failure)

- arterial blood gas (to exclude type A lactic acidosis)
- urinalysis (to exclude haematuria and myoglobinuria)
- halothane caffeine contracture test (to exclude malignant hyperthermia)
- capnography (elevated end-tidal CO₂ indicates malignant hyperthermia)
- drug toxicity screen (to exclude hyperthermia secondary to overdose or drug abuse)
- thyroid function tests; plasma and urinary catecholamines and metanephrines; cortisol; calcium; and parathyroid hormone (to exclude endocrinopathy associated with hyperthermia)
- MRI and CT of the brain (to exclude CNS disease causing hypothalamic dysfunction)
- lumbar puncture (to exclude CNS disease causing hypothalamic dysfunction)
- electroencephalography (to detect subclinical seizures)

Other diagnostic tests

Blood cultures and other microbiological samples should be taken as indicated by clinical history and examination (infection is an important differential diagnosis of heat illness).

Introduction to therapy

The following points should be noted:

- Heat illnesses can be life-threatening and, in all but the most minor cases of heat exhaustion, senior assistance should be sought.
- An airway, breathing, and circulation (ABC) approach should be taken so as to rapidly establish a safe airway, ensure adequate ventilation, and restore circulating blood volume
- Multi-organ failure is likely, so the patient should be managed in an intensive care unit or high-dependency ward.
- In cases of hyperpyrexia (>41.5°C), immediate cooling is required; a variety of methods are available (although all of these methods are successful, the patented devices seem to be the most efficient):
 - evaporative cooling; this relies on spraying the body with tepid (15°C) water while cooling with air flow from large fans; this technique has been successfully deployed on victims of heat stroke at the annual Hajj (Muslim pilgrimage to Mecca)
 - iced water immersion
 - rapid intravenous administration of cold (4°C) Hartmann's solution (30 ml/kg of ideal body weight), followed by surface cooling using ice or cold packs
 - patented devices (water-circulating external cooling devices, air-circulating external cooling devices, and intravascular cooling systems)
 - cardiopulmonary bypass
- Dantrolene is a muscle relaxant that works by blocking the release of calcium from the sarcoplasmic reticulum, thus reducing the amount of heat produced by the muscles. This drug is recommended as a specific therapy for malignant hyperthermia and NMS.
- Dopamine agonists (to treat hyperthermia) and benzodiazepines (to treat muscular rigidity) have been used for NMS.
- Definitive treatment requires identification and management of the underlying cause but, in cases of hyperpyrexia, ascertaining the diagnosis should not delay cooling.

Prognosis

The mortality rate for heat stroke has been reported to range from 10% to 70%. While some of this is attributable to comorbidity and increasing age, higher death rates were reported in those patients when treatment was delayed for more than 2 hours. In the 1960s, the mortality rate for malignant hyperthermia was 80%. Today, with earlier recognition and the use of dantrolene, the mortality rate is around 10%. The key message is that heat illnesses are all potentially lethal and that prognosis can be improved by early recognition and instigation of timely and effective treatment.

How to handle uncertainty in the diagnosis of this symptom

Provided the core temperature has been measured accurately, there is little uncertainty in the diagnosis of hyperthermia. Uncertainty resides in diagnosing the underlying cause. This requires a meticulous history and examination as well as appropriate investigations. However, this process should not delay treatment of life-threatening hyperpyrexia.

78 Hypothermia

Matt Wise and Paul Frost

Definition

Hypothermia is defined by a core body temperature of $<35.0^{\circ}\text{C}$, and may be further characterised as mild (32.0°C – 34.9°C), moderate (28.0°C – 31.9°C), or severe ($<28.0^{\circ}\text{C}$). Primary hypothermia is the result of environmental exposure, while in secondary hypothermia there is an underlying medical condition which perturbs thermoregulation.

Differential diagnosis

The number of cases of hypothermia and the aetiology of the underlying cause are greatly influenced by the local environment. Common characteristics of people with hypothermia are given in Box 78.1. Many individuals die of hypothermia without coming into contact with healthcare professionals.

Mild hypothermia (32.0°C – 36.0°C) has been used as a therapeutic modality in intensive care for traumatic brain injury, to lower intracranial pressure, although a recent, large, multicentre trial suggested that its use may actually increase mortality. It has also been used following out-of-hospital cardiac arrest, to improve neurological outcomes. However, recently, a large, international, multicentre trial found that 36.0°C was equally as effective as 33.0°C in relation to death and poor neurological outcome. International guidelines, therefore, recommend maintaining a constant temperature between 32.0°C – 36.0°C in unconscious survivors of out-of-hospital cardiac arrest. Hypothermia and even hypothermic circulatory arrest are also used during cardiac surgery and aortic root replacement surgery.

Box 78.1 Common characteristics of people with hypothermia

Found outside

Urban

- young male
- alcohol use
- drug intoxication
- deliberate self-harm
- mental illness
- homelessness
- assault

Extra-urban

- young male
- water pursuits
- water immersion
- outdoor pursuits
- primary exposure
- trauma (falls)

Found inside

- elderly
- stroke
- endocrine disorders:
 - diabetes (common)
 - hypothyroidism
 - hypopituitarism
 - adrenal insufficiency
- infection
- self-neglect
- fall or immobility

Context

It is difficult to know exactly how many individuals are affected by hypothermia because the number of estimated cases greatly exceeds officially recorded numbers. Many individuals succumb to hypothermia without ever coming to the attention of healthcare workers until after death. The prevalence varies enormously, depending on environmental and economic circumstances. It is commoner in cold or rapidly changing climates, or in areas where there is a focus on pursuits such as mountaineering, fell-walking, or outdoor water sports. Alcohol, drugs, and mental illness are important etiological factors in patients found hypothermic in urban areas and reflect local socio-economic demographics.

The diagnosis is obvious when a patient is discovered cold after being lost on a mountain or pulled from prolonged immersion in water. Individuals, particularly when found inside, pose more of a diagnostic challenge when suffering from mild hypothermia as they may be confused, dysarthric, ataxic, or dizzy. These findings may raise the possibility the patient is suffering from a stroke, diabetic complication, or infection. However, the patient's clinical findings may be the result of primary hypothermia or secondary hypothermia related to sepsis, hypoglycaemia, or stroke.

Clinical findings in hypothermia

Mild hypothermia

The clinical findings for mild hypothermia are:

- shivering
- hypertension
- tachycardia
- tachypnoea
- confusion (e.g. paradoxical undressing)
- dysarthria
- ataxia
- apathy
- diuresis

Moderate hypothermia

The clinical findings for moderate hypothermia are:

- the patient is not shivering (at this stage, the shivering stops)
- hypotension
- bradycardia
- hypoventilation
- stupor
- hyporeflexia
- dilated pupils
- sluggish pupillary reflexes

Severe hypothermia

The clinical findings for severe hypothermia are:

- coma
- apnoea
- absent reflexes, including pupillary reflexes
- muscle rigidity mimicking rigor mortis
- ventricular fibrillation (VF) or asystole may occur spontaneously

Approach to diagnosing hypothermia

All patients admitted to hospital have a temperature recorded, so a diagnosis of hypothermia may be quickly established. Oral temperature is not an accurate representation of core temperature.

A low-reading thermometer should be used to accurately record core temperature. Core temperature can be recorded with a tympanic, rectal, or oesophageal thermometer. Oesophageal temperature most accurately reflects core temperature during rewarming. Recording core temperature is extremely important in the prehospital setting to prevent an additional decrease (after-drop) of core temperature, which can occur following rescue and is often the cause of post-rescue collapse.

Specific clues to diagnosis

Patients with hypothermia will not complain that they are cold and may be confused or comatose. Nevertheless, temperature is measured on all hospital admissions and so the diagnosis should not be overlooked. If the temperature is recorded as $<35.0^{\circ}\text{C}$, a low-reading thermometer must be used.

Key diagnostic tests

The majority of investigations in hypothermic patients are focused on causes of secondary hypothermia:

- CT head, to exclude:
 - intracerebral, subdural, or extradural haemorrhage
 - traumatic brain injury
 - haemorrhagic or ischaemic stroke
 - empty sella syndrome
 - pituitary tumour
- blood glucose, to exclude:
 - hypoglycaemia
 - diabetic ketoacidosis (acute hypothermia can elevate plasma glucose)
- toxicology plasma or urine (to exclude accidental or intentional self-harm), to exclude the presence of:
 - alcohol
 - benzodiazepines
 - opiates
 - gamma-hydroxybutyric acid
 - barbiturates
 - carbon monoxide
 - paracetamol
 - salicylate
 - tricyclic antidepressants
 - phenothiazines
 - ethylene glycol
- blood, urine, sputum, ascites, or CSF culture, in suspected sepsis
- imaging:
 - radiographs or CT in suspected trauma
 - a chest radiograph, to look for aspiration pneumonia, community-acquired pneumonia, or fractured ribs
- endocrine tests:
 - thyroid function
 - Synacthen test
- ECG, which will show features such as:
 - J waves
 - bradycardia
 - conduction delays
 - atrial or ventricular arrhythmias

Introduction to therapy

Prehospital care

The principle aims of treatment in prehospital care are to:

- prevent heat loss
- rewarm the core temperature
- avoid precipitating VF

In mild hypothermia, wet clothing should be removed and replaced with dry clothing; the patient should be made to exercise, to keep warm; and the peripheral limbs should be massaged. Giving alcohol to the patient may drop the core temperature further and should be avoided.

Moderate-to-severe hypothermia requires core rewarming, which may be achieved with humidified, warmed (42.0°C) oxygen in the prehospital environment. VF can occur spontaneously below 30.0°C , so the patient should be kept in the horizontal position. Unnecessary movement or intervention should be avoided, as this may precipitate VF, which is resistant to drugs and defibrillation unless the core temperature is raised to above 30.0°C . Core temperature, vital signs, and ECG readings should be monitored.

Hospital care

Patients who are comatose should be intubated and mechanically ventilated with warmed, humidified oxygen. Central access must be established, as peripheral cannulation is difficult, and flow to the central circulation is variable. Wet clothing should be removed, if not done previously, and an ECG monitor attached. Core temperature must be monitored. Manipulation of the patient should be kept to a minimum if a cardiac rhythm is present, as needless intervention or movement of the patient can precipitate VF. If the patient has no palpable pulse for >45 seconds, CPR should be initiated. Defibrillation, vasoactive drugs, including adrenaline and atropine, and cardiac pacing are largely ineffective unless the core temperature exceeds 30.0°C . Thus, if initial defibrillation for VF is unsuccessful, further defibrillation and drugs should be withheld until the core temperature exceeds 30.0°C . Importantly, repeated administration of drugs at temperatures below 30.0°C leads to accumulation and toxicity. Life-threatening trauma should be excluded either as the cause or a complication of the patient's hypothermia and should be treated accordingly. An inspection should be made for frostbite.

Mild hypothermia has a good prognosis in the absence of an underlying medical condition, and treatment is aimed at reducing further heat loss. Patients can be left to passively rewarm in mild hypothermia by moving to a warm, dry environment and being allowed to shiver. Rewarming is slow by this method and relies on normal endocrine function and adequate energy stores. Active external rewarming with forced air warming blankets has been used in such cases, but caution should be exercised, as this technique can reduce core temperature further. It is preferable to use warmed, humidified oxygen or warmed fluids at 40.0°C – 42.0°C .

It is uncertain how quickly the patient should be rewarmed in moderate-to-severe hypothermia. Only techniques aimed at increasing core temperature should be used. An oesophageal temperature probe most closely correlates with cardiac temperature during rewarming and should be monitored in preference to rectal or tympanic temperature, when available.

Increasing the core temperature

The following may be used to increase the core temperature:

- humidified, warmed oxygen
- warmed intravenous fluid (Hartmann's solution may increase already elevated lactate levels, as liver metabolism of lactate is impaired in hypothermia)
- gastric, peritoneal, thoracic, or bladder lavage with warm fluids
- haemofiltration or haemodialysis
- intravascular cooling devices developed for therapeutic hypothermia in the intensive care unit, as these also can be used to rewarm hypothermic patients
- cardiopulmonary bypass may be required for core rewarming in severe cases

Complications following return to normal temperature

The following complications may occur after the core temperature has returned to normal:

- arrhythmia
- pulmonary oedema
- hypotension
- infections, including pneumonia
- pancreatitis
- rhabdomyolysis
- severe electrolyte disturbance

Prognosis

Prognosis depends principally on the severity of hypothermia and the presence of any underlying medical condition. In previously fit individuals with no trauma, prognosis is excellent, providing after-drop is avoided and the patient does not sustain VF. Mortality is extremely high in severely hypothermic patients with trauma or an underlying medical condition such as sepsis or stroke. In one study of patients admitted to urban hospitals in the west of Scotland over a winter period, one-half had an underlying medical condition, and mortality was 31%.

How to handle uncertainty in the diagnosis of hypothermia

There should be little diagnostic uncertainty of hypothermia in a hospital setting because all patients have their temperatures recorded. If a temperature $<35.0^{\circ}\text{C}$ is measured, a low-reading thermometer should be used to accurately record a low core temperature. However, a number of diagnostic uncertainties surround hypothermia. The following points should be noted:

- If there is no response to rewarming, suspect sepsis or an endocrine disorder.

- Be sure to exclude an underlying medical condition, such as diabetes, stroke, sepsis, trauma, and intoxication with drugs or alcohol.
- As coagulation tests and blood gases are performed at 37.0°C , patients may show clinical evidence of bleeding but have normal laboratory coagulation results, because enzymes are temperature dependent. Coagulopathy resolves with correction of core temperature. Uncorrected blood gas analysis is recommended.
- Severe hypothermia mimics death and it can be difficult to know when to stop resuscitation. Patients have survived with intact neurological function when core temperatures as low as $<15.0^{\circ}\text{C}$ have been documented. If the chest is frozen or there is an injury incompatible with survival, resuscitation should not be attempted. Resuscitation may be abandoned when the core temperature exceeds 32.0°C and there is no response to advanced cardiac life support.

79 Fatigue

Trudie Chalder and Matteo Cella

Definition of the symptom

Fatigue is a term used to describe difficulty in sustaining physical or mental effort. It should be distinguished from weakness, which is an inability to generate normal muscular strength. Fatigue is a natural signal to reduce or stop physical activity, but also a common subjective experience which may escalate to a significant health complaint as either a primary or a secondary (or supporting) symptom to an existing condition.

Differential diagnosis

Fatigue is the one of the commonest symptoms experienced by the general population. Approximately 25% of patients attending their general practitioner complain of fatigue. However, only 10%–15% of these patients will receive a diagnosis of a physical illness (see Tables 79.1 and 79.2).

Context

Fatigue is a common and natural experience in everyday life; nonetheless, it is a somehow vague and imprecise concept, difficult to measure, and with a broad range of possible etiologies. Patients generally describe fatigue with terms such as tiredness, exhaustion, or weariness. Fatigue may be associated with pain, aches, anxiety, low mood, irritability, and frustration. Moderate fatigue can occur as a result of stressful situations or illness, and in these settings is usually transient. Extreme and persistent levels of fatigue are associated with high levels of disability, limitations in mental, physical, and social functioning, and considerable social and economic impact because of increased consumption of healthcare and absenteeism from work. Prevalence studies find 25%–30% of patients in general practice complaining about fatigue, while as many as 30%–50% reported symptoms of fatigue in the general population at large.

A severe, incapacitating, chronic fatigue that is not caused by an underlying medical condition can be diagnosed as chronic fatigue syndrome (CFS). CFS has been reported with a prevalence of 0.1%–2.6% in the community and in primary-care-based studies, depending on the criteria used. Women are at higher risk of developing CFS than men are. Although many patients report a viral infection prior to the onset of chronic fatigue, no physiological link has been established which could be solely responsible for the onset of the illness. To date, CFS is conceptualized mainly as a disorder with a mixed

etiology in which psychological and physical factors are thought to work together to predispose an individual to develop chronic fatigue, and to precipitate and perpetuate the illness.

Approach to diagnosis

One of the key aspects in assessing fatigue is to ascertain whether the fatigue is a manifestation of an underlying medical condition. When fatigue is a symptom within the context of a medical condition, it is likely that, by treating the main illness, the fatigue severity will recede. This type of fatigue is sometimes referred to as secondary fatigue, as it is not the patient's primary complaint and it is the product of a clear, medical condition. Multiple sclerosis, cancer, and a number of endocrine, inflammatory, and immune disorders are known to cause secondary fatigue.

When fatigue is medically unexplainable, a diagnosis of CFS can be considered. CFS can be diagnosed in individuals who report signs of persistent and debilitating fatigue for at least 6 months. In addition to this criterion, routine laboratory tests (e.g. full blood count, erythrocyte sedimentation rate, renal, liver, and thyroid function, and urinary protein and glucose) and a physical and mental state examination need to be performed in order to rule out any other possible explanation for the fatigue. In 1994, the Centers for Disease Control (CDC) operationalized the criteria for the diagnosis of CFS. According to these criteria, a diagnosis of CFS can be made when patient presents with persistent or relapsing fatigue which starts with a definite onset, remains unexplained after clinical evaluation, produces a marked decline in the patient's previous level of occupational and social activities, and lasts for at least 6 months. In addition, patients should present with at least four of the following eight possible subjective complaints: muscle pain, joint pain, headaches, sore throat, tender lymph nodes, unrefreshing sleep, post-exertional malaise, and impaired short-term memory and concentration. According to the CDC criteria, conditions such as morbid obesity, drug or alcohol abuse, and psychiatric disorders such as psychosis, dementia, and eating disorders would invalidate the diagnosis of CFS, whereas conditions such as non-psychotic depression, anxiety disorder, and somatoform disorder would be consistent with a CFS diagnosis.

Although CFS is the most frequently used diagnostic label to identify a pathology of unexplained and debilitating fatigue, this condition is sometimes referred to by alternative terms, including myalgic encephalomyelitis, chronic fatigue and immune dysfunction syndrome, or post-viral fatigue syndrome.

Specific clues to the diagnosis of chronic fatigue

There is currently no diagnostic test or pattern of tests that can assist the diagnosis of CFS. Specialists generally carry out investigations for

Table 79.3 Aspects that should be taken into consideration for a diagnosis of chronic fatigue syndrome

	Secondary fatigue	Primary fatigue or chronic fatigue
Viral infection	Acute or remission phase	Fully remitted
Situation	May be linked to treatment due to side effects of drugs	May be linked to levels of activity and/or stress
Weekly variation	Often improvement	Stable
Onset	With medical condition	Sometimes with viral infections but not necessarily
Duration	Variable	More than 6 months
Cognitive symptoms	Sometimes	Often
Associated symptoms	Variable	Pain, sleep problems, concentration and memory problems
Comorbid diagnosis	Unspecific	Depression, IBS, anxiety, fibromyalgia, pain
Physical examination	Could be positive to a medical illness	Normal
Laboratory tests	Could be positive to a medical illness	Negative to medical conditions
Beliefs	Sometimes catastrophic	Fear of engaging in activity Focus on symptoms Somatic illness attributions Catastrophizing Perfectionism

unusual patterns in the patient's history (e.g. pronounced weight loss, foreign travel), look for any abnormality in symptom presentation (e.g. no cognitive symptoms), and carry out a physical examination and basic laboratory tests to screen for other possible explanations for fatigue. Nevertheless, acute and debilitating fatigue is also present in a number of conditions as a secondary symptom. Table 79.3 attempts to summarize some of the aspects that should be taken into consideration for a diagnosis of CFS and may be helpful in distinguishing fatigue as a primary complaint from secondary fatigue.

Key diagnostic tests

As the diagnosis of chronic fatigue is achieved by 'exclusion' of other possible explanations of fatigue, all the investigations to be conducted are aimed at confirming the absence of a condition that could account for the abnormal levels of fatigue. The first step for the diagnosis of CFS is a comprehensive clinical investigation comprising a detailed history and physical examination. Further, a number of laboratory investigations are recommended in order to exclude underlying medical conditions. Recommended laboratory investigations are full blood count, erythrocyte sedimentation rate or C-reactive protein, urea and electrolytes, thyroid function tests, and urine for protein and sugar. It may be also helpful to consider the following: rheumatoid factor, Epstein-Barr serology, antinuclear factor, and serological tests for cytomegalovirus, Q fever, toxoplasmosis, and HIV.

In addition to the physical examination, a psychiatric screening needs to be conducted to exclude the presence of a major psychiatric condition. Fatigue is a common complaint in mental disorders and, where it can be fully explained by a specific psychiatric disease, a diagnosis of CFS should not be made. However, a number of psychiatric conditions, particularly depression, anxiety, and somatoform disorder, commonly occur as comorbid features of CFS.

Introduction to therapy

To date, evidence suggests that behavioural interventions are the most effective treatment strategies for fatigue symptoms. In

particular two approaches, cognitive behavioural therapy (CBT) and graded exercise therapy (GET), have been shown to be effective in reducing fatigue symptoms, disability, and fatigue-associated complaints. CBT involves the use of specific techniques to alter and modify thoughts and actions that maintain and exacerbate fatigue-related behaviour. These strategies involve planned activity and rest, sleep management, activity monitoring, cognitive restructuring for unhelpful beliefs, and challenging of unhelpful assumptions.

GET involves an individually tailored, structured exercise programme aimed at gradually increasing the level of aerobic activity. The suggested exercise is usually walking, and patients are advised not to exceed the prescribed exercise duration or intensity.

Pharmacological intervention specifically targeting fatigue-related symptoms is per se unwarranted by research evidence. Medication acting against viral persistence or targeting immune function does not show a sizable reduction in fatigue levels in CFS patients. Similarly, treating chronic fatigue with antidepressants does not produce marked improvement on fatigue, but such treatment is often justified and helpful in treating frequently associated mood disorders.

There is insufficient evidence to recommend dietary supplementation, interferon, evening primrose oil, or intramuscular magnesium as a treatment for CFS. Prolonged rest cannot be recommended as a treatment of chronic fatigue, as this strategy may in fact perpetuate or increase fatigue in people recovering from viral infection.

In the case of secondary fatigue (e.g. related to cancer or multiple sclerosis), both CBT and GET can help alleviate the symptoms and associated disability.

Prognosis

The prognosis of fatigue is variable and depends largely on the condition responsible for the fatigue exacerbation. If an organic condition can be ascertained and fatigue is a clear by-product of such a condition, recovery from the condition will most likely result in an improvement of fatigue symptoms, although not always.

Prognosis of CFS shows considerable variability, but it is never associated per se with an increased risk of mortality.

In the case of untreated CFS, full recovery is rare and only a small proportion of individuals report improvement in symptoms. CBT and GET improve fatigue and disability in about 50%, and two studies showed that about 25% make a full recovery at 2 and 5 years after a course of CBT. Poor prognostic outcomes are associated with psychiatric comorbidity, while good prognostic outcomes are associated with low severity of fatigue symptoms, illness attribution style which is not physical, and a sense of control over symptoms. CFS is associated with significant disability and dysfunction both at home and at work, with rates of CFS-related unemployment as high as 37%. For CFS patients seen in primary care, symptom improvement is more commonly reported than full recovery.

How to handle uncertainty in the diagnosis of this symptom

Fatigue is a common symptom shared by many disorders. It is therefore important to initially assess the aetiology of the symptoms; in particular, clarify if the fatigue is the result of a medical condition or is medically unexplained. Laboratory tests, medical examination, and specialists' opinions may be helpful in the first instance to establish the cause of fatigue. If criteria for the diagnosis of CFS can be satisfied, the patient should be introduced to fatigue management strategies and referred to specialist clinics.

Clark, LV, Pesola, F, Thomas, JM, Vergara-Williamson, M, Beynon, M, and White, PD. Guided graded exercise self-help plus specialist medical care versus specialist medical care alone for chronic fatigue syndrome (GETSET): a pragmatic randomised controlled trial. *Lancet* 2017; 390: 363–73.

80 Unintentional weight loss

Satish Keshav and Alexandra Kent

Definition of the symptom

Unintentional weight loss refers to weight loss that is not voluntary, and can reflect serious underlying pathology. It can be caused by inadequate nutritional intake, increased metabolism, malabsorption, or a combination of these factors. Weight loss of 5% of body weight over 6–12 months should be investigated. Cachexia is a complex syndrome in which loss of body mass (fat and protein) cannot be reversed nutritionally, that is, is due to underlying disease processes inducing catabolism, rather than to inadequate nutritional intake.

The differential diagnosis in primary care and secondary care

Box 80.1 outlines the differential diagnosis in primary care and secondary care, ordered by probability.

Context

Body weight is determined by the combination of metabolic rate, calorie intake, and activity levels. Clinically relevant weight loss is considered to be $\geq 5\%$ of body weight over 6–12 months; $\geq 10\%$ weight loss can lead to physiological impairment (e.g. impaired immune system, increased infections), and $\geq 20\%$ leads to organ dysfunction. Men reach their maximum weight in the fifth decade, and women in their sixth. Beyond this, natural weight loss is usually due to declining muscle mass, with the redistribution of muscle mass in the extremities, leading to greater truncal fat stores.

Approach to diagnosis

Patients will often have had their weight documented at previous, possibly unrelated, outpatient clinics, or the GP may have previous weights

Box 80.1 Differential diagnosis in primary care and secondary care, ordered by probability

Common

- coeliac disease
- systemic disease causing wasting and disordered metabolism (e.g. diabetes mellitus, thyrotoxicosis, tuberculosis, lymphoma, HIV, emphysema, heart failure)
- medications that suppress appetite or cause nausea and food aversion (e.g. opiates, amphetamines, antibiotics, chemotherapeutics)
- poor dentition and oral ulceration
- social isolation and poverty
- disseminated malignancy (e.g. from breast, lung, prostate)

Uncommon

- chronic pancreatitis and pancreatic insufficiency
- Crohn's disease and ulcerative colitis (less frequently)
- oesophageal dysmotility (especially in the elderly)
- mucocutaneous candidiasis
- psychiatric disease, including depression and anorexia nervosa (begging the question of intentionality)

Rare

- Upper gastrointestinal malignancy (especially oesophageal and gastric cancer)

documented in their records. It is important to attempt to quantify and confirm weight loss as it is often very subjective. Furthermore, the initial consultation should identify the most likely physiological cause of weight loss: malabsorption, increased metabolism, catabolism, and so on. It is important to ask the patient the following questions:

- How much weight have you lost?
- When did the weight loss begin?
- Over what period of time has the weight loss occurred?
- Are you eating less?
- How is your appetite?
- Have you changed your diet?
- Are you on any new medications?
- Are you doing more exercise?
- Have you been unwell recently?
- Do you have any underlying medical problems?
- Have you been feeling more stress or anxiety than usual?
- Have you had constipation or diarrhoea?
- Are there any additional symptoms?

Twenty-five per cent of patients with cancer suffer from anorexia, and up to 60% have cachexia. Weight loss is common in patients with lung and gastrointestinal cancers, especially of the oesophagus, stomach, and pancreas. Conversely, weight loss is rare in breast or prostate cancer, unless there is disseminated disease.

Specific clues to the diagnosis

True weight loss is often apparent, with the patient's clothes hanging loosely, although this may not be obvious in patients who originally had a high BMI. Specific questions which can aid diagnosis include:

- Do you have any dental problems or mouth sores?
- Do you have occasional uncontrollable hunger with palpitations, tremor, and sweating? (This suggests hyperthyroidism.)
- Do you have increased sensitivity to cold or heat? (This suggests thyroid dysfunction.)
- Do you have increased thirst or are you drinking more? (This suggests diabetes mellitus.)
- Are you urinating more than usual? (This suggests diabetes mellitus.)
- What medications/drugs are you taking? (The use of diuretics, laxatives, alcohol, and illicit drugs can lead to weight loss.)
- Do you feel low? Do you suffer with poor sleep? (This suggests depression.)
- Are you pleased or concerned with the weight loss? (This question may help differentiate between pathological and psychological weight loss.)

Age will immediately influence the differential diagnosis, with cancers being more common in patients over 50 years. Younger patients are more likely to suffer from malabsorption. Patients with weight loss related to chronic disease will invariably be aware of the chronic disease diagnosis, although it is often important to ensure weight loss is not related to a coincidental pathology. With elderly patients, assess how they obtain their food, especially in those with ill health or reduced mobility. Shopping and preparing meals may be problematic, and poor dentition or ill-fitting dentures may make chewing difficult. Social support, such as 'Meals on Wheels', may be a simple measure that will prevent further weight loss.

Key diagnostic tests

Key diagnostic tests are as follows:

Full blood count: Normocytic anaemia may occur with chronic disease, and renal failure. Malabsorption can result in microcytic or

macrocytic disease, depending on the underlying cause, and the nutritional deficiency. A full blood count should be accompanied by haematinics to identify the cause of anaemia. Combined iron and folate deficiency is usually due to untreated coeliac disease. Iron deficiency anaemia should be considered a sign of gastrointestinal disease unless there is a clear alternative diagnosis.

Erythrocyte sedimentation rate (ESR) and/or C-reactive protein (CRP):

These inflammatory markers, when raised, are non-specific indicators of disease, malignancy, infection, or connective tissue disorder.

Urea, creatinine, and electrolytes: These tests are used to exclude renal failure and Addison's disease.

Fasting blood glucose: This is used to exclude diabetes mellitus.

Albumin: Albumin levels can reflect nutritional intake, although they can also be reduced in chronic disease.

Liver function tests, clotting screen: These are used to exclude liver failure.

Thyroid function tests: These are used to exclude hyperthyroidism.

Chest X-ray: This is used to exclude malignancy and tuberculosis.

Coeliac serology: This is used to exclude coeliac disease.

CT scan: Patients (especially those >50 years) with weight loss of unknown cause and with no specific clues to the diagnosis, will invariably undergo a CT scan of the chest, abdomen, and pelvis, to exclude underlying malignancy.

Other diagnostic tests

Further investigations depend on the associated symptoms, which direct you to the body system likely to be responsible for the weight loss. For example, weight loss and microcytic anaemia suggest a gastrointestinal cause, and would be investigated by a gastroscopy and colonoscopy (either endoscopically or radiologically). Patients with non-specific abdominal or pelvic pain may be referred for an abdominal and pelvic CT scan. Bone pain would initiate X-rays and/or a bone scan. Patients with progressive weight loss and for whom you are suspicious of an unidentified underlying malignancy may benefit from a PET scan.

Overall, potential further investigations include:

- HIV serology
- an autoimmune disease screen
- screening for tumour markers (these are not sensitive for detecting cancer, but may help direct investigations)
- endoscopic examination
- ultrasound scan
- CT scan
- MRI
- PET scan

Introduction to therapy

Clear documentation of the patient's weight is necessary, to set a benchmark for future reviews. Inpatients can be weighed once or twice a week, in order to provide the overall trend, and outpatients should have a weight documented every time they attend the hospital clinic. Food diaries are useful resources, helping the doctor or dietician assess the average oral intake and dietary balance of nutrients. Food diaries can also be used to correlate food intake with symptoms; this is a useful process in patients with gastrointestinal symptoms.

The mainstay of management for weight loss is directed at treating the underlying cause and providing nutritional support. Improving a patient's general health will improve their appetite. Specific electrolyte and nutritional supplements (e.g. potassium, folate, vitamin B₁₂) can be replaced. Patients who are severely malnourished may

Box 80.2 Refeeding syndrome

This condition usually occurs after 3–4 days feeding in a malnourished patient. The underlying cause is the shift from fat to carbohydrate metabolism, which leads to increased insulin release and the resultant cellular uptake of phosphate. Patients characteristically develop hypophosphataemia, although many electrolyte disturbances can occur. This, in turn, can lead to neurological, cardiological, muscular, and haematological disturbances. Patients should be closely monitored as nutrition is reinstated, and phosphate replacement should be given as required.

benefit from intravenous therapy, with vitamin and/or iron infusions. Any patient who recommences feeding after a period of poor intake should be monitored for refeeding syndrome (see Box 80.2).

Consideration should be given to the patient's environment, and their ability to obtain and prepare food. If they lack interest in food and have an inability to eat, weight loss is almost inevitable. Approaching these problems often requires a multidisciplinary team, with community support and social services. Finally, patients may benefit from enteral supplementation via a nasogastric tube or percutaneous gastrostomy. This is necessary in patients with neuromuscular problems that cause dysphagia, and may be a temporary measure in patients with nutritional deficiencies, to allow continuous feeding through the night. Placement of these feeding tubes does not prevent normal eating and drinking.

Prognosis

It is well recognized that underweight patients have a greater incidence of complications and higher mortality. Although prognosis is hugely related to the underlying diagnosis, overall recovery will be reduced in an undernourished patient. Specific complications associated with abnormally low weight include infection, depression, poor wound healing, oedema, muscle wasting, fatigue, weakness, and subsequent immobility.

How to handle uncertainty in the diagnosis of this symptom

Weight loss is a subjective symptom, but is considered to be an 'alarm sign', due to the association with malignancy and overall poor health. Therefore, it is not a symptom to be ignored. If no cause is found after initial investigations, radiological imaging should be performed in order to exclude underlying malignancy. Many patients are unable to quantify their weight loss, and clearly documenting weight is extremely important for confirming the patient's complaint. Associated symptoms will help direct the need for investigations and the most appropriate ones. Although monitoring weight will confirm the diagnosis, it is inappropriate to delay investigations

81 Obesity: differential diagnosis

John Newell-Price, Alia Munir, and Miguel Debono

Definition of the symptom

Obesity is defined as a body mass index (BMI; calculated as the weight in kilograms divided by the square of the height in metres) of 30 or above (Table 81.1). While BMI is the most commonly used measure of obesity, the waist to height ratio correlates better with visceral obesity.

The differential diagnosis of obesity in primary care and secondary care

Box 81.1 shows the differential diagnosis of obesity in primary care and secondary care, ordered by probability.

Context

The International Obesity Task Force has recently estimated that at least 1.1 billion adults are overweight worldwide. It is only in less than 1 out of every 100 cases that a medical cause for obesity is found. Usually, a patient becomes obese in the setting of recent lifestyle changes, such as eating more calories than is necessary or increasing the amount of alcohol intake or the use of drugs of abuse. Reducing the total amount of physical activity and leading a sedentary lifestyle are other important and frequent causes for this problem. If the amount of calories provided by the daily food intake is more than the calories one burns off, the body will store the energy as fat, resulting in obesity. In a smaller number of cases, a medical cause may be responsible. Obesity-related syndromes like Laurence–Moon–Biedl syndrome may be inherited, while a number of endocrine disorders, like Cushing's syndrome or hypothyroidism, or disorders affecting the hypothalamus may also cause obesity. The diagnosis of obesity may be easily made in clinic by measuring BMI or waist circumference. The consequences of obesity are serious. Approximately 50% of all hypertension is secondary to obesity, and the heart may also be harmed by obesity-induced chronic volume overload and ischaemic heart disease. Insulin-related changes are the most damaging. Obesity contributes strongly to the pathophysiology of type II diabetes and its consequences. Furthermore, obese patients have higher rates of stroke, osteoarthritis, obstructive sleep apnoea, gastro-oesophageal

Box 81.1 Differential diagnosis of obesity in primary and secondary care (ordered by probability)

Primary care

- exogenous obesity
 - lifestyle related
- constitutional obesity
 - family history
 - polygenic
 - 20%–40% of all obesity cases
- drug induced
 - glucocorticoids
 - phenothiazines
 - combined oral contraceptive

Secondary care

- endocrine-related causes
 - <1% of all obesity cases
 - hypogonadism
 - polycystic ovary syndrome
 - hypothyroidism
 - Cushing syndrome
- hypothalamic-related causes
 - <1% of all obesity cases
 - trauma (base of skull injury)
 - midbrain tumours affecting hypothalamus
 - inflammation (meningitis, encephalitis)
- rare genetic disorders
 - <1% of all obesity cases
 - Laurence–Moon–Biedl syndrome
 - Prader–Willi syndrome

reflux, chronic liver disease, and infertility. Obesity increases the incidence of some cancers (e.g. breast, prostate, and colorectal). The psychological and social effects of obesity are also important, and include higher rates of depression and anxiety, and reduced employment.

Approach to diagnosis

On becoming obese, one gradually develops mild symptoms which become more severe on worsening of the obesity. Initially, patients may complain of breathlessness, increased sweating, difficulties coping with sudden physical activity, and increasing lethargy, especially at the end of the day. Some patients complain of back pain and joint pains. Eating behaviour and physical activity should be assessed.

Complications of obesity should be identified by history, examination, and investigations. Psychosocial distress and lifestyle, environmental, social, and family factors—including a family history of overweight and obesity—and comorbidities should be covered.

Specific points in the history and on examination for medical causes of obesity should be identified (e.g. family history of autoimmune disorders or hereditary syndromes, signs of endocrine disorders), and a drug history should be taken.

Healthcare professionals should use their clinical judgement to decide when to measure a person's height and weight.

Table 81.1 The World Health Organization international classification of body weight, according to body mass index

Classification	BMI(kg/m ²)
Underweight	<18.50
Severe thinness	<16.00
Moderate thinness	16.00–16.99
Mild thinness	17.00–18.49
Normal range	18.50–24.99
Overweight	≥25.00
Pre-obese	25.00–29.99
Obese	≥30.00
Obese class I	30.00–34.99
Obese class II	35.00–39.99
Obese class III	≥40.00

Reprinted from BMI classification, World Health Organization http://apps.who.int/bmi/index.jsp?introPage=intro_3.html.

Specific clues to the diagnosis

The following medical causes need to be excluded:

- hypothyroidism (indicated by increasing lethargy, constipation, cold intolerance, menorrhagia, hoarseness)
- hypogonadism (indicated by small testes, decreased body and facial hair, a high-pitched voice, gynaecomastia, muscle weakness)
- polycystic ovary syndrome (PCOS; indicated by hirsutism, acne, oligomenorrhoea)
- Cushing's syndrome (indicated by myopathy, easy bruising, thin skin, purple striae, hypertension)
- hypothalamic disorders (indicated by visual field defects, signs of multiple pituitary hormone deficiencies, a history of trauma or meningitis, insomnia, disorders of thirst, appetite, temperature regulation)

Key diagnostic tests

Tests should exclude causes and complications. All patients who are obese should have the following tests:

- fasting glucose test
- oral glucose tolerance test
- lipid profile
- blood pressure test

One should consider taking the following tests only when there is a high clinical index of suspicion:

- thyroid function tests (for hypothyroidism)
- luteinizing hormone, follicle-stimulating hormone (in women); 9 am testosterone (in men); sex hormone binding globulin, free androgen index (for hypogonadism, PCOS)
- overnight dexamethasone suppression test; to be used only if there is a high clinical index of suspicion (for Cushing's syndrome; see 'Specific clues to the diagnosis').

Other diagnostic tests

If clinically indicated, the following tests may also be performed:

- MRI pituitary/hypothalamus
- pituitary function tests
- ECG, echocardiogram, elective stress test; consider these tests if the patient complains of cardiac type-chest pain or shortness of breath
- sleep study; consider this test if the patient shows symptoms suggestive of obstructive sleep apnoea
- joint X-rays (osteoarthritis)

Introduction to therapy

More than half the adult population is obese or overweight, and a large proportion will need help with weight management. The aim of treatment is to lose weight, with the aim of improving physical health and ameliorating psychological well-being and quality of life. Losing weight is a long-term commitment which may be hard, and one should be encouraged to try and maintain excellent calorie control. Managers and health professionals should ensure that preventing and managing obesity is a priority. The NICE guidelines for obesity in 2006 suggested the following lines of management for these patients:

- lifestyle change
- dietary control
- exercise
- weight loss groups
- drugs
- surgery

Lifestyle change

Lifestyle management should be implemented as follows:

- Assess the patient's readiness to make lifestyle changes.
- Explore barriers to lifestyle changes.

- Tailor lifestyle advice according to the patient's social background.
- Encourage the patient's workplace/school to provide opportunities to eat a healthy diet and be physically active.
- Advise the patient to check weight periodically.

Dietary control

One should aim to lose 0.5–1.0 kg (1–2 lb) of weight per week, which usually means eating 500 to 1000 calories less than before. The ideal approach is to reduce intake of saturated fat and refined carbohydrates. Fruit, vegetables, fibre-rich foods, and unrefined carbohydrates should make up the bulk of the diet. A food diary to record the food one eats is recommended. Portion size should be controlled, and breakfast is recommended.

Exercise

To prevent obesity, most people should be advised to do 45–60 minutes of moderate-intensity activity per day, particularly if they do not reduce their energy intake. Types of activities recommended are ones that can be incorporated into everyday life, such as walking, gardening, or supervised walking programmes. One should also reduce the total time of inactivity.

Weight loss groups

Weight loss groups are recommended if they are based on achieving a balanced healthy diet, encourage regular physical activity, and expect people to lose no more than 0.5–1 kg (1–2 lb) a week.

People with certain medical conditions should check with their GP or hospital specialist before starting a weight-loss or exercise programme.

Drugs

Orlistat should be prescribed only as part of an overall plan for managing obesity in adults in patients with a BMI of 28.0 kg/m² or more and with associated risk factors, or a BMI of 30.0 kg/m² or more. Therapy should be continued beyond 3 months only if the person has lost at least 5% of their initial body weight since starting drug treatment.

Surgery

Bariatric surgery is recommended as a treatment option for adults with obesity if all of the following criteria are fulfilled:

- they have a BMI of 40 kg/m² or more, or a BMI between 35 kg/m² and 40 kg/m² and other significant disease (for example, type 2 diabetes or high blood pressure) that could be improved if they lost weight
- all appropriate non-surgical measures have been tried but have failed to achieve or maintain adequate, clinically beneficial weight loss for at least 6 months
- the person has been receiving or will receive intensive management in a specialist obesity service
- the person is generally fit for anaesthesia and surgery
- the person commits to the need for long-term follow-up

Bariatric surgery is also recommended as a first-line option (instead of lifestyle interventions or drug treatment) for adults with a BMI of more than 50 kg/m² and in whom surgical intervention is considered appropriate.

Prognosis

In England, over 9000 deaths per year are caused by obesity alone. Being obese can take up to 9 years off one's life span. Obesity increases one's risk of developing a number of complications. Mortality rates for men and women at least 50% above average weight are increased approximately twofold and, if diabetes is present, may increase fivefold in males and eightfold in females. Patients with a BMI >29 kg/m² have a quadrupled risk of developing ischaemic heart disease. Weight loss reduces risk of developing diabetes and improves diabetes control; in addition, every 1 kg of weight loss leads to a fall in blood pressure of 1–2 mm Hg.

How to handle uncertainty in the diagnosis of this symptom

Diagnosis of obesity is straightforward and should not cause any uncertainty. However, management of obesity is not easy and requires a combined multidisciplinary effort from healthcare authorities, carers, family members, and the patients themselves.

82 Self-harm

Roger Smyth

Definition of the symptom

Self-harm refers to self-poisoning or self-injury, regardless of the apparent purpose of the act. The term self-harm is preferred to the older terms **parasuicide/attempted suicide** (which suggests an intent to die which might not have been present) and **deliberate self-harm** (because self-harm may also occur without deliberate intent in dissociative states). Self-harm includes a wide range of behaviours, including poisoning with drugs, poisoning with toxic chemicals, cutting, mutilation, jumping from heights, jumping in front of moving vehicles, and attempted drowning, shooting, asphyxiation, and hanging.

Conventionally excluded from definitions of self-harm are (1) habitual behaviours where the harm is incidental to the primary purpose of the act (e.g. tobacco smoking, recreational drug use), (2) behaviour where the aim is adornment and where there is at least sub-cultural acceptance (e.g. tattooing, piercing, decorative scarring) and, (3) where the individual lacks capacity to understand the behaviour (e.g. self-injurious behaviour in patients with a learning disability).

Self-harm is a behaviour with a wide range of possible motivations, including a genuine wish to die with fortuitous survival, an attempt to escape an intolerable situation or emotional state, the relief of symptoms, the communication of distress, the relief of tension or anxiety, or an attempt to manipulate others. Self-harm can become a habitual behaviour in some individuals in response to ongoing psychological or social stressors.

The prevalence of self-harm, and the relative frequency of the method chosen, vary between counties and between population subgroups. The relative frequencies of the method chosen will also vary between those who do and those who do not seek hospital treatment.

Within the UK, among self-harm patients presenting to hospitals, roughly 75%–90% of cases will involve self-poisoning (the vast majority of these by prescribed or over-the-counter medication), approximately 10% will involve self-injury by laceration to limbs or torso, and less than 5% will involve more violent methods of self-injury. Conversely, in patients who do not seek hospital treatment following self-harm, self-laceration is the most common method.

Methods of self-harm also show considerable variation by age, gender, and country of origin, although, consistently, cutting and violent methods are found to be commoner in males than in females. In self-poisoning, the particular medication or combination of medications taken varies by country and within countries over time, as prescribing patterns and fashions change. Currently in the UK, overdose of paracetamol accounts for more than half of the cases of self-harm with medication.

Context

Self-harm is a behaviour which can lead to medical presentation, rather than a symptom in itself. The importance of self-harm is its association with later completed suicide and with the presence of mental disorder. There is also an association with psychosocial stresses of all kinds.

The period after a self-harm episode offers an opportunity for positive intervention to reduce suicide risk, diagnose and manage mental disorder, or to direct the patient to appropriate sources of practical or psychological help. Following immediate medical or

surgical management of the self-poisoning or self-injury, a psychosocial assessment should be carried out.

While a minority of cases of self-harm are individuals with a clear intent to die, the majority reflect other motivations or combination of motivations. These may be unclear and mixed and change with time, depending on when the assessment takes place. Key themes are often communication with others (e.g. of distress), escape from intolerable symptoms or an intolerable situation, attempts to influence the behaviour of others, and relief of tension or anxiety.

Approach to diagnosis

Usually the fact that poisoning or injury is self-inflicted is obvious and will readily be admitted by the patient. There may occasionally be diagnostic confusion with accidental self-harm (e.g. in children or confused elderly) or with accidental overdoses of drugs taken for therapeutic effect. Careful and empathic history taking can clarify the situation here; be alert to the risk of a patient who has a clear intent to die and is concealing his or her intent to try again.

Provisions for the assessment of patients following self-harm vary, with some centres providing on-site specialist mental health nurses or psychiatric liaison services. All clinicians should, however, be competent in carrying out basic risk assessment and assessment of mental state sufficient to allow initial management and appropriate onward referrals.

The diagnostic issues in the self-harm patient group are (1) distinguishing between those patients with previous or ongoing suicidal intent, and those without; (2) determining the presence or absence of mental disorder and, if present, its diagnosis; and (3) assessing currently active psychological or social stressors for which intervention could usefully be carried out.

The key method used in establishing the underlying meaning of the act is an empathic and thorough clinical interview. This should cover the nature and purpose of the act itself, review any symptoms of mental disorder, and establish the psychosocial context in which the act took place.

Specific clues to the diagnosis

When considering whether there is or was suicidal intent, the patient's account of their actions and the intent behind them is paramount. The examiner should explore the nature of the act, the patient's beliefs about the probable outcome, the amount of pre-planning, the presence of final acts (e.g. setting one's affairs in order, leaving a suicide note), and the route by which the patient has now come to medical attention. Intent to die is associated with violent methods, methods of high lethality, final acts, and precautions to avoid detection.

A majority of patients with self-harm will merit a diagnosis of mental disorder; the diagnosis rate will depend on the diagnostic method used. Common mental disorders seen in those with self-harm are depressive illnesses, personality disorders, drug and alcohol problems, and anxiety disorders. Functional psychoses such as schizophrenia are rarer but may be associated with bizarre self-harm related to delusions. Mental disorder is diagnosed clinically by examination of the current mental state and exploration of the patient's history (see 'Definition of the symptom').

Key diagnostic tests

Diagnostic tests appropriate to the method of self-harm should be carried out. Many units will also routinely screen for paracetamol and salicylate levels in those with self-poisoning. In psychiatric assessment following self-harm, the single most important diagnostic instrument is the clinical interview, which will include assessment of suicide risk, inquiry about symptoms of mental disorder, and a full psychosocial assessment.

Other diagnostic tests

A variety of assessment instruments are available, usually developed in research populations, which can aid clinicians in assessing patients after self-harm. They are generally self-report or clinician-rated structured clinical interviews producing a score validated against at-risk populations. Examples include the Beck Suicide Intent Scale, the Beck Hopelessness Scale, the Reasons for Living Inventory, and the Suicide Assessment Checklist (see Table 82.1). No currently available assessment instrument replaces clinical assessment, but such instruments may be helpful as screening tools, research tools, and for use in service audit.

A problem with the use of this type of instrument in the self-harm population is that, although the future risk of completed suicide is significantly raised compared with the general population, the absolute risk remains low. Currently validated rating scales are therefore poor at predicting future completed suicide. They generally have more success in identifying the group at risk of repeat self-harm.

Introduction to therapy

The first priority in management is the medical or surgical care of the patient, appropriate to their condition. Consultation with psychiatric services may occur early to clarify the situation regarding use of the Mental Health Act, and questions of capacity to refuse treatment.

The subsequent management will vary depending on the type of self-harm and the suicidal intent, and presence or otherwise of mental disorder. For patients with clear ongoing suicidal intent or severe mental disorder, transfer to inpatient psychiatric care (under the Mental Health Act, if necessary) is often required. For patients with mental disorder, there will be discussion with the mental health services about appropriate review and follow-up. Patients without mental disorder or ongoing suicidal intent but with ongoing psychosocial stressors can often be usefully referred on to appropriate services (e.g. social services, relationship counselling, bereavement

counselling, citizens advice, women's aid, domestic abuse services, or drug treatment services).

Prognosis

The rates for completed suicide in the period following self-harm are 0.5–2.0% in the first year. Between 10% and 20% of cases of self-harm will repeat in the subsequent year. The prognosis relates strongly to the type of mental disorder.

How to handle uncertainty in the diagnosis of this symptom

These patients will inevitably arouse anxiety in the treating team, not so much because of diagnostic uncertainties or difficulty in physical management but because of the risk of completed suicide and the possible presence of mental disorder. This may give rise to doubt about individual competence to manage these cases and uncertainty about how to proceed. This anxiety is best assuaged by a carefully taken and empathic history, documentation of decisions made, and discussion of selected cases with specialist services.

In a minority of cases, considerable additional anxieties are caused when the patient refuses treatment or absconds after initial assessment. Here, the anxiety arises because of uncertainty as to whether to accept the patient's desire not to be treated (and the risk of negative outcomes as a result), or proceed with treatment (with attendant worries about the legal basis for, and legal risks of, such actions).

For patients who refuse treatment, the issue is that of capacity to refuse treatment and whether there is evidence of a mental disorder impairing judgement. Lack of capacity to refuse medical treatment cannot be assumed on the basis of any previous diagnosis of mental disorder but should be assessed on a case-by-case basis. In brief, to have the capacity for medical treatment decisions, the patient must be able to understand and retain memory of the proposed treatment, believe and understand the information regarding the risks of having the treatment and those of not having the treatment, and be able to weigh up the information in order to arrive at a decision. Mental disorder, intoxication, acute distress, and the physical consequences of self-harm can all negatively affect capacity.

The law and the correct use of different aspects of the law is unclear in this area. Many clinicians would view it as reasonable to treat an incapable patient in an emergency setting under common law, while later considering the use of the Mental Health Act (to detain the patient in hospital and legally prevent them from leaving)

Table 82.1 The Beck Suicide Intent Scale, the Beck Hopelessness Scale, the Reasons for Living Inventory, and the Suicide Assessment Checklist

Name	Source	Structure	Content
Beck Hopelessness Scale	Beck et al. 1974a	20 items, self-report	Inventory covering three aspects of hopelessness: thoughts about the future, motivation, and expectations
Beck Suicide Intent Scale	Beck et al. 1974b	20 items, clinician rated	Assessment of current suicidal intent via examination of objective circumstances of most recent episode, and self-report of the patient's beliefs regarding risk
Suicide Assessment Checklist	Rogers et al. 1990	21 items, clinician rated	Contains items covering patient social and demographic features and psychological and psychosocial status
Reasons For Living Inventory	Linehan et al. 1983	48 items, self-report	Assessment of patient's reasons for wanting to live, in a series of subcategories of beliefs, responsibilities, fears, and moral objections

83 Alcohol intoxication

Satish Keshav and Palak Trivedi

Definitions

Alcohol intoxication occurs when the quantity of alcohol (ethanol) consumed exceeds one's tolerance for the substance, with consequent impairment of the individual's mental and physical functional status. **Alcohol abuse** is a broad term for general ill health (mental, social, and/or physical) resulting from the repetitive, compulsive, and uncontrolled consumption of alcoholic beverages. Manifestations of alcohol abuse include a failure to fulfil one's responsibilities, resulting in loss of employment, personal relationships, or finances. **Alcohol dependence** is a condition which arises as a result of alcohol abuse and occurs when an individual continually uses alcohol, despite significant areas of dysfunction, with evidence of physical dependence.

Alcohol withdrawal syndrome is the set of symptoms and physical signs observed when an individual reduces or abruptly stops alcohol consumption after prolonged periods of excessive intake; it is largely due to the development of a 'hyperexcitable' central nervous system. **Delirium tremens** (also known as 'DTs') is the most severe form of alcohol withdrawal; it manifests as altered mental status, hallucinations, and sympathetic overdrive, which may progress to cardiovascular collapse if left untreated.

Etiopathogenesis of alcohol abuse

Contributors to alcohol abuse are complex and are likely a combination of psychosocial factors, societal and economic factors, and genetic and biological factors.

Psychosocial factors

Psychosocial factors include risk-taking, expectancies, sensitivity, tolerance, personality and psychiatric comorbidity, a family history of alcoholism, childhood neglect, and physical or sexual abuse.

Societal and economic factors

Peer-pressure influences and inaccurate perceptions of the risks of alcohol abuse represent some of the commonest reasons for alcohol abuse amongst younger individuals. Moreover, the relatively cheap price of alcoholic beverages (e.g. in the UK the current price of grocery store cider is cheaper than that of bottled water) and easy availability further contributes to the development of pathological drinking behaviour.

Genetic and biological factors

Genetic and biological factors can influence alcohol absorption and metabolism, alcohol intoxication, alcohol withdrawal, and delirium tremens.

Alcohol absorption and metabolism

Twenty per cent of ethanol is absorbed into the bloodstream directly from the stomach, and 80% from the small intestine. The longer the alcohol remains in the stomach, the more slowly it will be absorbed. This explains the sobering effect of food, which slows the process of emptying the stomach contents and hence the absorption of alcohol. When alcohol is taken with food, absorption is generally complete in 1–3 hours, with blood alcohol concentration reaching a peak 20–60 minutes after ingestion. Once alcohol is absorbed, it is converted to acetaldehyde. The liver metabolizes about 90% of consumed alcohol, and the lungs excrete about 5% during exhalation. Another 5% is excreted into the urine. Alcohol metabolism involves three discrete enzymes: the microsomal

cytochrome P450 isoenzyme CYP2E1, the cytosol-based enzyme alcohol dehydrogenase, and the peroxisome catalase system. Acetaldehyde is then converted to acetate. Genetic polymorphisms coding for alcohol dehydrogenase, as well as the frequency at which ethanol is consumed and absorbed, also affect the speed of metabolism of alcohol.

Alcohol intoxication

Chronic ethanol exposure has been found to alter the phosphorylation of intra-cerebral GABA receptors, which consequently alters receptor function. Alcohol also inhibits the glutamate pathway, and long-term ingestion results in increased receptor turnover and synthesis. Several other neurotransmitter systems in the brain, including opiates, serotonin, and dopamine are also affected; increased opiate levels help explain the euphoric effect of alcohol ('alcohol reward effect'), while its effects on GABA receptors mediate the anxiolytic and sedative effects. Alcohol also enhances the function of components of several other neurotransmitter systems, including glycine, serotonin, and nicotinic acetylcholine receptors.

Alcohol withdrawal and delirium tremens

When ethanol is withdrawn, a functional decrease in the inhibitory neurotransmitter GABA is seen. Ethanol also acts as an NMDA receptor antagonist, causing the loss of inhibitory control of excitatory neurotransmitters such as norepinephrine, glutamate, and dopamine, as well as adrenergic hypersensitivity of the limbic system and brainstem. This results in the clinical manifestations of ethanol withdrawal. Past episodes of withdrawal lead to increased frequency and severity of future episodes, and persons who abuse alcohol over the long term are more prone to alcohol withdrawal syndrome than persons who have been drinking for only short periods of time. Opiate receptors are increased in the brains of recently abstinent alcoholic patients, and the number of receptors correlates with cravings for alcohol.

Symptoms of alcohol intoxication, alcohol dependence, and alcohol withdrawal

Symptoms of alcohol intoxication

The signs and symptoms of alcohol intoxication include confusion, aggression, and seizures (the latter more common with withdrawal). Cardiovascular effects include tachycardia and dysrhythmias, peripheral vasodilatation, and volume depletion. Respiratory effects such as reduced airway sensitivity to foreign material and reduced ciliary clearance may also be seen, and reduced respiratory rate may be noted in cases of severe alcohol poisoning. Acute alcohol intoxication can cause upper gastrointestinal symptoms such as nausea and vomiting, and a dysfunction of oesophageal, gastric, and duodenal motility is also commonly recognized. An increase in duodenal propulsive waves toward the ileum results in increased transit of intestinal contents, contributing to the diarrhoea seen in alcoholics.

The effects of alcohol vary widely from person to person. The following factors may account for differences in how alcohol affects one person more than another:

Habituation: Prior experiences with alcohol in long-time, heavy drinkers may result in blood alcohol concentration levels that would normally be fatal for the casual drinker. Conversely, a novice drinker may have severe symptoms with the ingestion

of a moderate amount of alcohol. As a person's drinking habit increases, the liver will increase its capacity to metabolize alcohol, and the brain becomes used to frequent, even constant, high blood alcohol concentrations.

Concomitant medication/drug ingestion: The effects of alcohol are enhanced if a person is taking sedatives, and are altered by other medications which affect the metabolism of alcohol (e.g. metronidazole, nitrofurantoin, isoniazid, nitrates).

Blood alcohol concentration is commonly expressed in percentages or milligrams per decilitre, whereby 0.1% is equal to 100 mg/dl. Although there is a tremendous variation from person to person, and not all people exhibit all the effects, the following scale serves as a guide to blood alcohol concentration and its effects on a typical social drinker:

- Serum levels <25 mg/dl are associated with a sense of warmth and well-being.
- Levels between 25 and 50 mg/dl give rise to euphoria and decreased judgement.
- Levels of 50–100 mg/dl can lead to incoordination and decreased reaction time and reflexes. Ataxia may be noticeable.
- Cerebellar dysfunction (i.e. ataxia, slurred speech, nystagmus) is seen with 100–250 mg/dl.
- Coma can occur at levels >250 mg/dl, and respiratory depression, loss of protective reflexes, and death can occur with levels >400 mg/dl.

Symptoms of alcohol dependence

Alcohol dependence is recognized via the following criteria, which were incorporated into the fourth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV):

- tolerance
- withdrawal symptoms when attempts at abstinence are made
- the consumption of larger amounts of alcohol over time, or for longer periods than intended; in addition, larger quantities of alcohol being needed to achieve the subjective desired effect
- persistent desire or unsuccessful efforts to cut down on alcohol use
- the majority of the individual's time being spent on obtaining alcohol or recovering from its effects
- social, occupational, and recreational pursuits being given up or reduced because of alcohol use, or revolving around activities central to alcohol
- continued use of alcohol, despite knowledge of alcohol-related harm (physical or psychological)

Symptoms of alcohol withdrawal

Alcohol withdrawal can be classified based on the following symptoms and signs, which develop in a temporal manner:

Minor: These usually occur after a short interval (6–24 hours) following the last drink. Symptoms include tremor, anxiety, nausea, vomiting, and insomnia.

Major: These occur 10–72 hours after last drink and can manifest as hallucinations (usually visual but can be auditory), hypertension, diaphoresis, and global tremulousness.

Seizures: These are generalized motor seizures which tend to occur within the first 6–48 hours after withdrawal. They usually occur only once or twice and generally resolve spontaneously

Delirium tremens: This is the most severe form of alcohol withdrawal and can occur 3–10 days following the last drink, with a peak incidence around Day 5. Symptoms are characteristically worse at night and include agitation, global confusion, disorientation, hallucinations, altered perception and visual illusions, formication, paranoia, autonomic hyperactivity (hypertension, diaphoresis, and tachycardia), and fever. Delirium tremens should be distinguished from alcoholic hallucinosis, the latter occurring in approximately one-fifth of hospitalized alcoholics but without a risk of significant mortality. In contrast, delirium tremens carries up to 15% mortality with treatment, and 35% mortality without treatment.

Demographics of the disease

Alcohol abuse

Alcohol represents the oldest and most diffuse substance of abuse. The full economic cost of alcohol abuse in European countries is estimated to be 2%–5% of gross national product. Alcohol intoxication is becoming increasingly recognized in the teenage population, both in Europe and the United States. A large group of patients may present with ethanol intoxication as their sole problem but many others have it as part of a larger picture. The morbidity is often from co-ingested substances or coexisting injuries and illnesses. Alcohol intoxication is common in modern society, and some studies suggest more than half of all trauma patients are intoxicated with ethanol at the time of arrival to the emergency department. Alcohol is also commonly taken as part of suicide attempts. Europe has the highest levels of alcohol consumption and alcohol-related harm in the world, with a total economic cost of around €125 billion per year. Alcohol use alone causes is responsible for 10% of total disability-adjusted life years lost, and the harm to self and others inflicted by alcohol exceeds that caused by cocaine and heroin. Alcohol consumption is markedly skewed, and determining the exact percentage of the UK population with alcohol-related disorders is difficult. Studies suggest that alcohol abuse is most prevalent between the ages of 15 and 24, and epidemiological data from the United States estimate that 12% of the North American population are affected with alcoholism. Approximately three-quarters of such patients never receive medical treatment.

Alcohol withdrawal and delirium tremens

Approximately 50% of alcohol-dependent persons develop significant withdrawal symptoms necessitating pharmacological intervention upon cessation of alcohol intake. Fewer than 5% of patients with ethanol withdrawal progress to DTs. The influence of gender in the rates of development of severe alcohol withdrawal is not clear. Currently recognized risk factors for alcohol withdrawal include:

- prior ethanol withdrawal seizures ('kindling')
- race; black patients have a lower risk of developing withdrawal than white patients do
- previous history of delirium tremens
- concurrent illness
- daily heavy and prolonged ethanol consumption
- greater number of days since last drink
- severe withdrawal symptoms at presentation
- prior attempts at detoxification
- intense craving for alcohol

Natural history and complications of the disease

People who have been drinking heavily for several days or weeks may have withdrawal symptoms after the acute intoxication has subsided. Excessive consumption of large amounts of alcohol persistently can lead to the development of memory loss, blackouts, and pathological drunkenness symptoms. Alcoholism is significantly associated with suicide and violence, with rates approaching 80% and 60%, respectively, as a result of alcohol abuse. Long-term persistent consumption also leads to several deleterious biological health effects; these include traumatic injury, ketosis, hypoglycaemia, hypertriglyceridaemia, hyperuricaemia, insulin resistance, and the following types of end-organ damage:

- alcoholic liver disease (fatty liver, acute alcoholic hepatitis, or chronic liver disease; 10% of alcoholics develop cirrhosis over 10 years)
- cardiomyopathy
- acute and/or chronic pancreatitis
- dementia
- cerebellar degeneration

Chronic alcoholism may also lead to malnutrition and hypovitaminosis. A commonly recognized complication is that of thiamine

deficiency, which, if left untreated, can lead to the development of Wernicke's encephalopathy. This is characterized clinically by the presence of:

- disordered ocular motility, including nystagmus (commonest abnormality), bilateral lateral rectus palsies, disorders of conjugate gaze, and, less frequently, pupillary abnormalities, ptosis, scotomata, and anisocoria
- truncal and gait ataxia, often as a presenting symptom; this is a combination of vestibular paresis (most often in the acute state), polyneuropathy, and cerebellar damage
- encephalopathy characterized by a global confused state, disinterest, inattention, and agitation; stupor and coma are uncommon

When persistent deficits are present, patients with Wernicke's encephalopathy may progress and develop Wernicke–Korsakoff syndrome. Academically, this represents two distinct syndromes, with potentially reversible features as part of Wernicke's encephalopathy, and persistent and irreversible findings of dementia constituting Korsakoff's syndrome. Moreover, individuals with Wernicke–Korsakoff syndrome may have additional abnormalities detectable on clinical assessment, including painless vision loss, diplopia, a wide-based, short-stepped gait, inability to walk or stand without assistance, apathy and indifference, paucity of speech, hallucinations, agitation, anterograde and retrograde amnesia (incomplete), and confabulation.

Approach to diagnosis

Although not a substitute for careful history taking, a range of validated questionnaires can be used to screen for alcohol misuse behaviour and alcohol dependence. These include the Alcohol Use Disorders Identification Test (AUDIT), a 10-item screening tool developed by the World Health Organization (<https://www.drugabuse.gov/sites/default/files/files/AUDIT.pdf>), the Fast Alcohol Screening Test (http://www.effectivepi.co.uk/files/FAST%20&%20other%20AUDIT%20questions_EPI%20version%20Mar%202009.pdf), and the T-ACE Screening Tool (http://www.mirecc.va.gov/vishn22/T-ACE_alcohol_screen.pdf). A commonly used method for assessing (and treating) patients with suspected alcohol withdrawal is the Clinical Institute of Withdrawal Assessment for alcohol (CIWA-Ar) scale (http://umem.org/files/uploads/1104212257_CIWA-Ar.pdf). While valuable as a clinical tool, the 67-point scoring system may not be practical to use on a day-to-day basis. A more concise model is the Glasgow Modified Alcohol Withdrawal Score (<http://qjmed.oxfordjournals.org/content/qjmed/105/7/649.full.pdf>). Although easier to use, this model requires the patient to have been abstinent for a minimum of 8 hours before administering treatment.

Other diagnoses that should be considered

A detailed alcohol history is of paramount importance in the assessment of any individual presenting with altered mental status. However, alcohol intoxication predisposes patients to other causes of altered consciousness such as head trauma, and one must also be vigilant to consider other substance abuse which, when ingested may cause a similar presentation. Diagnostic overshadowing is common in alcohol-intoxicated patients, who require a thorough workup to exclude other pathophysiological processes (see Box 83.1).

The differential diagnosis of delirium tremens includes Wernicke–Korsakoff syndrome, and thiamine replacement therapy should be instituted in all patients suspected of alcoholism (see 'Treatment and its effectiveness'). Additional differentials of Wernicke–Korsakoff syndrome may include:

- temporal lobe epilepsy
- transient global amnesia
- concussive head injury
- Lewy-body dementia
- third ventricle ('ball-valve') tumour
- meningoencephalitis

Box 83.1 Differential diagnosis of alcohol intoxication

Metabolic causes

- hypoglycaemia
- diabetic ketoacidosis
- alcohol ketoacidosis
- hyperosmolar non-ketotic coma
- Wernicke–Korsakoff syndrome
- hypothermia

Systems failure

- acute liver failure
- acute renal failure

Stroke

- stroke
- subdural haematoma
- subarachnoid haemorrhage

Sepsis

- meningitis
- encephalitis

Other substance misuse

Use of:

- barbiturates
- benzodiazepines
- ethylene glycol and methanol
- other sedative–hypnotics
- heroin or other opioids
- cocaine

Miscellaneous

- hypoxia
- dehydration

'Gold-standard' diagnostic tests

Gold-standard diagnostic tests are as follows:

For alcohol intoxication: In alcohol intoxication, the blood alcohol level is grossly elevated. Alternatives such as field-sobriety tests ('breathalysers') are less accurate.

For alcohol dependence: Alcohol dependence is diagnosed based on three out of seven of the DSM-IV criteria (see 'Symptoms of alcohol dependence').

For alcohol withdrawal and delirium tremens: Although a single diagnostic test for alcohol withdrawal does not exist, a history of pathological drinking behaviour prior to hospital admission is suggestive of the diagnosis when combined with the classical clinical features of alcohol withdrawal.

Other relevant investigations

The extent of the diagnostic workup depends partly on the history as well as the clinical presentation. Although it is often difficult, the quantity of alcohol and the type of beverage consumed, the time course of symptoms, circumstances, and eventual injuries are important to ascertain. Physical examination must include an analysis of vital signs as well as nutritional status, hydration, and alcoholism-related signs, as well as features of alcohol-induced end-organ damage such as chronic liver disease. Physical assessment must be repeated frequently, often in order to follow up acute alcohol intoxication-related alterations. Evaluation for traumatic head injury is vital, and exclusion of an acute subdural haemorrhage with CT scanning may be necessary for the newly diagnosed alcoholic patient with altered mental status. The following additional investigations centre on assessing evidence of alcohol-induced end-organ damage as well as ruling out other serious metabolic or infectious etiologies which may be masked by the alcohol history:

Serum glucose: Hypoglycaemia is not uncommon, particularly in younger patients with alcohol intoxication.

Electrolytes, renal, liver function, and coagulation studies: These are used to look for signs of dehydration and end-organ damage.

Serum salicylate and paracetamol (acetaminophen) levels: In intentional suicidal ingestions, the presence of other toxic substances must be determined.

Blood gas analysis: A determination of the pH is important when polysubstance ingestion or ketoacidosis is suspected. The $p\text{CO}_2$ is useful in assessing respiratory depression; pH also can help exclude co-ingestion of methanol and ethylene glycol.

Serum osmolality: The osmolar gap can provide information about the ethanol concentration in the blood as well as give clues when suspecting the ingestion of other alcohols.

Full septic screen: CSF analysis may also be necessary if cause of altered mental state remains unclear.

Serum thiamine levels: These have been used in case reports to confirm Wernicke–Korsakoff syndrome. However, studies have not directly examined the correlation between a critical serum thiamine level and the development of the disease; thus, this test is seldom performed.

Prognosis

Only a quarter of patients with alcohol dependence receive medical treatment, yet after one year more than 50% of patients are still dependent or continue to experience symptoms related to chronic alcoholism. Continued consumption of alcoholic beverages, even in small quantities, increases the chances of relapse in an individual with previous alcohol dependence. According to the World Health Organization, morbidity attributable to alcohol in countries with an established market economy is 10.3% of disability-adjusted life years, second only to that of tobacco (11.7%). Although cardiovascular disease is one of the commonest causes of death relating to alcohol, 10% of all alcoholics develop cirrhosis over 10 years, with liver disease being responsible for 70% of the 'directly attributed' mortality from alcohol. Conversely, alcohol causes around 80% of deaths from liver disease, and trends in liver mortality reflect trends in overall alcohol-related harm. Another common cause of death in alcoholics is suicide (18% of alcoholics), the risk of which increases the longer a person drinks. This is likely a combination of alcohol causing physiological distortion of brain chemistry, as well as social isolation. In fact, over 25% of suicides in adolescents are related to alcohol abuse.

Treatment and its effectiveness

The management of a patient with acute alcohol intoxication is dependent upon the patient's current mental status and consciousness level, and whether there is an extensive background history of chronic alcohol dependence. Initial treatment should include medically stabilizing the patient by assessing respiratory, circulatory, and neurological systems. A patient intoxicated to the point of psychosis is considered a medical emergency because of the risk of unconsciousness, withdrawal seizures, and delirium tremens.

Patients with alcohol dependence require a multifaceted approach assessing biological and psychosocial factors, both those predisposing to the patient's current status of ill health as well as those likely to contribute to perpetuating the cycle of continued alcohol consumption and its associated consequences. In the acute setting, management focuses on stabilizing the patient, excluding other serious differential diagnoses, identifying and treating alcohol-induced end-organ damage (e.g. acute alcoholic hepatitis, alcoholic pancreatitis), the prevention and treatment of withdrawal symptoms, and preventing the development of Wernicke–Korsakoff syndrome.

Prophylactic thiamine replacement can be offered orally or parenterally to heavy or harmful drinkers. The latter is the preferred option in those patients attending the emergency department.

Those at high risk of withdrawal seizures, vulnerable patients, and adolescents/children under the age of 16 should be offered admission to hospital.

In states of established alcohol withdrawal, benzodiazepines should be offered. Practice varies from institution to institution but the ultimate aims are to follow a 'symptom-triggered' regimen; using the minimum dosage required to abolish withdrawal symptoms while

simultaneously recognizing features of breakthrough. A common starting regimen is chlordiazepoxide 40 mg four times daily, tapering down to 5 mg four times daily gradually over a period of 5 days (e.g. 40 mg four times daily on Day 1, 30 mg four times daily on Day 2, etc.). Diazepam is also used as an alternative in some centres.

Patients presenting with established features of delirium tremens may warrant parenteral therapy. Lorazepam and haloperidol are currently used in UK clinical practice, although neither has UK marketing authorization for this indication.

The key to reducing the long-term burden of alcohol-related diseases is prevention and early identification of pathological drinking behaviours. A person-centred approach is advocated, taking into account an individual's needs, preferences, and capabilities. Abstinence is the goal of all preventative measures. Many people, in particular those with severe problems and complex comorbidities, do not appear to benefit from treatment and/or frequently lose contact with healthcare services. One common approach is to offer intensive residential rehabilitation. However, the evidence on the effectiveness of residential rehabilitation is uncertain, as many of the more severely ill alcoholics are not entered into clinical studies. As a result, clinical opinion is divided on the benefits of residential rehabilitation, with some authorities suggesting that those who benefit are a 'motivated and selected group' who may do just as well with intensive community treatment, but this too is currently limited in availability.

Harmful drinkers with mild alcohol dependence should be offered psychological support with cognitive behavioural therapy or social-network therapy. Younger patients also benefit from multicomponent programmes (multidimensional family therapy, brief strategic family therapy, functional family therapy, or multisystemic therapy). The latter approach is also advocated for those with significant comorbidities and/or limited social support. Following successful withdrawal in individuals with moderate-to-severe alcohol dependence, the National Institute of Clinical Excellence recommends that pharmacological therapy be prescribed in combination with psychological approaches. The following agents are generally only effective when used in combination with psychological therapies:

Acamprosate: As chronic alcohol consumption inhibits NMDA and consequently leads to the overproduction of NMDA receptors, sudden abstinence will cause the excessive numbers of NMDA receptors to be more active. This leads to the symptoms of delirium tremens, and excitotoxic neuronal cell death. Alcohol withdrawal also induces a surge in release of excitatory neurotransmitters like glutamate, which in turn activates NMDA receptors. The exact mechanism of action of acamprosate is unknown but it is believed to possess 'dual function properties' which block glutamatergic NMDA receptors while activating GABA receptors. By reducing the excessive NMDA activity which occurs at the onset of alcohol withdrawal, acamprosate can also reduce or prevent withdrawal-related neurotoxicity. Compared with placebo, acamprosate reduces drinking frequency and effectively increases abstinence in patients with alcoholism.

Naltrexone: This drug functions as an opioid antagonist, thus preventing the 'euphoric' effects which follow alcohol consumption. It is effective in reducing cravings for alcohol, and a number of studies have demonstrated its efficacy in reducing the frequency and severity of relapse to drinking. Patients must be abstinent for 5–7 days before naltrexone can be administered.

Disulfiram: This drug blocks aldehyde dehydrogenase in the liver and thus inhibits the metabolism of acetaldehyde. Continued alcohol consumption leads to increased concentrations of acetaldehyde, resulting in an unpleasant reaction characterized by flushing, nausea, hypotension, and palpitations. In addition, disulfiram prevents the conversion of intracerebral dopamine to noradrenaline. Studies have shown that oral disulfiram was not significantly different from placebo in preventing relapse to alcohol consumption nor was the rate of discontinuation different between the two groups. However, in comparison with acamprosate and naltrexone, disulfiram is more likely to increase the time until participants first drink alcohol again, and is effective in reducing rates of heavy drinking, the amount of alcohol consumed, and the number of drinking days.

Other pharmacological agents: Other pharmacological agents which have been trialled in alcohol dependence include SSRIs, baclofen,

and the anticonvulsants topiramate and gabapentin. These agents have less evidence supporting their use in preventing relapse to drinking, and are not currently licensed in the UK.

84 Intravenous drug use

Bryan Timmins

Definition of the symptom

Intravenous drug use (IVDU) is the unlawful self-administration of a psychopharmacologically active substance by the intravenous route. Opioids such as heroin (diamorphine), buprenorphine (especially in France), and morphine (usually medicinal morphine sulfate ground into powder and suspended in partial solution) are the drugs most commonly taken intravenously. Amphetamine sulfate, cocaine, and increasingly crack cocaine (especially in Latin America) and short-acting benzodiazepines such as temazepam and lorazepam are also frequently injected. Single drug use is rare and many users will experiment with different compounds and may have comorbid alcohol abuse or dependency and major psychiatric disorders such as depression and schizophrenia or schizoaffective disorder.

Context

Home Office data identify 0.5 million intravenous drug users (IDUs) in the UK, with 2001 prevalence data ranging from 1.2%–2%. The global estimate is 11.6 million, with 1.1 million in Western Europe and 1.6 million in North America alone. The number of IDUs has been increasing for 30 years, although smoking of heroin and snorting or smoking of cocaine and its derivative crack cocaine are more prevalent and often act as a gateway to intravenous use. The increase in the intravenous use of opioids in particular is believed to be due to law enforcement driving up prices and reducing the potency of drugs reaching the street dealers. Abusers are then tempted into getting the best effect they can by injecting rather than smoking heroin. In addition, the increased availability of clean needles and syringes via exchange services may have encouraged higher numbers of users to experiment with intravenous and subcutaneous drug use.

Approach to diagnosis

An open-minded and non-judgemental approach will encourage honest disclosure of drug type and amounts and frequency of use. You must emphasize your impartiality and, unless otherwise required by law, the confidentiality of any admission of drug use.

The patient needs to trust the clinician and to feel respected even if his or her lifestyle is obviously harmful. Most regular drug users will know that they are risking their health, and an approach based upon motivational interviewing techniques will facilitate accurate diagnosis and treatment.

Specific clues to the diagnosis

If confronted with an unusual group of signs or symptoms, especially in a younger person, allow yourself to consider the possibility and then ask tactfully about alcohol and drug habits. Clinicians faced with unexplained medical complications may not recognize the patient as a current or former drug user and may feel uncomfortable asking about illegal activities for fear of angering the patient. A negative drug screen should not be taken as evidence that a patient is not actively using drugs, and not all IDUs are regular users or even drug dependent.

A history of IVDU can usually be obtained from the patient or reliable collateral sources. These include previous A & E records, family, friends, community mental health and drug treatment teams, general practice records of care, police national computer records, and police intelligence reports.

Physical examination will usually reveal stigmata of repeated venepuncture in readily accessible sites such as the antecubital fossae.

Bruising from extravasation thrombophlebitis and venous ulceration are less common with older experienced drug abusers, especially where needle exchange services operate (only approximately 25% have access to exchange services). Many regular users will have thrombosed easily accessible sites and moved onto injecting saphenous, femoral, cervical, and even genital veins.

IDUs experience suppressed appetite, malnutrition, and self-neglect. Personal care may be poor, minor cuts and abrasions may be untreated, and clothing may be dirty and contain items used in the preparation of injections (e.g. citric acid powder and syringes, needles, and burned spoons). Staff should take care with any blood-contaminated items found. The patient may also hide drugs in body cavities and, depending on the type of drug, the amount of it, and the security of its wrapping, these drugs may affect the clinical state at the time of assessment or later during the care pathway. Be particularly alert to collapsed patients received from airports, as they may have ingested large quantities of drugs. Patients under arrest who suddenly collapse may also have swallowed excessive amounts to avoid conviction for supplying drugs. Such patients, fearful of criminal consequences, may conceal their use from the clinical team. The author encountered one case where nursing colleagues discovered that heroin, which had been wrapped in cling film, was hidden beneath the foreskin of a prisoner who had been admitted to the ITU for ventilatory arrest believed due to asthma. Removal of the drug was followed by prompt recovery.

Unexplained bizarre behaviour or significant neuropsychiatric manifestations may be caused by drug intoxication or withdrawal reactions and by related problems such as epileptic seizure, traumatic brain injuries, encephalopathies, and sepsis. A large proportion of IDUs have hepatitis C (70%), compared to the background population prevalence of 0.7%, and many female addicts are also involved in prostitution. Of the known HIV cases outside sub-Saharan Africa, 30% are due to IDUs. The health impact of hepatitis C and sexually transmissible diseases such as syphilis is considerable and may be delayed by decades. Patients may by then have moved out of drug abuse and be reluctant to acknowledge their previous habits. Early genotypes of hepatitis C were circulating amongst prison populations of addicts from the mid-1970s. The author has diagnosed several patients who presented up to 30 years after IVDU with chronic fatigue states and slight but persistently raised alanine aminotransferases.

Key diagnostic tests

Key diagnostic tests are as follows:

- a mental state examination, including a structured cognitive assessment (e.g. a Mini-Mental State Examination (MMSE))
- urine, saliva, and serum drug testing (see Table 84.1): NB: a positive result does not imply drug dependency

Other investigations

Other investigations include:

- urea and electrolytes
- liver functions tests
- a viral hepatitis screen
- C-reactive protein
- full blood count
- blood cultures
- plain chest X-ray for pulmonary fibrosis due to talc granulomatosis, then possibly CT scan for pulmonary fibrosis
- 12-lead ECG (methadone causes QTc prolongation), and echocardiography if infective endocarditis suspected

Drug or its metabolite(s)	Duration of detectability in urine samples
Amphetamines, including methylamphetamine and MDMA detectable	up to 2 days
Benzodiazepines:	
• Ultra-short-acting (half-life 2h) (e.g. midazolam)	@ 12hrs
• Short-acting (half-life 2–6h) (e.g. triazolam)	@ 24hrs
• Intermediate-acting (half-life 6–24h) (e.g. temazepam, chlordiazepoxide)	@ 2–5 days
• Long-acting (half-life 24h) (e.g. diazepam, nitrazepam)	@ 7 days
Buprenorphine and metabolites	@ 8 days
Cocaine metabolites	@ 2–3 days
Methadone (maintenance dosing)	7–9 days (approximate)
Codeine, dihydrocodeine, morphine, propoxyphene heroin is detected in urine as the metabolite morphine)	Up to 48 hours

Reproduced from Department of Health (England) and the devolved administrations (2007). Drug Misuse and Dependence: UK Guidelines on Clinical Management. London: Department of Health (England), the Scottish Government, Welsh Assembly Government and Northern Ireland Executive.

- baseline EEG, if seizure suspected
- CT scan brain if the Glasgow Coma Scale is reduced or cerebral abscess suspected

Other diagnostic tests

Other diagnostic tests include counselling, and HIV/other STD testing. Hair samples are now routinely used as forensic evidence in the courts to reveal past use of drugs and can identify type and duration of use; however, they are insensitive to recent use.

Introduction to therapy

Therapy begins with developing the patient's trust in the clinical team and is maintained by honesty and open collaboration, even if the patient's initial response is not positive. Many patients vacillate about the need to stop or change their ingrained habits and can be greatly influenced to do so by trained counsellors employing motivational interviewing techniques. Most healthcare systems have access to dedicated drug treatment services, and patients are able to get general healthcare advice, support for drug cessation or substitution (e.g. methadone and buprenorphine), and follow-up monitoring, as well as a host of psychosocial and welfare advocacy. There are specific agencies working with vulnerable groups such as prostitutes, those with dual-diagnosis mental disorders, and young offenders, often with the compulsion of court orders and probation services. Referral to specialist services (usually within the local mental health network) as per the National Institute for Health and Care Excellence (2007a, b) guidelines on drug misuse is strongly encouraged.

The management of acute and secondary complications such as sepsis, hepatitis, and HIV are beyond the scope of this chapter, and the reader is directed to the relevant sections of this book. There is no evidence that active IVDU reduces the efficacy of antiviral treatments, and nearly all attempts to treat IDUs yield benefits in hard outcomes such as mortality.

Subtle yet significant long-term benefits can be achieved, particularly if lifestyles and risk taking can be shaped by contact with services. Those who stay in touch with treatment agencies, even if still using, have a much greater chance of eventually giving up their habit. Services have generally more impact if they are adaptable enough to seek out and engage addicts without being restricted to conventional outpatient settings. Visiting needle exchange points and offering health checks and general advice about common complications such as leg ulcers can result in simple effective improvements, such as the use of NSAIDs and paracetamol instead of opiates for ulcer pain.

The management of acute withdrawal reactions depends on the type and strength of drug a patient has been using. Street drugs are often diluted and mixed with inert fillers, such as starch, cellulose, and talc, by drug suppliers who usually have no experience or knowledge of the basic chemistry of the drug or possible harm caused to the users by their choice of filler. Embolic events can easily arise when drugs not intended for intravenous use are injected in suspension. Pulmonary fibrosis due to talc-induced granulomas can develop insidiously and become massive, with associated pulmonary hypertension and right-sided cardiac failure. This can be further complicated by infective endocarditis.

The difficulty in calculating equivalent pharmaceutical doses based on users' accounts of their habit is due largely to the varying purity of street drugs, especially heroin. Patients often report amounts based on cost alone (e.g. the popular £10 bag). Unintentional overdoses with resulting respiratory depression are often encountered by IV heroin users when either their own tolerance has been reduced by enforced abstinence, perhaps following a period in prison or hospital, or if the supplier sells a stronger batch of the drug.

In acute clinical settings, the decision to start a substitution regime or manage a withdrawal reaction should not be made without a multidisciplinary review. The safest approach is to add nothing other than supportive measures such as fluids and vitamins, especially thiamine, and to treat specific complications as they arise. Heroin and amphetamine withdrawal are unpleasant but not life-threatening. Poorly calculated substitution attempts, especially with methadone, can kill. All staff should be aware that drug abuse may occur on the wards, and patients who are expecting withdrawal symptoms may have brought drugs in or have them delivered during their admission.

Benzodiazepine abusers are at risk of extreme agitated withdrawal reactions similar to delirium tremens and may develop epileptic seizures. A safe approach is to substitute with oral diazepam at a sufficient dose to suppress agitation and autonomic arousal. The dose can then be reduced by one-eighth every two weeks.

Occasionally, a functional psychotic disorder such as schizophrenia will be encountered, although many patients experience brief polymorphic psychotic symptoms such as transient hallucinations, paranoid feelings, and short-lived delusions. Some may react dangerously, attempting to flee tormenting images or being commanded by voices to jump through windows. Careful nursing in well-lit settings, with reassurance and judicious use of diazepam or antipsychotic drugs such as olanzapine, which is available in both oral and intramuscular forms, or risperidone, under guidance from liaison psychiatrists or following hospital rapid tranquilization policies, can help avoid unnecessary distress and risk of injury.

Prognosis

The outcome for IV drug abusers as a group is poor, with up to 50% dying prematurely from a range of physical conditions. The annual mortality is estimated at 2.2%. The UK has one of the worst records for IDU deaths in Europe: 1500 died in England alone in 2005. In one study, 22.3% of deaths were due to overdose, 14% were due to chronic liver disease, and 10.2% were due to accidents. The population also suffers from a very high rate of mental disorder and suicide. The criminal association of drug use brings many into conflict with their families, leading to rejection, social isolation, and, particularly for women, sexual exploitation and child neglect. Surveys identify up to 78% of street prostitutes have used heroin, with 63% claiming their drug use as the reason for prostitution.

There is a general decline in prevalence of IVDU with age, and an associated reduction in mortality in each age group. The highest risk group remains the young, inexperienced IV abusers below the age of 25, as these are 11.5 times more likely to die prematurely. The estimated third who leave drug use permanently remain at higher risk of late complications such as cirrhosis and mental illness, particularly depressive disorders and alcohol abuse.

How to handle uncertainty in the diagnosis of this symptom

The main issue with diagnosing IV drug abuse is to consider the diagnosis. Once considered, there is less likely to be uncertainty

about confirming IV drug misuse. The patient usually knows what they have used and for how long and probably what risks they have been exposed to. Whether they will admit this to a clinician or even to themselves depends upon many factors outside the clinician's control. Any legal proceedings, especially if this involves family courts and child access, can result in denial, as can the shame of making an admission in front of families or friends. Patients who are receiving methadone may be at risk of having their script withheld if they are found to have used heroin and may conceal use for this reason.

Doubt about the cause of psychotic episodes often results in delaying the formal diagnosis of mental illnesses such as schizophrenia and can lead to long periods of inadequate treatment for this disorder in particular. The diagnosis may be delayed for months or years before positive drug testing or an admission or disclosure of use by a collateral source occurs.

PART 3

Cardiovascular disorders

85 Normal function of the cardiovascular system

Manish Kalla and Neil Herring

Cardiac physiology

The cardiac cycle: The ECG, blood flow, and heart sounds

The cardiac cycle represents the electromechanical events that take place from one heartbeat to the next. This is divided into two phases: relaxation of the ventricle, or diastole, which allows the heart to fill with blood, and contraction of the ventricle, or systole. Knowledge of this cycle is essential for understanding the cardiovascular examination at the bedside.

Electrical impulses generated by spontaneous depolarization of the sinoatrial node in the high right atrium initiate a cycle. This is followed by atrial depolarization, generating a P wave on the ECG. The P wave is followed by small rise in atrial pressure and, as there are no valves between the right atrium, the superior vena cava, and the jugular vein, this causes the A wave of the jugular venous pulse (JVP). There is a delay of 0.12–0.2 seconds until ventricular depolarization, largely due to slow atrioventricular (AV) node conduction, allowing more time for the ventricles to fill.

Ventricular depolarization is responsible for the QRS segment of the ECG, and occurs briefly before the rise in ventricular pressure caused by contraction. Pressure rises rapidly, leading to closure of the AV valves and thus generating the first heart sound. A further increase in pressure occurs over 0.02–0.03 seconds to generate enough force to open the aortic and pulmonary valves. This phase is known as isovolumetric contraction, as there is an increase in tension with no change in ventricular volume. Ejection of blood occurs once the ventricular pressure exceeds the aortic (80 mm Hg) or the pulmonary artery pressure (8 mm Hg) for the left and right ventricles, respectively.

Ventricular repolarization or relaxation in preparation for the next contraction is represented by the T wave on the ECG. This corresponds with relaxation and a rapid fall in pressure. The higher pressure in the aorta and the pulmonary artery then closes the aortic and pulmonary valves, generating the second heart sound. A brief period of relaxation then occurs without change in ventricular dimension; this is known as isovolumetric relaxation.

During ventricular systole, continuous venous return fills the atria, leading to an increase in atrial pressure (the V wave of the JVP). Once atrial pressure is higher than the ventricular pressure at the start of diastole, the AV valves open, leading to ventricular filling. Eighty per cent of ventricular filling occurs rapidly by passive flow, and is sometimes associated with a quiet, third heart sound, with a final 20% generated by atrial contraction in the healthy adult. Atrial contraction is sometimes associated with a quiet, fourth heart sound, especially during exercise, when the diastole shortens and ventricular filling by atrial contraction becomes more important. This sequence repeats with each heartbeat and is summarized in Figure 85.1.

Control of cardiac output

Cardiac output is the volume of blood ejected into the aorta by the left ventricle each minute, while venous return is the volume of blood returning to the right atrium each minute. These volumes must be balanced to avoid congestion of blood. Cardiac output at rest is approximately 5.6 l/min for males, and 4.9 l/min for females, but is influenced by basal metabolic rate, age, and body size. In clinical practice, cardiac output is often defined in terms of cardiac index to adjust for the influence of body surface area (3 l/min m⁻² for a 70 kg

adult). Cardiac index increases rapidly in childhood (4 l/min m⁻²), and then declines with increasing age (2.4 l/min m⁻²).

The contractile properties of any muscle are also dependent upon the degree of tension applied prior to contraction, and the resistance against which the contraction takes place. For the heart, the former is the preload, which is dependent on venous filling pressure, and the latter is the afterload, which is the pressure in the aorta. Significant disruption to both these parameters occurs in disease states, leading to changes in cardiac output and function.

Venous return and control of cardiac output: The Frank Starling law, and Bainbridge effects

Cardiac output is controlled locally by changes in venous return, which in turn affects stroke volume (volume ejected per contraction) and heart rate. The Frank Starling law describes how stroke volume adapts to changes in venous return. An increase in venous return causes increased left ventricular (LV) end diastolic volume. The resulting ventricular dilatation causes an increase in force generation, thereby emptying the increased return (see Figures 85.2 and 85.3). Right atrial stretch caused by volume loading results in increases in heart rate driven by the sinoatrial node. This is the Bainbridge effect. However, if the heart is excessively stretched, heart valves leak and

contractile performance is impeded, as it becomes less efficient at converting circumferential tension into radial pressure (the law of Laplace).

The role of the autonomic nervous system

Cardiac output is also controlled by the autonomic nervous system to maintain blood pressure in response to short-term haemodynamic disturbance via the baroreflex, or increase cardiac output during exercise (see Figure 85.4). Sympathetic stimulation increases inotropic (force of contraction) and chronotropic (heart rate) performance. Stroke volume can double and heart rate can increase up to 200 beats/min (depending on age), with up to a six- to sevenfold increase in cardiac output in elite athletes. A reduction in sympathetic stimulation has the converse effect. Parasympathetic stimulation via the vagus nerve can cause a strong slowing of heart rate, and even transient standstill, with a subsequent slow escape rhythm during ongoing stimulation. Contractile function can also be reduced up to 30%. The greater chronotropic effect is explained by the greater parasympathetic innervation of atrial tissue, as compared to the ventricles.

Vascular physiology

The circulatory system's function is to provide blood flow to body tissues and remove waste products. The rate at which blood is

Figure 85.3 The relationship between cardiac output and central venous pressure in the intact heart.

delivered is closely regulated to maintain optimum conditions for cellular and organ function. Each vascular structure in the circulation fulfils a specific role for which it is adapted. Arteries transport blood under high pressure to tissues and divide into terminal branches called arterioles, which control the flow of blood into capillaries. Capillaries allow exchange of blood constituents across their membranes and the interstitial fluid. Capillary outflow enters venules, which coalesce to form veins. Veins transport blood back to the heart and also act as major capacitance or storage vessels in the circulation. Blood pressure also changes with transition between each of these circulatory vessels (see Figure 85.5).

Control of local blood flow

For a given perfusion pressure (arterial–venous pressure), individual organ beds can regulate their own blood flow, depending on metabolic need, by modulating the local resistance to blood flow. A constant flow is needed to maintain capillary pressure, which ensures adequate solute transport without causing oedema. This autoregulation process is mediated by changes in arteriolar radius. Resistance to flow is inversely proportional to the radius raised to the fourth power; therefore, halving the radius of the vessel can compensate for a 16-fold increase in perfusion pressure. This allows vascular beds to maintain capillary flow between perfusion pressures ranging from 50–150 mm Hg.

The cellular mechanisms that underlie this process include:

Metabolic vasodilatation: Hypoxia, acidosis, and metabolites caused by low perfusion lead to vasodilatation in arteriolar smooth muscle cells.

Myogenic vasoconstriction: In regions of high perfusion pressure (e.g. the feet), capillary pressure nears venule rather than arteriolar levels. Increased vascular tone is mediated by wash out of vasodilatory metabolites, and stretch-dependent Ca^{2+} entry into arteriole smooth muscle.

The vascular endothelium also contributes to local regulation of blood flow. These mechanisms are crucial for maintaining adequate blood flow in the event of vessel vasodilatation in an organ bed. This could potentially 'steal' blood from other beds supplied by the same feeding artery. A change in shear stress in the affected and feeder vessels result in an endothelial-dependent vasodilatation throughout the vascular tree. This process is mediated by changes in endothelial-derived relaxation (for example via nitric oxide) and hyperpolarization, as well as endothelial-derived vasoconstriction (for example via endothelin).

Capillary transfer

Capillaries constitute the microcirculation and are responsible for nutrient transport and removal of waste products. This purpose is reflected by capillary wall structure, which is constructed of a single-cell layer of highly permeable endothelial cells. Capillary inflow is controlled by arteriolar tone and local factors (as previously described), thereby allowing each tissue to control flow in relation to need.

Particles continually diffuse between the plasma and the interstitial fluid, with overall filtration determined by the differences in the hydrostatic pressure and the osmotic pressure exerted by proteins (colloid or oncotic pressures) on each side of the capillary barrier, as well as the filtration coefficient (a property of the barrier itself). This relationship between these 'Starling forces' is shown in Figure 85.6.

If the sum of these forces is positive, fluid filtration across the capillary wall will occur; if it is negative, absorption will take place. Capillary hydrostatic pressure can be elevated due to raised venous pressure in congestive heart failure, or secondary to a deep vein thrombosis, leading to tissue swelling and oedema. Conversely, tissue swelling can also occur if capillary colloid pressure is reduced, as occurs in nephrotic syndrome or liver failure. The filtration coefficient can be increased due to the release of local inflammatory mediators, which increase capillary permeability.

Integrated cardiovascular control

Arterial blood pressure (ABP) is described in terms of systolic (SBP) and diastolic (DBP) blood pressure. These values differ from LV systolic pressure due to the elastic properties of arteries. In the young adult, blood pressure is typically in the region of 120/80 mm Hg (SBP/DBP). ABP varies beat to beat, has diurnal variation, and responds acutely to stress and exercise. ABP can be defined as the product of cardiac output and total peripheral resistance (TPR), and the control of cardiac output has previously been discussed. Autoregulatory processes in each organ system underpin the local control of TPR, while overall control of cardiac output, TPR, and ABP encompasses short-term baroreflex-dependent mechanisms, and long-term mechanisms linked to renal perfusion and regulation of fluid volume and osmolality.

Short-term or beat-to-beat changes in ABP are monitored by arterial baroreceptors in the aortic arch and carotid sinus, which influence cardiovascular autonomic control. These mechanisms do not set ABP but control fluctuations by adjusting cardiac output and TPR, while resetting of its operating pressure allows an increase in ABP and heart rate during exercise. The baroreceptors respond to the rate of change of transmural pressure during systole. A drop in ABP results in reduced stretch, which results in reduced afferent traffic via the ninth and tenth cranial nerves to the central cardiac and vasomotor centres. The efferent response increases sympathetic activity and decreases vagal tone, leading to positive chronotropy and inotropy, and increased sympathetic activity leads to vasoconstriction of resistance arterioles. The increase in cardiac output and TPR thereby

restores ABP to its original level. An increase in ABP is adjusted by the converse effect.

Long-term regulation of ABP is coupled to renal perfusion, blood volume, and osmolality. These mechanisms are important during cardiovascular shock and salt-sensitive hypertension. An increase in central blood volume is sensed by cardiopulmonary baroreceptors that mediate a reflex vasodilatation and release of atrial natriuretic peptide to cause natriuresis. Conversely, the juxtaglomerular apparatus in the kidney releases renin in response to reduced arteriolar perfusion pressure, a reduced sodium load in the distal convoluted tubule, and sympathetic nerve stimulation. Renin catalyses the first step in the production of angiotensin II, which acts as a potent vasoconstrictor, potentiates norepinephrine release from sympathetic nerve terminals, and promotes aldosterone release from the adrenal cortex. Aldosterone acts upon the distal convoluted tubule and collecting ducts of the nephron to promote sodium and water reabsorption. Central hypothalamic osmoreceptors can also alter blood volume by detecting and responding to a 2%–3% change in blood osmolality. They strongly influence the release of antidiuretic hormone, which promotes reabsorption of water at the collecting ducts of the kidney, and promote the perception of thirst to encourage fluid intake.

86 Risk factors for cardiovascular disease

Amitava Banerjee and Kaleab Asres

Introduction

The most prevalent cardiovascular diseases (CVDs) are atherosclerotic, affecting all arterial territories. Figure 86.1 illustrates the major contributors to CVD, showing the predominance of coronary artery disease (CAD) and cerebrovascular disease (stroke and transient ischaemic attack). Globally, every year 7.3 million people die from CAD, and 6.2 million from stroke, with far-reaching associated costs.

Over 50 years of large-scale epidemiologic studies such as the Framingham and INTERHEART studies have firmly established the commonest or 'traditional' risk factors for CVD; namely, smoking, hypertension, diabetes mellitus, hypercholesterolaemia, and a family history of CVD. The 'risk-factors approach' to CVD looks at these factors, individually and in combination, in the causation of disease (Figure 86.2). The complex causation pathways involve interplay of individual factors, whether genetic or environmental. More recently, there has been increasing interest in 'epigenetics' or the way in which the environment interacts with genes in the process underlying CVD.

Traditional risk factors

Blood pressure

Much of our current understanding about the role of blood pressure in CVD can be attributed to decades of high-quality research from the Framingham study. This was established in 1949 with the aim of securing epidemiological data on atherosclerotic and hypertensive CVD. Their first major report, after 14 years of follow-up of a cohort of 5127 subjects, showed that elevated blood pressure was a major risk factor for CAD, as well as for all forms of stroke. This link has

been made in many other studies; however, the lower limit of where this risk becomes apparent was more difficult to establish. A major contribution was made by Lewington and colleagues (2002), who performed a meta-analysis of individual data for over 1 million adults from 61 prospective studies. They showed that, throughout middle and old age, blood pressure is strongly and directly related to stroke, ischaemic heart disease, and overall mortality, without any evidence of a threshold, down to at least 115/75 mm Hg. Many interventional studies have gone on to show that treatments aimed at reducing blood pressure are associated with improved outcomes.

Age

The risk of coronary heart disease (CHD) increases markedly with age. Some of this can be explained by a worsening in risk factor profile with increasing age. For example, in most populations, serum total cholesterol increases as age increases. In men, this increase usually levels off around the age of 45–50 years, whereas, in women, the increase continues sharply until the age of 60–65 years. Blood pressure also tends to increase with age. The increases in blood pressure are explained in part by increasing BMI and obesity. These observations provide an example of the importance of interaction between risk factors in determining overall cardiovascular risk. When all major risk factors are accounted for, however, increasing age remains an independent predictor of adverse cardiovascular outcomes.

Gender

There is a marked difference in CHD, with all major epidemiological studies showing higher risk in men. Among middle-aged people, the incidence of CAD is approximately two times more common in men

Figure 86.1 Distribution of global cardiovascular disease deaths due to ischaemic heart diseases (coronary artery disease), cerebrovascular diseases, and other types of cardiovascular diseases in males (left panel) and females (right panel).

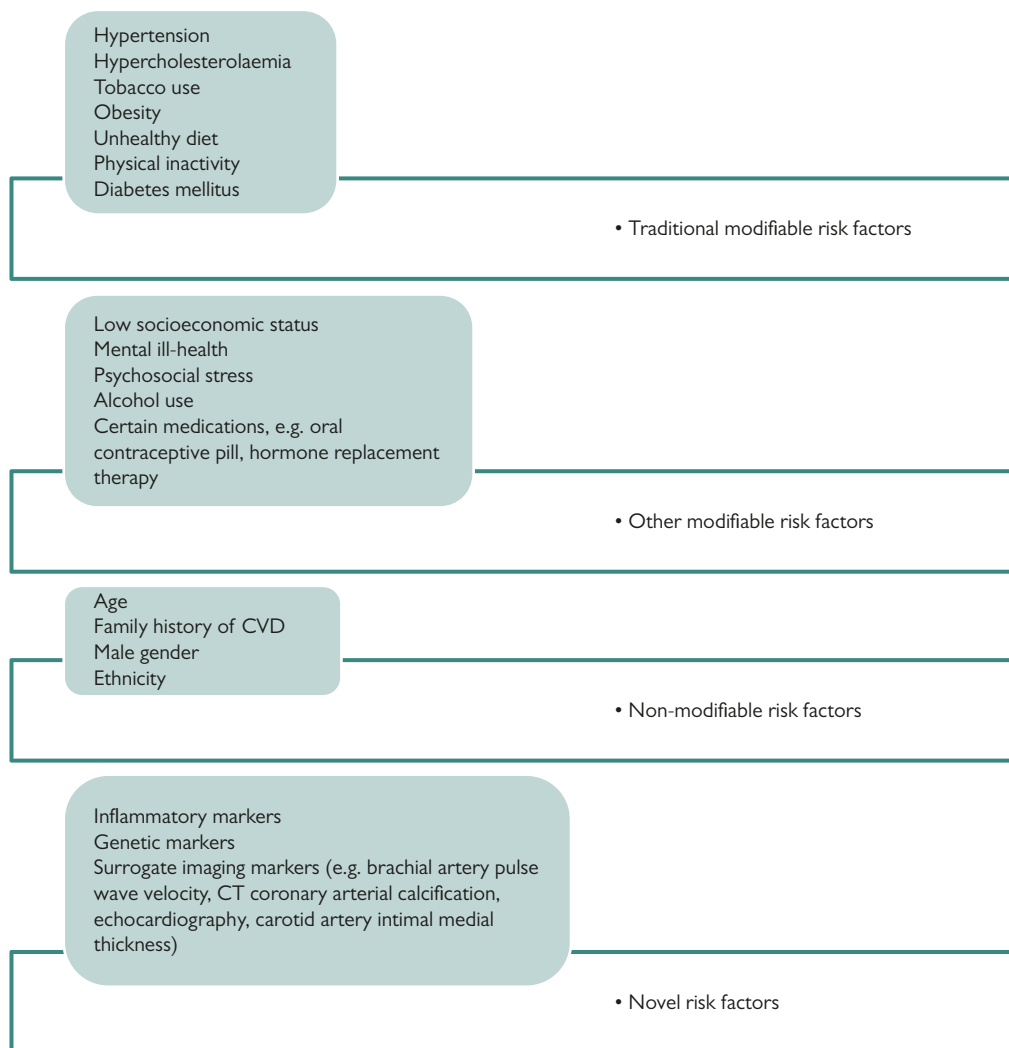

Figure 86.2 Risk factors for coronary artery disease and other cardiovascular disease (CVD).

than in women, with mortality being five times greater, with this sex ratio varying between populations. In a large prospective Finnish study of 14,786 subjects, equating to 156,095 person-years of follow-up, it was found that the sex differences in measured cardiovascular risk factors explained nearly half of the observed sex difference in CHD incidence and mortality, with the difference in the HDL/total cholesterol ratio being the major determinant of the difference in risk.

Lipids

Once again, the Framingham study led the way in establishing the importance of lipid abnormalities in increasing CVD. They showed that serum cholesterol and lipoprotein levels were powerfully related to the subsequent rate of CHD. Most of the risk can be attributed to elevated LDL, with HDL being protective. Data on the link with stroke were more difficult to establish. This was primarily due to the fact that many of the early trials did not distinguish between haemorrhagic and thromboembolic stroke, as well as the difficulty in establishing the diagnosis by imaging in very large studies, some of which predated routine use of CT scanning in stroke patients. The Multiple Risk Factor Intervention Trial of 350,977 subjects showed that there is an inverse relation between serum cholesterol level and the risk of death from haemorrhagic stroke, but its public health impact is overwhelmed by the positive association of higher serum cholesterol levels with death from non-haemorrhagic stroke and total CVD. Several interventional trials have consistently shown that treatment with

statins, resulting in lower LDL, results in reduced cardiovascular risk. In subsequent years, interest focused on the importance of the lipid-transporting apolipoproteins. ApoB transports all potentially atherogenic very low-density lipoprotein, intermediate-density lipoprotein, and LDL particles, and ApoA-I transports and acts as the major anti-atherogenic protein in the HDL particles. The INTERHEART study showed that a raised ApoB:ApoA-I ratio was the strongest risk factor for predicting adverse cardiovascular risk. Contemporary guidelines on lipid management remain predominantly targeted at reducing LDL.

Diabetes mellitus

There is overwhelming evidence of the link between all forms of diabetes mellitus (DM) and cardiovascular risk, and DM is an independent risk factor for several forms of CVD. Furthermore, diabetics suffering with CVD have a worse prognosis than non-diabetics. Cardiovascular sequelae of DM include CHD, stroke, peripheral arterial disease, nephropathy, retinopathy, neuropathy, and cardiomyopathy. Type 2 DM is the most prevalent form, arising from a combination of insulin resistance and the defective secretion of insulin by pancreatic beta cells. Due to the aging population, increasing prevalence of obesity, and sedentary lifestyle, which all predispose to type 2 DM, the global burden of diabetes mellitus is increasing at an alarming rate. The metabolic syndrome encompasses a cluster of metabolic risk factors associated with increased risk for type 2 DM and

CVD. Insulin resistance, in the absence of overt DM, is increasingly recognised as an independent risk factor for CVD, as well as playing an important role in the pathophysiology of the metabolic syndrome.

Smoking

The association between smoking and CVD was first established in large epidemiological studies, including the Framingham study and the British Doctors Study. It can result in a sevenfold increase in the risk of peripheral arterial disease, and at least a twofold increase in risk of CAD. It has a greater impact on acute, typically thrombotic, events than on atherogenesis; this effect is most marked in young and middle-aged adults, in whom smoking is responsible for approximately 50% of premature acute myocardial infarctions. Numerous studies have demonstrated a substantial decrease in CHD mortality associated with smoking cessation, as compared to that associated with continuing smokers, with this diminution in risk occurring relatively soon after cessation of smoking. Similar rapid decreases in risk with smoking cessation are also seen for ischemic stroke.

Family history

A positive family history has long been associated with increased risk of CVD. However, when individual risk factors are accounted for, the impact becomes significant less. For example, in the INTERHEART study, when adjustments are made for the nine risk factors (smoking, raised ApoB/ApoA-I ratio, history of hypertension, abdominal obesity, psychosocial factors, daily consumption of fruits and vegetables, regular alcohol consumption, and regular physical activity), the attributable risks to the populations studied only rose from 90.4% to only 91.4%, indicating that, although family history is an independent risk factor for myocardial infarction, most of the associated risk burden can be accounted for through the other risk factors studied.

Ethnicity

Cardiovascular risk varies by ethnic group. Relative to white subjects, Afro-Caribbeans and people of African descent have high incidence of stroke and end-stage renal failure, whereas CHD is less common. On the other hand, South Asians (from the Indian subcontinent) have a higher incidence of CHD. Although a different genetic make-up might, in part, explain such differences, environmental and modifiable factors relating to diet and lifestyle play an important role. What remains clear is that, on a population survey, hypertension and diabetes were raised two- to threefold in South Asians, Caribbeans, and West Africans in Britain; with obesity being above national targets in all ethnic groups. These have to be borne in mind when developing public health policies.

Alcohol

Moderate alcohol consumption is believed to be protective against CHD, with a J-shaped relationship; the lowest risk is seen among light-to-moderate drinkers, and higher rates are seen among abstainers and heavy drinkers. This is complicated by the observation that this relationship is significantly affected by ethnicity, gender, type of alcoholic beverage, and pattern of alcohol intake. In a prospective study in African Americans, no J-shaped curve was found; instead, there was no beneficial effect, and mortality increased with increasing average consumption of more than one drink a day. Similar patterns were seen in a study of Indian men. In the INTERHEART study, alcohol use was protective against myocardial infarction in the entire study population (recruited from 52 countries around the globe), although it was harmful amongst Indians. The protective effect of alcohol is strongest in studies conducted in Mediterranean countries, where drinking habits are typically characterized by the use of daily constant amounts of alcohol mainly in the form of wine, while in Northern Europe and in the United States, alcohol is commonly consumed during the weekend in the form of beer and spirits. Data on whether this observation is due to the form of alcohol consumed or pattern of consumption remain unclear.

Diet

There is extensive evidence about the role of nutrition in CVD, through a direct influence on atherogenesis or effects on other risk factors such as lipid levels, blood pressure, and glucose metabolism. As an example, Table 86.1 summarizes the impact

Table 86.1 Impact of specific dietary and lifestyle changes on favourable lipid profile

Lifestyle intervention to improve lipid profile ¹	Magnitude of effect ²	Level of evidence ³
Reduce dietary saturated fat	+++	A
Increase dietary fibre	++	A
Reduce dietary cholesterol	++	B
Utilize functional foods enriched with phytosterols	+++	A

¹ Reduce total cholesterol or LDL, reduce triglycerides, or increase HDL levels.

² Standard deviation of daytime systolic blood pressure; +++ = general agreement on the effects on lipid level; ++ = less pronounced effects on lipid levels, although the weight of evidence/opinion is in favour of efficacy; + = conflicting evidence, where the efficacy is less well established by evidence/opinion.

³ Level of evidence A = derived from multiple randomized clinical trials or meta-analyses; B = data derived from a single randomized clinical trial or large non-randomized studies.

of dietary intake and specific lifestyle on lipid levels. When the global patterns of dietary intake are studied, an unhealthy diet, assessed by a simple dietary risk score, increases the risk of acute myocardial infarction and accounts for approximately 30% of the population-attributable risk.

Body weight

Body weight is closely related to several traditional cardiovascular risk factors, including hypertension, age, insulin resistance, social factors, and lipid profile. When these are taken into account, obesity, particularly abdominal obesity, remains an independent risk factor for CVD. The attributable risk is much higher in high- and middle-income countries, where the risk can be greater than that associated with smoking. Weight reduction and physical exercise programmes have been shown to result in improvement in risk both in primary and secondary prevention of CVD.

Psychosocial factors

There is a large body of evidence showing that psychosocial factors increase cardiovascular risk. As well as interacting negatively with many traditional risk factors, they also increase risk independently. These include low socio-economic status, education, deprivation, lack of social support, social isolation, stress, and depression. In addition to increasing the risk of a first event, these factors also worsen prognosis, as well as acting as a barrier to treatment compliance and efforts to improved lifestyle. There is also evidence of the beneficial effects of psychosocial interventions for patients with CVD.

Table 86.2 provides a summary of the major determinants of cardiovascular risk.

Table 86.2 A summary of the major determinants of cardiovascular risk

Hypertension	Family history
Age	Ethnicity
Gender	Alcohol intake
Lipid profile	Diet
Smoking	Waist circumference
Diabetes mellitus	Psychosocial factors

Non-traditional risk factors

The risk factors just summarized can account for the vast majority of the attributable risk to CVD. The majority of primary and secondary prevention measures are aimed at addressing these. There are, however, a whole host of other recognized or emerging markers of increased cardiovascular risk. As many of these are much newer, our understanding of their mechanisms for increasing risk, whether they are casual or an effect of another process, remains up for debate. A summary of these factors is presented in this section.

It has long been recognized that **systemic inflammation** increases the risk of CVD. These observations were first made in sufferers of inflammatory disorders such as rheumatoid arthritis and SLE. Certain traditional risk factors such as hypertension and overt DM are more common in autoimmune inflammatory disorders, although this does not account for all of the excess risk. There has been intensive work assessing global biomarkers of inflammation in CVD. Several have been shown to predict increased cardiovascular risk, including **C-reactive protein, fibrinogen, D-dimers, and homocysteine** levels. These may serve alongside traditional risk factors to identify individuals at increased risk of cardiovascular events, as well as being potential targets for intervention.

JUPITER, a large randomized trial, has shown the benefit of using statin therapy in apparently healthy individuals with elevated high-sensitivity C-reactive protein levels, resulting in a significant reduction in major cardiovascular events. This shows the importance of continuing to look above and beyond traditional risk factors to identify patients at increased cardiovascular risk, with the aim of identifying proportions of the population that may benefit from risk factor modification. A variety of additional markers that reflect various elements of the complex systems governing inflammation, including pro- and anti-inflammatory cytokines, mediators of cellular adhesion, and matrix degradation enzymes, continue to be studied and may offer mechanistic insight as well as therapeutic potential.

Other biomarkers associated with increased cardiovascular risk include high haemoglobin levels, tissue plasminogen activator, and serum amyloid A; angiotensin-converting enzyme polymorphism; elevated von Willebrand factor levels; elevated gamma-glutamyltransferase levels; and overexpression of receptor activator of nuclear factor-kappa B ligand.

Genetic factors

CVD risk, including all the risk factors described so far, is ultimately determined by genetic factors, environmental factors, and the interaction between the two. Large-scale genome-wide association studies have identified several gene loci underlying susceptibility to CAD, and similar strategies are being employed in ischaemic stroke. This information has been used to develop genetic risk scores to identify individuals at increased risk, although the clinical utility and cost effectiveness of such scores are currently debated. What is clear is that there is limited association between these identified gene polymorphisms and traditional risk factors, suggesting that they act through previously unidentified pathways and thus providing new avenues for research into prevention and treatment strategies. Similarly, the epigenetics governing the interaction of genes with environmental factors in determining gene expression is increasingly recognized as important in contributing to cardiovascular risk, offering potential for earlier prevention and novel therapeutic options.

87 Diagnosis and investigation in suspected heart disease

Colin Forfar

Introduction

The past 20 years have seen significant changes in both the demographics and natural history of many cardiovascular diseases. Important reductions in case-fatality rates (such as in acute coronary syndromes) have resulted from improved diagnostics and treatment options and better understanding of natural history. For others (such as infective endocarditis), improvements have been limited and disappointing. While advances in therapy and the scientific evidence underpinning treatments have been crucial, the importance of accurate diagnosis has remained a key element for progress.

Many of the principles needed for diagnosis are constant: the pre-eminence of a focused accurate history, complete physical examination, and timely and relevant investigation endures. It is essential to have a secure knowledge of the strengths and limitations of interpretation of a frequently bewildering array of tests. Progress in this field has been rapid; advances in ultrasound, scintigraphy, and cardiac magnetic resonance stand out at the interface between structure and function central to good patient care.

History taking

Chest pain

There are few areas in acute medicine where accurate and informed history taking has such dominance in clinical assessment. Despite chest pain being one of the commonest reasons for hospital referral and emergency admission, the importance of a comprehensive history is frequently overlooked. **Myocardial ischaemia** presents in both stable and acute forms, the latter acute coronary syndromes comprising unstable angina, ST-elevation myocardial infarction, and non-ST-segment elevation myocardial infarction. Ischaemic chest pain is likely to be associated with an enzyme rise if lasting more than 15 minutes and if associated with autonomic upset, including nausea/vomiting, sweating, and collapse. Stable angina has predictable triggers (effort, emotion), relief within minutes of rest, and exacerbation by effort performed postprandially, uphill, or in cold windy conditions. Discomfort or pain may be central within the anterior chest but variations and radiation to back arms and neck/jaw are common. The history must be placed in context with careful review of cardiovascular risk factors (Table 87.1). These explain at least 90% of acute coronary events.

The pain of **acute pericarditis** has a sharper quality, with positional variation usually worst on lying and on inspiration. An intercurrent viral prodrome is common, and fever and a friction rub may aid diagnosis. Although **acute aortic dissection** is a much less common diagnosis, its pain is often of instant onset, is very severe, and may progress from the anterior chest to the back as the dissection spreads. Awareness of this diagnosis should prompt immediate investigation and emergency treatment. Aortic dissections are usually spontaneous; risk factors include hypertension, Marfan syndrome, and other hereditary and congenital aortopathies. **Musculoskeletal chest pain** may be a diagnosis of exclusion but is preferred as a positive diagnosis. It is localized, positional, and variable in intensity and onset, may have point tenderness, and is rarely associated with systemic upset. Reassurance, patient explanation, simple analgesia, and avoidance of unnecessary investigation all facilitate effective management. **Pleuritic pain** usually has a clear inspiratory trigger and associated lung symptoms, while **oesophageal pain** causes burning central discomfort associated with food and acid reflux.

Table 87.1 Independent risk factors for cardiovascular disease

		Hazard ratio
Modifiable	Smoking	2.9
	Hyperlipidaemia (ApoB; Apo-I)	3.3
	Hypertension	1.9
Potentially modifiable	Diabetes	2.4
	Psychosocial factors	2.7
	Obesity	1.6
Protective	Alcohol	0.9
	Regular exercise	0.9
	Diet (fruit and vegetables)	0.7

Adapted from *The Lancet*, Volume 364, issue 9438, Yusuf S, Hawken S, Ounpuu S, on behalf of the INTERHEART Study Investigators, Effect of potentially modifiable risk factors associated with myocardial infarction in 52 countries (the INTERHEART study): case-control study, pp. 937-52, Copyright (2004), with permission from Elsevier.

Non-cardiac chest pain should be an uncommon conclusion on history, as this diagnosis limits focused investigation and often encourages inappropriate tests.

Breathlessness

Precise history taking allows the separation of cardiogenic from non-cardiogenic causes in most cases. Restriction of exercise capacity should be carefully documented in both a time-defined and a patient-specific context; orthopnoea, paroxysmal nocturnal dyspnoea, and symptoms of congestion provide strong clues to a cardiogenic cause; fatigue may be prominent. **Heart failure** is no more than a symptom complex and demands a cause, whether that cause is systolic or diastolic pump dysfunction or is secondary to valvular or extra-cardiac causes (Box 87.1). The history will identify the dominance of left or right heart symptoms, whether they are congestive and associated with fluid retention or the result of impaired forward flow. It is important to remember that physical limitation may result from transient as well as persistent ventricular dysfunction, as seen, for example, in exertional breathlessness as an angina equivalent in a patient with multivessel coronary artery disease.

Symptoms of fluid retention, whether pulmonary or peripheral, follow activation of the renin-angiotensin-aldosterone cascade and a renal response, as well as arterial vasoconstriction. Understanding of the complex mechanisms involved has promoted many therapeutic advances in medical treatment.

Palpitations

Awareness of one's heart beating is common, and most causes are benign, reflecting **ectopic heart beats** or **situational tachycardia** with, for example stress, exercise, caffeine, or alcohol. Each can usually be identified by a careful history and asking the patient to describe or tap out their sense of the rhythm change. It is rarely necessary and frequently inappropriate to investigate such individuals beyond history examination and ECG. Over-investigation can promote somatization.

Paroxysmal arrhythmias, including **regular supraventricular tachycardia**, are often of sudden onset and may be associated with sweating, chest tightness, and altered consciousness. Duration,

Box 87.1 Principle causes of the syndrome of cardiac failure

Ventricular dysfunction (systolic dominates)

- ischaemic heart disease
- hypertensive heart disease
- dilated or hypertrophic cardiomyopathy
- restrictive cardiomyopathy

Valvular disease

- aortic stenosis and/or regurgitation
- mitral stenosis and/or regurgitation
- rarely, pulmonary or tricuspid disease

Congenital heart disease

- left-to-right shunt lesions (ventricular septal defect, atrial septal defect, persistent ductus, truncus arteriosus)
- obstructive lesions (aortic stenosis, coarctation, pulmonary stenosis)
- complex (cyanotic) disease (tetralogy of Fallot, Eisenmenger reaction, pulmonary and tricuspid atresia, palliated syndromes)

Extra-cardiac disorders

- endocrine (hyper- and hypothyroidism, pheochromocytoma, acromegaly, hypercalcaemia)
- constrictive pericarditis
- severe anaemia, high-output states

Combination

- renal failure
- COPD
- pulmonary hypertension

frequency, triggers, and associations (e.g. polyuria) give clues to diagnosis. Loss of consciousness is an important association that should always be investigated. **Atrial fibrillation** may be of sudden onset and variable rate and duration and may occur with or without established cardiovascular disease. The irregularity may be prominent or not apparent but investigation is required to establish cause and the need for rhythm-stabilizing or antithrombotic therapies.

Ventricular tachycardia is associated with structural heart disease in most cases and requires full investigation and treatment determined by appropriate risk stratification. Antiarrhythmic therapy must be safe, targeted, and effective. For those at high risk, device therapy allowing both anti-tachycardia pacing and defibrillation therapy has been a substantial step forwards.

Syncope

Transient loss of consciousness may reflect cardiovascular, neurological, or neurally mediated mechanisms (Box 87.2). A prodrome of sweating, light-headedness, yawning, and altered hearing or vision is typical in simple **vasovagal syncope**. Trigger factors (pain, distress, unpleasant images) may be present. Injury and incontinence are unusual. The history provides the greatest clue to diagnosis and guides simple management advice: most importantly, for the patient to lie flat (if needed, with legs in the air) and perform isometric exercises to block the stimulation of vagal efferents from ventricular mechanoreceptors responding to adrenergic stimulation and emptying of the ventricles. **Carotid baroreceptor hypersensitivity** reflects abnormal activation of the reflex involved in blood pressure control through afferent, central, or efferent pathways and may be elicited by stimulation of the baroreceptor pathway via carotid artery massage; profound bradycardia or a period of asystole may follow. **Central autonomic dysfunction**, seen in long-standing diabetes and certain neurodegenerative conditions, can cause postural syncope and presyncope resulting from orthostatic hypotension. Antihypertensive drugs can be associated with postural hypotension.

Cardiac syncope may follow paroxysmal bradycardia or tachycardia sufficient to cause abrupt loss of cardiac output. The classical Stokes–Adams attack requires rapid but transient loss of consciousness and posture with early recovery and no ictal features. Ventricular standstill for 7 seconds or longer, from complete atrioventricular

Box 87.2 Common causes of syncope

Cardiovascular

- bradycardia (sinus pause, atrioventricular block)
- tachycardia (ventricular or supraventricular)
- structural (fixed: aortic stenosis; dynamic: hypertrophic cardiomyopathy, right ventricular outflow tract obstruction (RVOTO), myxoma)
- channelopathy (e.g. long-QT syndrome, Brugada syndrome)

Neurally mediated

- vasovagal syncope
- carotid sinus hypersensitivity
- reflex (cough, micturition)
- autonomic (central: multisystem atrophy, parkinsonism; peripheral: diabetic)

Neurological

- cerebrovascular disease
- migraine
- neuropsychiatric

block or sinus arrest, will result in syncope. Both ventricular and supraventricular tachyarrhythmias may also cause loss of consciousness. Cardiovascular adaptive mechanisms after arrhythmia onset determine whether consciousness is lost. Ventricular tachycardia causing loss of consciousness is a potentially life-threatening event, and urgent investigation to determine the cause and the possible presence of structural cardiac disease is essential. Substrates include various structural cardiac diseases, both genetic and acquired, as well as less common channelopathies.

Examination

The periphery, pulse, and blood pressure

Careful general examination will always pay dividends. **Cyanosis** (whether central or peripheral) reflects arterial desaturation in the relevant arterial bed and may be secondary to alveolar dysfunction, right-to-left shunting at the cardiac or pulmonary level, or localized hypoperfusion. **Tachypnoea** and **orthopnoea** may suggest interstitial lung oedema of cardiac origin. **Peripheral vasoconstriction** and delayed capillary filling may reflect a low cardiac output. Examination of the hands may reveal **pallor** (anaemia), **finger clubbing** (hypoxaemia), or **splinter haemorrhages** (vasculitis or embolism). **Skin rashes** or **conjunctival haemorrhage** may also reflect vasculitis or embolism. Peripheral pulse examination assesses **rate, rhythm, pulse volume** (normal, increased or decreased), and **character** (slow, normal, or rapid upstroke), as well as **presence and synchronicity** in upper and lower limbs. An abrupt drop in cardiac output and blood pressure with inspiration (so-called pulsus paradoxus) may indicate cardiac tamponade from a pericardial effusion compressing the right heart and impeding diastolic filling of the left ventricle. **Hepatosplenomegaly, ascites, peripheral oedema, or vascular bruits** may point to a number of primary cardiac diagnoses. General systematic medical examination is rarely a wasted endeavour. For example, a patient with chest pain may have evidence of hypercholesterolaemia (arcus lipidus, skin xanthelasma, or tendon xanthoma), peripheral vascular disease, or evidence of chronic tobacco use.

Blood pressure is recorded after a short rest period, at the brachial artery, using a sphygmomanometer and suitably sized cuff, and while the patient is sitting or semi-recumbent. The standard for diastolic measurement is disappearance of heart sounds (so-called Korotkoff V), unless there is more than 10 mm Hg difference between this and sound muffling (Korotkoff IV) when both are recorded. Three readings over at least 15 minutes or at intervals provide a better reflection of overall pressure and prognosis and should form the minimum to describe a diagnosis of hypertension or guide the need for changes in antihypertensive therapy. Ambulatory home or automated 24-hour blood pressure monitoring is widely used to further define average levels and thresholds for treatment.

The jugular venous pulse

Despite ready evaluation at the bedside and considerable information content, the **jugular venous pulse (JVP)** is frequently inadequately or incorrectly assessed. Given the absence of valves in the jugular veins and superior vena cava, and the normal variation in right atrial pressure with respiration, assessment of venous pressure should be described qualitatively but accurately rather than quantitatively and inaccurately.

The most useful element is **whether the JVP is elevated and abnormal**. To determine this, the patient should be relaxed, semi-recumbent at 45°, and with the head supported. At this angle, neck venous pulsation should not be visible above the clavicle. If it is, then a suitable description will reflect its height against relevant landmarks and patient position: appropriate descriptors might say, for example, 'venous pressure visible at base of neck at 45°' or 'venous pressure halfway up the neck at 45°' or 'venous pressure beyond the angle of the jaw sitting upright', reflecting mild, moderate, or severe elevation, respectively. If the neck venous pulsation is not easily visible at 45°, the patient should be repositioned to be either flatter or more upright, depending on suspicions. While the presence of hepatojugular reflux can be helpful in defining a low-normal level, it is not a substitute for careful observation of the neck with suitable angled lighting to facilitate visualization of pulsation. Venous pulsation is rarely palpable unless very high and is usually obliterated by light pressure.

Waveform can be most useful diagnostically. The internal jugular vein is more reliable for this purpose, although the external vein has utility provided it is not obstructed. **Presystolic pulsation** (timed from the carotid pulsation on the opposite side) reflects the atrial contraction waveform (a wave). It may point to elevated right heart pressures from left ventricular disease, pulmonary hypertension, or pulmonary valve stenosis. It is, of course, absent in atrial fibrillation. **Systolic pulsation** occurs with ventricular contraction (v wave) and reflects tricuspid valve regurgitation. External restriction to ventricular filling such as occurs in constrictive pericarditis results in rapid but truncated ventricular filling in the presence of elevated filling pressure and a rapid so-called x and y descent after the a and v waves, respectively. Inspiration causes a paradoxical increase in venous pressure, whereas it usually falls. Intermittent surges in JVP (**cannon waves**) reflect atrial contraction against a closed tricuspid valve from ectopy, usually ventricular or AV dissociation, such as complete heart block.

The precordium

The position of the **apex beat** reflects the most inferior and lateral impulse of the heart against the chest wall and defines clinical cardiomegaly, provided there is no chest deformity and the mediastinum is central. The normally positioned apex beat is within the midclavicular line and the fifth intercostal space. The impulse may be **tapping** (reflecting a palpable first heart sound seen in rheumatic mitral stenosis), **diffuse** (reflecting underlying ventricular dysfunction), **heaving** (reflecting pressure loading from hypertension or aortic stenosis), **thrusting** (reflecting volume loading such as mitral or aortic regurgitation), or **rocking/dyskinetic** (usually reflecting previous myocardial infarction). It may also be impalpable. A **parasternal lift** suggests right ventricular loading. The presence of any thrills (palpable murmurs) should be recorded, whether apical or basal, and whether systolic or, occasionally, diastolic. The latter is unusual and often associated with a shortened diastole; it is easily mistaken without careful timing of the cardiac cycle.

Heart sounds should be recorded for number, type, and timing within the cardiac cycle. The **first** and **second** sounds reflect closure of AV valves (mitral and tricuspid) and outlet valves (aortic and pulmonary), respectively. The second heart sound commonly splits with inspiration, as the right ventricular systole prolongs with increased venous return, and closure of the pulmonary valve is delayed. Paradoxical splitting of the second sound (split in expiration and single in inspiration) occurs when left ventricular activation is delayed (as seen in left bundle branch block (LBBB) or severe left ventricular systolic dysfunction). The **third** and **fourth** sounds are low-pitched, best heard with the bell, and occur in mid- and late diastole, respectively. Both are ventricular filling sounds. The third sound

usually signifies ventricular dysfunction, although it is physiological in the young. The fourth sound is presystolic and often reflects a relatively stiff heart, such as that seen in hypertension. **Valve clicks** may be systolic or diastolic, reflecting opening of diseased mitral (diastolic and apical), aortic (systolic and basal), or pulmonary (systolic and less audible) valves from acquired (rheumatic mitral) or congenital (aortic or pulmonary) disease.

Heart murmurs should be documented as to timing within the cardiac cycle (systole and diastole are easily separated by palpation of the carotid pulse), site, radiation, duration, quality, and intensity. They reflect the turbulence of blood passing through the heart as a result of stenosed or regurgitant valves or outflow chambers, or as a result of abnormal connections between different chambers. The intensity of a murmur reflects a complex interplay between pressure gradient and blood flow, and does not necessarily reflect the functional significance of the lesion. For example, a small ventricular septal defect may generate a loud, harsh, but localized systolic murmur close to the left sternal border as a result of a high pressure gradient between the ventricles throughout systole but with low blood flow, whereas severe aortic stenosis with impaired left ventricular contraction (a life-threatening situation) may result in a rather quiet ejection murmur at the base and neck. A large atrial septal defect may create a substantial shunt from the left to the right atrium but this does not per se cause a murmur, as the pressure gradient is very small. High flow results from the compliance of the right-sided chambers. In this condition, turbulence and a systolic murmur are caused by increased flow across the right ventricular outflow tract; occasionally, a mid-diastolic murmur is caused by enhanced flow across the tricuspid valve.

Mitral regurgitation causes a pansystolic or mid-late systolic murmur located at the apex and radiating towards the axilla. Severity correlates to an extent with murmur intensity unless there is major structural disruption of the valve, such as that seen after myocardial infarction. There are many causes of mitral regurgitation (Box 87.3) but mitral valve prolapse and calcific degeneration of the mitral valve apparatus are most prevalent in the Western world. Clinical cardiomegaly and a thrusting apex beat reflect the severity of valve regurgitation. Intervention (repair or replacement) is based primarily on symptoms or evidence of progressive left ventricular enlargement. **Mitral stenosis** is usually of rheumatic origin. The first heart sound may be loud as a result of abrupt closure of thickened but still mobile leaflets. Left ventricular filling causes a rumbling, low-pitched, apical mid-diastolic murmur after valve opening (opening snap), with presystolic accentuation if sinus rhythm (and hence atrial contraction) persists.

Aortic stenosis causes an ejection systolic murmur which is located at the base and commonly radiates to the neck and apex. In an adult with acquired calcific disease, findings of clinical left ventricular hypertrophy, a narrowed pulse pressure, a slow-rising carotid pulse, and a soft or absent closing sound are all clues to severity of obstruction, and their presence mandates further investigation. **Aortic regurgitation** causes a high-pitched decrescendo murmur usually best heard upright in held expiration, at the lower left sternal edge. Again, severity does not necessarily relate to the intensity or duration of the murmur. With severe aortic regurgitation, high left ventricular filling pressure (which can approach aortic diastolic pressure) may soften the murmur in late diastole. Peripheral evidence of chronic aortic regurgitation, such as a collapsing pulse, nail-bed pulsation, and several other eponymous signs all reflect a chronically enhanced left ventricular stroke volume and reduced diastolic pressure. A pulse may be described as bisferious (or double impulse) in the presence of both stenosis and regurgitation.

Hypertrophic obstructive cardiomyopathy typically produces an ejection systolic murmur increasing in intensity in late systole as the severity of left ventricular outflow tract obstruction increases. The pulse may have a jerky character. Associated mitral regurgitation is common. Murmurs originating from the right side of the heart are less common. **Tricuspid regurgitation** is best diagnosed from assessment of the JVP but results in a soft systolic murmur at the base. **Pulmonary stenosis** produces an ejection systolic murmur at the base, more to the upper left sternal edge but often radiating to the back. An opening systolic click is common. **Pulmonary**

Box 87.3 Causes of mitral regurgitation

Mitral leaflet prolapse (chordal rupture)

- congenital/genetic
- Marfan syndrome
- Ehlers–Danlos syndrome
- osteogenesis imperfecta

Papillary muscle dysfunction secondary to ischemic heart disease (IHD)

- myocardial infarction with partial or complete rupture
- myocardial infarction or IHD with chronic with papillary muscle stunning or hypocontraction

Functional secondary to mitral annulus dilatation

- IHD
- dilated cardiomyopathy

Rheumatic heart disease

Vasculitis/inflammatory

- SLE
- polyarteritis nodosa
- other arteritides

Infective

- bacterial endocarditis

Other

- degenerative (calcific)
- atrial myxoma
- hypertrophic cardiomyopathy
- endocardial tumours (rare)

regurgitation is more common than is clinically apparent, although it is rarely of clinical significance. However, it may be a dominant issue in some forms of treated congenital heart disease, such as after repair of the tetralogy of Fallot or of right ventricular outflow tract obstruction.

The chest

In the appropriate clinical setting, basal crackles (crepitations) with tachypnoea suggest interstitial pulmonary oedema. Wheeze is, of course, most commonly secondary to obstructive airways disease but occasionally reflects bronchospasm from left heart failure. Evidence of chronic pulmonary disease is helpful to place cardiac disease in context.

General

A focused general examination of a patient with suspected cardiovascular disease is always rewarding. Many genetic diseases with important cardiovascular involvement may be recognized at the bedside (Table 87.2). Despite the considerable utility of both simple and sophisticated investigations in suspected cardiovascular

Table 87.2 Systemic genetic diseases with important cardiovascular involvement

Condition	Cardiovascular manifestations
Marfan syndrome	Aortic root dilatation/dissection; aortic and mitral regurgitation
Myotonic dystrophy	Atrial (ventricular) arrhythmias; heart block/conduction disease
Duchenne dystrophy	Cardiomyopathy; ECG changes
Becker dystrophy	Cardiomyopathy; ECG changes
Familial hypercholesterolaemia	Ischaemic heart disease
Osteogenesis Imperfecta	Aortic and mitral regurgitation
Haemochromatosis	Congestive cardiomyopathy
Down's syndrome	Atrioventricular septal defects; pulmonary hypertension: tetralogy of Fallot
DiGeorge syndrome	Tetralogy of Fallot; ventricular septal defect; aortic arch anomalies
Fabry's disease	Cardiomyopathy; hypertension

disease, as discussed in 'Investigation of cardiovascular disease', it is both poor quality and wasteful medical practice to rely on tests without careful consideration of all relevant clinical signs. Accurate interpretation of these signs not only points to the correct diagnosis but allows focused and valuable investigation and earlier and more effective treatment for the individual. The art of medicine must never be subordinate to overzealous application of its science.

Investigation of cardiovascular disease**ECG**

With surface traces of human heart activation in use for over a century, the **standard 12-lead ECG** (Figure 87.1) retains great utility, with virtues of availability, ease, and speed of recording and standardization.

The electrical signature created from bipolar (limb leads I, II, and III), complex bipolar (limb leads aVr, aVl, and aVf) and 'unipolar' (chest or V leads) recordings are primarily of value in the detection of **rhythm disturbances, activation changes, hypertrophy, and ischaemia/infarction**. However, they may also provide clues to several genetic cardiac abnormalities, such as **long-QT syndrome** or **Brugada syndrome**, and inherited muscle diseases—either cardiac-specific ones, such as **hypertrophic cardiomyopathy**, or ones that are primarily skeletal but with cardiac involvement, such as **myotonic dystrophy** or the **dystrophinopathies**.

The basic PQRST waveform reflects atrial activation from the sinus node (P wave), conduction across the atrium and delay through the AV junction (PR interval), ventricular activation (QRS), and repolarization (ST segment and T wave).

Rhythm disturbances

Ectopic activity may be of atrial, junctional, or ventricular origin and is rarely of clinical significance. Frequent atrial ectopic activity may be associated with both paroxysmal **atrial tachycardia** and **atrial fibrillation**. In the latter, atrial activation becomes chaotic, and mechanical function of the atrium is largely lost (Figure 87.2).

Atrial flutter usually persists and follows a re-entrant pathway, commonly within the right atrium. The typical flutter waves have a cycle length of 200 milliseconds, giving a rate of 300 bpm. The ventricular rate is dependent on refractoriness of the AV junction, which may conduct at 3:1, 2:1, or even 1:1, giving ventricular rates of 100, 150, and 300 bpm, respectively. **Regular supraventricular tachycardia** results from either an abnormal AV junction with zones of slow conduction (**atrioventricular nodal re-entrant tachycardia**) or the presence of an abnormal pathway separate from the junction (**atrioventricular re-entrant tachycardia**), which may or may not be discerned on the surface ECG, depending on its site and antegrade conduction properties (Figure 87.3).

Ventricular tachycardia may be paroxysmal or sustained. The threat depends on the speed and duration of the arrhythmia, the extent of associated structural cardiac disease, and the clinical syndrome. Syncope or presyncope is always significant. Most ventricular tachycardia of left ventricular origin occurs as a result of a zone of slowed or blocked conduction from scar tissue, for example, after myocardial infarction (Figure 87.4). Ventricular tachycardia originating from the right ventricle may reflect scarring or infiltration of the body or outflow tract, as seen, for example, in arrhythmogenic right ventricular cardiomyopathy.

Activation changes

Conduction delay may occur at atrial, junctional, or ventricular levels and is classified according to type and resulting rhythm. Impulse delay from the sinus node or into the atrium (sinoatrial disease) results in pauses in atrial activity. The presence of an accessory pathway separate from the AV node and inserting into ventricular muscle may produce a short PR interval and slurred upstroke to the QRS deflection (**Wolf–Parkinson–White syndrome**). **Heart block** may be first degree, where the PR interval is above 200 milliseconds; second degree, where AV conduction intermittently fails with incremental (**Wenckebach**) or fixed (**Möbitz**) AV delay on conducted beats; or complete, resulting in an escape ventricular rhythm of narrow or

Figure 87.1 The normal ECG. The leads are displayed in four columns. In addition, a rhythm strip (conventionally lead II) runs along the bottom of the ECG. The ECG is usually recorded at a paper speed of 25 mm/s, and at a sensitivity of 10 mm/mV, but these settings can be adjusted on most ECG machines, if required.

Reproduced with permission from Houghton and Gray, *Electrocardiography in Oxford Textbook of Medicine*, Oxford University Press, Oxford UK.

broad (Figure 87.5) configuration. Conduction abnormalities below the AV junction result in **right bundle branch block (RBBB)** or **LBBB**, with characteristic ECG signatures. In RBBB, delayed activation of the right side results in QRS delay at or beyond 120 milliseconds, and delayed activation of the right side. With LBBB, the usual left-to-right septal depolarization is lost, and left-sided activation is delayed. ST depression and T-wave inversion reflect abnormal repolarization when depolarization is abnormal, and have little diagnostic value. Pathological Q waves in the presence of LBBB, however, do reflect myocardial infarction.

Hypertrophy

The standard criterion for electrocardiographic evidence of **left ventricular hypertrophy** is the presence of an R wave >11 mm in

height in aV1 (90% specificity), or the sum of the heights of the S wave in V1 or V2 and the R wave in V5 or V6 being greater than 35 mm (75% specificity). However, both criteria lack sensitivity. The presence of repolarization changes (asymmetrical ST depression and T-wave inversion; the so-called strain pattern) enhances both the sensitivity and the specificity of the voltage criteria. Nonetheless, caution is needed in interpretation, especially in the young or those with a narrow chest.

Right ventricular hypertrophy shifts the frontal axis to the right and increases right ventricular activation, giving an increase in the R wave in right-sided leads, and a prominent S wave on the left.

Ischaemia/infarction

The hallmark for acute myocardial infarction is ST-segment elevation of 1 mm or more in two contiguous standard leads, or 2 mm

Figure 87.2 Atrial fibrillation with abnormal intraventricular conduction. The combination of left anterior hemiblock (giving marked left axis deviation) and complete right bundle branch block (delayed activation of the right ventricle resulting in an rsR' pattern in V1 and broad S wave in leads I and V6) is one form of bifascicular block.

or more in the chest leads. The cornerstone of immediate diagnosis of this emergency is provided by the history and the 12-lead ECG (Figure 87.6). Emergency coronary reperfusion, preferably by coronary angioplasty, thrombus extraction, and stenting, has become the gold standard for care and should be delivered as quickly as possible at an appropriate heart attack centre. Most but not all ST-elevation

myocardial infarction ECG patterns evolve over hours to days into pathological Q waves and T-wave inversion, but overlap with non-ST-elevation infarction is considerable.

Myocardial ischaemia usually changes the repolarization signature in the ECG, causing ST-segment depression and variable T-wave changes. ST elevation is less common. Exercise ECG (see 'Additional

Figure 87.4 An ECG showing several diagnostic features of ventricular tachycardia (VT). First, the QRS duration is approximately 200 ms. Second, there is a fusion beat (indicated by the arrow), which demonstrates independent P wave activity. Third, the morphology of the ECG is 'RBBB-like' (i.e. similar to that seen in right bundle branch block: positive in V1, negative in V6) but the appearance is highly atypical, with a deep S wave in V6, suggesting that the left ventricle is the origin of the VT. Fourth, the inferior leads are negative, further localizing the origin of the VT to the inferior portion of the left ventricle. Fifth, the aVR is positive, and the frontal ECG axis is 210°.

applications of ECG) is particularly useful, as changes are temporary and reflect the imbalance between supply and demand as the latter is increased through increases in heart rate and blood pressure.

Additional applications of ECG

Symptom-limited **treadmill or bicycle exercise testing** has considerable utility in the evaluation of patients with suspected symptomatic angina and in evaluating the prognosis in patients with established ischaemic heart disease. Parameters of value include symptoms, exercise capacity, systolic blood pressure, and ECG changes. Importantly, treadmill exercise ECG has limited, if any, utility in the evaluation of non-cardiac chest pain and should not be used as a 'rule out' where there is genuine diagnostic uncertainty after careful history and examination. In patients with suspected angina, the development of 1 mm horizontal or downsloping ST depression in two or more leads has 75% specificity and sensitivity for myocardial ischaemia; using ≥ 2 mm of ST depression as the criterion for diagnosis increases specificity but reduces sensitivity. Patients who are unable to exercise to within 90% of their predicted heart rate maximum for whatever reason should either undergo alternative testing for suspected ischemic heart disease or be regarded as being at high risk. Careful clinical supervision throughout the test and in recovery is essential, with interval assessment of systolic blood pressure. The diagnostic value of the ECG is often greatest in early recovery.

Ambulatory 24- or 48-hour ECG recording utilizes a solid-state or analogue recording device, typically with three chest leads, and is valuable for suspected tachy- or bradyarrhythmias, especially those that are transient or associated with altered consciousness. Ventricular tachycardia, atrial fibrillation, and various conduction blocks may be demonstrated and direct treatment. This analysis is, however, relatively labour-intensive and should not be used when the history strongly suggests simple ectopy and examination, and the ECG is normal.

Several **ECG event recording** devices are available and can be helpful for evaluating less frequent events suggestive of an arrhythmia. They do, however, require patient activation, and recording quality may be a limitation. For rare but potentially serious rhythm disturbances, an **implantable loop recorder** may be considered. These devices are relatively expensive, and their battery life is limited to several months, but they can be activated after a clinical event (e.g. on recovery from loss of consciousness) or programmed to record suspected tachy- or bradyarrhythmias (Figure 87.7).

Echocardiography

Few technologies in medicine have advanced as dramatically as **transthoracic echocardiography (TTE)** and **transoesophageal (TOE) echocardiography**. Both use high-frequency sound to penetrate tissues and reflect sound according to acoustic impedance.

Bone or air-filled structures such as the lung reflect sound and prevent penetration to deeper structures—hence the importance of a suitable acoustic window for good quality images. The Doppler shift principle allows quantification of blood or tissue velocity as a result of frequency shift of reflected sound moving towards or away from the receiving transducer. TOE utilizes the proximity of the oesophagus and stomach to the heart to eliminate acoustic interference. Three-dimensional reconstruction may provide added detail of valve structure and function.

Standard TTE allows long-axis, short-axis, apical, subxiphoid, and, if needed, suprasternal images of the heart. The technique is safe, simple, reproducible, and inexpensive, although it requires technical skill for image generation and interpretation. Atrial and ventricular dimensions at end-systole and diastole, myocardial thickness, systolic and diastolic function, valve function, and proximal great vessel structure can all be reliably determined in most patients. TTE should be a routine investigation in suspected valvular, myocardial, or congenital heart disease. A comprehensive TTE evaluation will take 20 minutes, and central physician-accessible image recording is becoming routine. However, there remains a place for limited study where only specific questions need to be answered, such as, for example, the presence of left ventricular hypertrophy in a hypertensive, or follow-up of known valvular heart disease.

TOE is usually performed with throat anaesthesia and under light sedation as needed. It has advantages of avoiding limited transthoracic windows and having close proximity to the heart and great vessels. Specific adult applications include detailed valve function, for example, accurate assessment of site and extent of anterior and posterior mitral valve regurgitation; valve detail, such as identification of vegetations in suspected endocarditis; and perioperative use

for monitoring ventricular and valve performance during and after cardiac surgery. Appropriate training and expertise is essential to maximize the information content of the investigation, particularly with the routine use of multiplane imaging. However, the procedure is invasive to a degree and should not be regarded as a substitute for careful clinical evaluation and TTE.

Stress echocardiography utilizes the changes in myocardial contraction as a result of induced ischaemia to identify the extent and severity of myocardial perfusion abnormality. Epicardial coronary anatomy is not defined but the functional significance of disease, important for prognosis, is indicated through observation of initially increased (without ischaemia) then hypocontractile (ischaemic) regional wall motion as myocardial oxygen demand is increased by intravenous inotrope infusion (commonly dobutamine). Infarcted areas remain thinned and akinetic or dyskinetic. Good TTE windows are essential for accurate diagnosis. Changes in global ventricular function can also be determined.

Nuclear scintigraphy

Intravenous injection of a radiolabelled chemical allows analysis of myocardial perfusion and/or myocardial function via a gamma camera, either by single-photon emission CT (SPECT; using thallium-201) or multiple-gated acquisition (using technetium-99m). SPECT imaging with sestamibi or tetrofosmin is useful in defining the extent and territory of coronary perfusion abnormality (Figure 87.8), guiding both prognosis and intervention threshold in patients with single or multi-vessel coronary artery disease, as well as identifying those in the low-risk group for which intervention on prognostic grounds would not be justified. The radiolabels used have a short physical and biological half-life. Several stress protocols are used, including treadmill or bicycle

Figure 87.8 Myocardial perfusion imaging with single-photon emission computed tomography (SPECT): An example of inducible hypoperfusion in the anterior wall and apex. Panels, from left to right, show representative vertical long-axis (VLA), horizontal long-axis (HLA), and mid short-axis (SAX) slices, with stress above rest. The white arrows show a perfusion defect which is present on the stress slices but which resolves at rest. Please see colour plate section.

Figure 87.11 To assess the fractional flow reserve, which is the ratio of the pressures distal to and proximal to a stenosis, a small flexible wire with two separate pressure sensors is placed across a candidate coronary artery stenosis. Under resting conditions (A), there is only a 10 mm Hg gradient (ΔP) across the lesion but, under maximal hyperaemia ('adenosine i.v.': B), the gradient increases markedly to 33 mm Hg, with a mean distal-to-proximal pressure ratio of 0.56. Thus, in this case, the fractional flow reserve indicates the presence of a functionally significant stenosis, and coronary angioplasty is indicated; FFR, fractional flow reserve; i.v., intravenous. Please see colour plate section.

exercise, as well as pharmacological 'stress' with either inotropic agents, such as dobutamine, or vasodilators, such as dipyridamole or adenosine. The latter two agents highlight relative perfusion defects in ischemic myocardium through the enhancement of perfusion in non-ischaemic areas. Injection of the radiochemical is typically undertaken at peak stress, with images acquired shortly thereafter compared to those acquired after a period of rest and re-equilibration.

The most valuable use of myocardial perfusion imaging is in assessing risk in patients with established ischemic heart disease and recurrent chest pain, and in determining risk in patients with intermediate probability of symptomatic coronary heart disease.

CT scanning

Contrast-enhanced CT has offered detailed images of cardiac structure and anatomical relationships for several decades. Well-established applications include evaluation of the great vessels, such as, for example, for identifying suspected aortic dissection or a major pulmonary embolism, or evaluating an aortic aneurysm or coarctation, but recent advances in signal processing and improvements in resolution have made coronary angiography a reality. Reasonable anatomical detail of proximal and mid-sized epicardial coronary vessels can be obtained with modest radiation exposure and avoidance of further investigation in suitably selected patients (Figure 87.9).

Cardiac magnetic resonance

Few technologies in medicine have advanced as rapidly as the application of cardiac magnetic resonance imaging (CMRI) to aid understanding of both structure and function of the human heart. By using a pulsed radiofrequency wave in the presence of a strong magnetic field, it is possible to create high-quality images in any plane, from the signal generated from the hydrogen nuclei in water and fat molecules. Spectroscopy adds the ability to obtain additional signals from phosphorus and other nuclei, thus affording insights into the metabolic state of cardiac tissue.

Although capital costs are high, and acquisition times relatively long, the technology allows detailed assessment of molecular structure, anatomical relationships, and myocardial perfusion without the use of ionizing radiation. Signal-processing techniques and the use of contrast-enhancing agents such as gadolinium allow identification of myocardial scar, tissue oedema, and assessment of valve regurgitant fraction and stenosis severity. Advanced techniques, such as 'four-dimensional flow', and the use of hyperpolarizing agents and high magnetic field strengths hold promise for future understanding of

disease pathogenesis. In the space of a few years, CMRI has become an invaluable and increasingly available tool for cardiologists, and an essential element for managing ischaemic, congenital, and valvular heart disease. Indeed, while it lacks the availability and relative simplicity of ultrasound, it has better signal-to-noise characteristics and will undoubtedly develop considerably in the coming years. An example of an image obtained via a current CMRI technique, steady-state free precession imaging, is shown in Figure 87.10.

Invasive assessments

Recognition that injection of iodinated contrast into cardiac structures, including the coronary arteries, can be safely performed now enjoys a 50-year history and remains a centrepiece of cardiovascular investigation and therapy. The modern cardiac laboratory should offer both diagnostic and treatment facilities, preferably 24/7, with a skilled team available to assess haemodynamics, anatomy, structure, and function, as well as offer planned and emergency reperfusion therapy for acute ST-elevation and non-ST elevation myocardial infarction and chronic stable angina. The rapid expansion of 'minimally invasive' procedures for the treatment of both congenital and acquired valvular disease, as well as expansion of interventional electrophysiology procedures, has meant that the 'cathlab' has become the home of diverse subspecialty interests in cardiology, and the hub of a cardiac centre. The role of invasive diagnostics will continue to decline as non-invasive technologies develop further, limited to an extent by more sophisticated applications such as coronary lesion-specific functional assessments (e.g. pressure-wire fractional flow reserve (see Figure 87.11) and new techniques for assessing coronary microcirculation, such as flow reserve and microvascular resistance. However, there remains a place for invasive haemodynamic assessment for the diagnosis of several cardiac conditions, including valve diseases, such as mitral stenosis, and constrictive and restrictive cardiomyopathy, and for diagnostic coronary angiography in dilated cardiomyopathy and left ventricular dysfunction, when an ischemic aetiology is suspected. Consequently, it is premature to write the obituary of the skilled cathlab diagnostic cardiologist.

88 Congenital heart disease in adults

Liz Orchard

Introduction

Congenital heart disease is the most common congenital abnormality, affecting 0.8% of births. There have been major advances in both the surgical and interventional treatment of congenital heart disease, with about 85% of patients surviving into adulthood. It is estimated that there are about 250 000 adults with congenital heart disease in the UK, and the number of adults with congenital heart disease now exceeds the number of children. As these patients live longer, the likelihood of them developing problems in later life increases. Despite this, there are fewer adult congenital cardiologists than paediatric cardiologists in the UK, and thus it is increasingly likely that general cardiologists and physicians will manage these patients either acutely or in outpatients. Cardiologists need to have an understanding of the complex physiology of these patients, in case they develop complications which require immediate treatment, such as heart failure, arrhythmias, thrombosis, or endocarditis.

Congenital heart disease can be divided into simple and complex lesions. Simple lesions include atrial septal defect (ASD), ventricular septal defect (VSD), patent ductus arteriosus (PDA), coarctation of the aorta, and left ventricular outflow tract lesions. More complex lesions include transposition of the great arteries (TGA), tetralogy of Fallot, single ventricle/Fontan physiology, pulmonary atresia/VSD or pulmonary atresia/intact septum, and Ebstein's anomaly of the tricuspid valve.

Simple congenital heart disease

Ventricular Septal Defect (VSD)

A VSD is a direct communication between the right and left ventricles, and is the commonest form of congenital heart disease, accounting

for about 20% of all lesions (see Figures 88.1 and 88.2). The size of the VSD and the degree of pulmonary vascular resistance determine the degree and direction of the right to left shunt.

VSDs can be described by position: muscular VSD (completely enclosed by muscle; 10%–15% of VSDs), perimembranous VSD (partly enclosed by the fibrous continuity between aortic and tricuspid valves; 80% of VSDs), or doubly committed VSD (partly enclosed by the fibrous continuity between aortic and pulmonary valves; 5% of VSDs). VSDs are also described according to size: it is 'restrictive' or 'small' when the defect limits the amount of blood flow between the left and right ventricles and therefore does not produce left ventricle dilatation, and is 'non-restrictive' when the defect is moderate or large (pulmonary flow:systemic flow > 1.5:1), leading to markedly increased pulmonary flow, initially with left ventricle dilatation, and failure to thrive and, if untreated, to the development of pulmonary hypertension.

Restrictive defects are not normally operated on unless the patient has suffered from infective endocarditis or has developed aortic regurgitation from prolapse of a leaflet. Non-restrictive VSDs are normally operated on in childhood to prevent the development of Eisenmenger syndrome (irreversible pulmonary hypertension due to a large systemic-to-pulmonary artery shunt).

Clinical findings for VSD

Patients with VSD have a holosystolic murmur—the smaller the defect, the louder the murmur. The apex is displaced if there is a significant shunt. P2 is loud if there is pulmonary hypertension.

Atrial Septal Defect (ASD)

An ASD is a communication between the right and the left atrium, and can be a secundum ASD (within the oval fossa; 75% of ASDs); a primum ASD, or partial atrioventricular septal defect (AVSD);

Figure 88.1 Schematic representation showing the sites of different types of ventricular septal defects (VSDs). The heart is in cross-section, viewed from the right ventricular aspect. I, muscular VSD; IIa, perimembranous outlet VSD; IIb, perimembranous inlet VSD; III, doubly committed subarterial VSD; AV, aortic valve, seen through VSD; PV, pulmonary valve; TV, tricuspid valve.

common atrioventricular junction with a cleft in the left atrioventricular valve; 10%–15% of ASDs); a sinus venosus ASD (communication between the superior or the inferior vena cava and the left atrium); or a coronary sinus ASD, where there is a connection between the left atrium and coronary sinus (see Figure 88.3).

Clinical presentation of ASD

Symptoms of an ASD include dyspnoea, palpitations, or a stroke due to a paradoxical embolism. If ASD is left untreated, excessive pulmonary blood flow leads to right heart dilatation. Signs of ASD include a pulmonary-flow murmur, a fixed, split, second heart sound, and cyanosis if there is a right to left shunt.

Complications of ASD

Complications of ASD include arrhythmia, which can present even after surgery; right heart failure; and paradoxical emboli. If ASDs are diagnosed in childhood, and the shunt is >2:1, they are generally repaired before school age. If they are repaired when the patient is <25 years old, then the patients should have normal long-term survival.

Atrioventricular Septal Defect (AVSD)

An AVSD is a communication at the junction of the atria and ventricles (see Figure 88.4). It can be classified as follows:

- Complete:* primum ASD and non-restrictive VSD, with a five-leaflet atrioventricular valve; >75% of patients with complete AVSD have trisomy 21
- Intermediate:* primum ASD and restrictive VSD, with abnormal but separate atrioventricular valves
- Partial:* ostium primum ASD, with a cleft in the mitral valve

Clinical findings for AVSD

As with other left-to-right shunts at the atrial or ventricular level, complete AVSDs are normally repaired in early infancy to prevent the development of Eisenmenger syndrome. Partial AVSDs are normally repaired in early childhood. Repaired AVSDs can still develop problems with mitral or tricuspid regurgitation or stenosis, subaortic stenosis, atrial arrhythmias, or complete atrioventricular block

Figure 88.3 Sites of atrial septal defects. The shaded area delineates the true atrial septum. Sinus venosus and coronary sinus defects are therefore not strictly atrial septal defects, although they permit shunting at atrial level; ASD, atrial septal defects; IVC, inferior vena cava; SVC, superior vena cava. PDA

PDA is a remnant of the fetal circulation, connecting the proximal left pulmonary artery to the descending aorta distal to the left subclavian artery. Its significance depends on the size of the duct, with large ducts leading to increased pulmonary blood flow and left atrial and ventricular dilatation, with the long-term development of pulmonary vascular disease and Eisenmenger syndrome.

Clinical findings for PDA

Patients with a PDA have a continuous murmur which is holosystolic, and diastolic loudest at the left upper sternal edge. If Eisenmenger syndrome develops, there is a differential cyanosis between upper and lower limbs. PDA can present with an acute endarteritis and should be closed if there is endarteritis or left ventricle volume overload; it can be closed percutaneously with a device.

Coarctation of the aorta

Coarctation of the aorta is a narrowing of the aorta, normally at the isthmus (site of the ductus arteriosus). In neonates/infants, it can present as an emergency when closure of the duct leads to underperfusion of the lower half of the body, and prostaglandins are required in order to maintain perfusion prior to operative correction. In adults it can present as an uncommon cause for hypertension which is resistant to treatment (see Figure 88.5). Coarctation can be associated with hypoplastic aortic arch, anomalies of head and neck vessels, intra-cerebral berry aneurysms, and a bicuspid aortic valve (50% of patients).

Investigations for coarctation of the aorta

Investigations for coarctation of the aorta include an ECG for left ventricular hypertrophy, an echo which will demonstrate a narrowed descending aorta with increased velocity, and a chest X-ray; in the latter, look for rib notching due to the erosion of the inferior edge of the ribs by dilated intercostal arteries. CT and MRI will give detailed information of the coarctation site.

Repair of coarctation

Coarctation is normally repaired in childhood by subclavian flap repair or end-to-end anastomosis. Patients who have undergone these procedures can develop aneurysms at the site of repair; these require intervention to prevent rupture. Patients with primary coarctation presenting in adulthood can be treated by direct stenting, due to the surgical risk of repair, from long-standing collateral vessels. Post repair these patients often remain hypertensive, despite adequate luminal patency, and there is little data on best medical therapy for hypertension.

Figure 88.5 MRI of a 20-year-old woman who presented with hypertension. There is a severe discrete coarctation (indicated by the arrow), multiple tortuous collaterals, and a dilated ascending aorta (indicated by the asterisk) associated with a bicuspid aortic valve.

Reproduced with permission from Warell, Cox & Firth, *Oxford Textbook of Medicine*, Fifth Edition Oxford University Press, Oxford, UK, Copyright © 2012.

Left ventricular outflow tract lesions

Left ventricular outflow tract lesions can be:

- subvalvar, if there is discrete fibrous membrane or a tunnel below the valve
- valvar, if there is a bicuspid aortic valve (this affects 2% of the population and is associated with an abnormality of aortic root tissue)
- supralvalvar, if there is aortic narrowing at the sinotubular junction (this is associated with Williams syndrome)

Clinical findings for left ventricular outflow tract lesions

Symptoms of left ventricular outflow tract lesions include dyspnoea on exertion, angina, and syncope if there is severe obstruction.

Clinically, patients may have a slow rising pulse, low pulse pressure, and ejection click if the valve is pliable, with an ejection systolic murmur. Treatment of subvalvar or supra-valvar obstruction is with surgical resection.

Valvar stenosis can be treated with either surgical valvotomy or resection, or balloon dilatation, and depends on the age of the patient at presentation, and the pliability of the valve (pliable valves can be balloon dilated and this is the preferred treatment in childhood). Treatment is warranted for:

- relief of symptoms
- severe aortic stenosis (peak gradient of 80 mm Hg, or valve area $<0.5 \text{ cm}^2/\text{m}^2$ on echocardiography)
- catheter peak gradient of 60 mm Hg
- an abnormal ECG response to exercise

In adults, aortic valve replacement is considered the best treatment.

Complex congenital heart disease

Transposition of the Great Arteries (TGA)

In TGA, the aorta arises from the right ventricle, and the pulmonary artery from the left ventricle; this condition can be simple or complex (i.e. associated with other lesions such as VSD; see Figure 88.6). Simple transposition is not compatible with life, due to the circulation being in parallel, unless mixing of the circulation occurs (e.g. via an ASD).

Two types of operation are undertaken for TGA:

Atrial switch: In this procedure, the Senning or Mustard procedure (see Figure 88.7; also see 'Surgical procedures'), the atrial blood is redirected so that the right ventricle receives pulmonary venous blood, making it the systemic ventricle; the left ventricle receives systemic venous blood. Most adults who have undergone repair for TGA have had this operation. However it has now been replaced by the arterial switch.

Arterial switch: In this procedure, the aorta and the pulmonary artery are 'switched' to the correct position, and the coronary arteries are reimplanted (see 'Surgical procedures').

Figure 88.6 Schematic representation of complete transposition of the great arteries (discordant ventriculo-arterial connections). The pulmonary and systemic circulations are completely separate once the arterial duct and foramen ovale close. Without intervention, the condition is not compatible with life; Ao, aorta; LA, left atrium; LV, left ventricle; MV, mitral valve; PA, pulmonary artery; RA, right atrium; RV, right ventricle; TV, tricuspid valve; * patent arterial duct; ** patent foramen ovale.

Figure 88.7 Repair of complete transposition of the great arteries, via atrial switch (using the Senning procedure or the Mustard procedure); Ao, aorta; LV, left ventricle; MV, mitral valve; PA, pulmonary artery; PVA, pulmonary venous atrium; RV, right ventricle; SVA, systemic venous atrium; TV, tricuspid valve.

Reproduced with permission from Warell, Cox & Firth, *Oxford Textbook of Medicine*, Fifth Edition Oxford University Press, Oxford, UK, Copyright © 2012.

Complications post atrial switch

Most complications occur post atrial switch and include:

- atrial tachyarrhythmia (atrial re-entrant tachycardia) and bradyarrhythmia (sinus node dysfunction) secondary to extensive atrial surgery
- right ventricle dysfunction, and failure of the systemic right ventricle
- tricuspid regurgitation
- risk of sudden death
- obstruction of systemic or pulmonary venous pathways ('baffle obstruction')

Post-atrial switch patients are complex to manage; their arrhythmias often require ablation, and they need a thorough assessment of right ventricle dysfunction and the severity of tricuspid regurgitation, and this can be difficult to obtain. However, the final pathway for a failing systemic right ventricle is transplantation.

Complications post arterial switch

There is 88% 15-year survival post arterial switch; however, complications include:

- pulmonary stenosis
- dilatation of the neo-aortic root, with aortic regurgitation
- coronary ostia stenosis due to reimplantation

Congenitally corrected TGA

In congenitally corrected TGA (ccTGA), the ventricles are inverted, the systemic venous return reaches the pulmonary artery via the left ventricle, and the pulmonary venous return enters the right ventricle and is pumped to the aorta; therefore, the circulation is 'physiologically' corrected (see Figure 88.8). It is a rare condition: ccTGA cases constitute $<1\%$ of all cases of congenital heart disease. In addition, 95% of ccTGA cases are associated with other lesions (e.g. VSD, pulmonary stenosis, aortic stenosis, AVSD, Ebstein's anomaly of the tricuspid valve).

Complications of ccTGA

If ccTGA is not associated with other abnormalities, it can present late in life. However, complications include development of heart block, systemic ventricular failure, and tricuspid regurgitation.

Management of ccTGA

Management of ccTGA includes pacing and the use of angiotensin-converting enzyme (ACE) inhibitors and diuretics for right ventricular dysfunction. Tricuspid valve replacement is

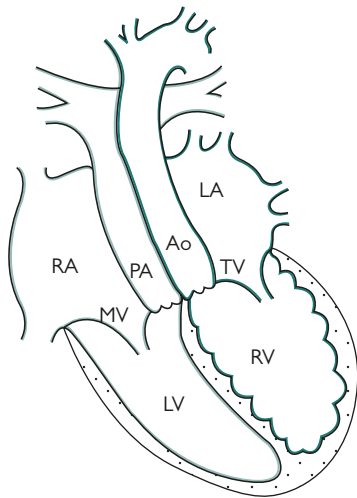

Figure 88.8 Schematic representation of congenitally corrected transposition of the great arteries (discordant atrioventricular and ventriculo-arterial connections). The circulation is congenitally physiologically 'corrected' in that systemic venous blood reaches the pulmonary artery (via the left ventricle) and pulmonary venous blood reaches the aorta (via the right ventricle); Ao, aorta; LA, left atrium; LV, left ventricle; MV, mitral valve; PA, pulmonary artery; RA, right atrium; RV, right ventricle; TV, tricuspid valve.

Reproduced with permission from Warell, Cox & Firth, *Oxford Textbook of Medicine*, Fifth Edition Oxford University Press, Oxford, UK, Copyright © 2012.

undertaken for severe tricuspid regurgitation, and transplantation is performed for end-stage right ventricle dysfunction. Children presenting with tricuspid regurgitation can be considered for an anatomical repair via either a double switch (atrial and arterial switch) or a combined Senning–Rastelli operation (see 'Surgical procedures').

Tetralogy of Fallot

In tetralogy of Fallot, anterocephalad deviation of the outlet septum leads to hypertrophy of septoparietal trabeculations, and right ventricular outflow tract obstruction (RVOTO)/pulmonary artery obstruction (see Figure 88.9).

Figure 88.9 Schematic representation of tetralogy of Fallot. Anterocephalad deviation (indicated by the asterisk) of the outlet septum creates a ventricular septal defect, subpulmonary stenosis, aortic overriding of the crest of interventricular septum, and secondary right ventricular hypertrophy; Ao, aorta, LA, left atrium, LV, left ventricle, PA, pulmonary artery, RA, right atrium, RV, right ventricle.

Reproduced with permission from Warell, Cox & Firth, *Oxford Textbook of Medicine*, Fifth Edition Oxford University Press, Oxford, UK, Copyright © 2012.

This produces:

- VSD
- right ventricle hypertrophy
- aortic override

The timing and presentation of patients in infancy depends on the severity of the RVOTO, as a significant obstruction leads to early cyanosis. Tetralogy of Fallot is associated with 22q deletion in 15% of patients, with the presence of a right aortic arch in 25% of patients, and with coronary artery abnormalities in 10% of patients. Patients are offered primary repair before 18 months of age (VSD closure, relief of RVOTO—sometimes with patch enlargement of pulmonary valve annulus), but neonates who are symptomatic with cyanosis are palliated with a Blalock–Taussig (subclavian-to-pulmonary artery) shunt (see 'Surgical procedures').

Complications of tetralogy of Fallot

The following complications are seen with tetralogy of Fallot:

- pulmonary regurgitation with right ventricle enlargement and dysfunction
- RVOTO—at the infundibular, pulmonary valve, or branch pulmonary level
- aneurysmal dilatation of the right ventricular outflow tract (predisposes to ventricular tachycardia)
- residual VSD
- aortic regurgitation +/- aortic root dilatation
- arrhythmia:
 - atrial: scar-related intra-atrial re-entrant tachycardia
 - ventricular: associated with right ventricle dilatation; a QRS duration >180 milliseconds is a marker for sustained ventricular tachycardia

Management of tetralogy of Fallot

Pulmonary valve replacement is recommended for patients with severe pulmonary regurgitation; the replacement can be either surgical or percutaneous.

The development of arrhythmia requires a thorough haemodynamic and electrophysiological assessment.

Single ventricle circulation

The term 'single ventricle circulation' encompasses many complex congenital abnormalities; however, in all of them, the pulmonary and the systemic venous returns drain into a functional single ventricle that then pumps to both the pulmonary artery and the aorta (see Figure 88.10).

Figure 88.10 Schematic representation of tricuspid atresia. Systemic venous blood leaves the right atrium via an atrial septal defect and mixes with pulmonary venous blood in the left atrium. The left ventricle thus supports both the systemic and pulmonary circulations, and the patient is cyanosed. The rudimentary right ventricle does not play a functional role; Ao, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

Reproduced with permission from Warell, Cox & Firth, *Oxford Textbook of Medicine*, Fifth Edition Oxford University Press, Oxford, UK, Copyright © 2012.

There is also a more rudimentary ventricle, with the functional ventricle being either of left or right morphology. However, due to the complexity of the anatomy, a biventricular repair is not surgically possible.

The anatomical configurations of a single ventricle defect include:

- tricuspid atresia (rudimentary right ventricle)
- unbalanced AVSD
- a double-inlet left ventricle, often with transposition and pulmonary stenosis
- pulmonary atresia with a hypoplastic right vesicle

The Fontan procedure, used to repair single ventricle circulation, was originally a direct right atrium to pulmonary artery anastomosis; however, due to complications, patients now undergo a total cavopulmonary connection. This procedure combines a Glenn anastomosis (superior vena cava to the pulmonary artery connection), which is performed before the patient is 1 year of age, and a connection from the inferior vena cava to the pulmonary artery, which is created either via a lateral tunnel (using the atrial wall) or through an extra-cardiac conduit and is made when the patient is around 5 years old (see Figure 88.11; also see 'Surgical procedures').

Complications of single ventricle circulation

Complications associated with single ventricle circulation are:

- arrhythmias:
 - atrial re-entrant tachycardia (commonly)
 - sinus node dysfunction
- thromboembolic events

- right atrial dilatation, and hepatic dysfunction due to high hepatic venous pressure
- protein-losing enteropathy (intestinal protein loss leading to low serum protein, peripheral oedema, and ascites)
- ventricular dysfunction
- obstruction/leak of Fontan pathway
- systemic venous collateralization
- failing Fontan

Survival at 15- to 20-years after the Fontan procedure ranges from 60 to 85%, and is influenced by the underlying cardiac diagnosis. Further interventions (e.g. Fontan revision, pacemaker implantation) are commonly needed.

Eisenmenger syndrome

Eisenmenger syndrome arises due to excess pulmonary blood flow from a left to right shunt leading to the development of irreversible pulmonary vascular disease. The shunt can occur at atrial, ventricular or arterial level, and with the development of pulmonary hypertension, the shunt reverses to right to left and cyanosis occurs. Patients with Down's syndrome are at increased risk of developing Eisenmenger physiology. The over-all incidence is reducing, due to early diagnosis of congenital heart disease and consequently earlier surgery, with better outcomes.

Complications of Eisenmenger syndrome

The complications associated with Eisenmenger syndrome are:

- the development of iron deficiency

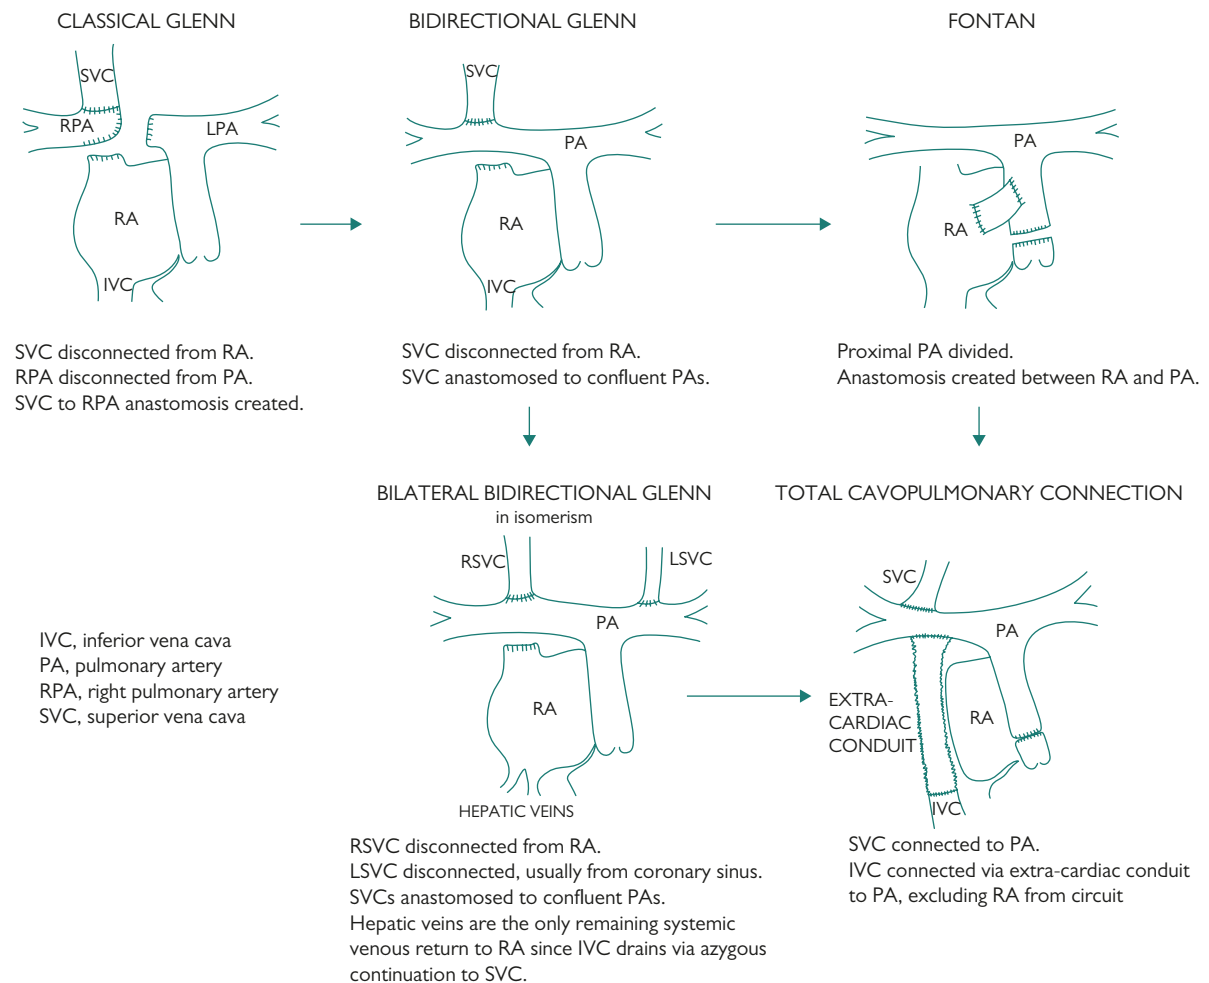

Figure 88.11 Evolution of the Fontan and total cavopulmonary connection operations; IVC, inferior vena cava; PA, pulmonary artery; RPA, right pulmonary artery; LSVC, left superior vena cava; RSVC, right superior vena cava; SVC, superior vena cava.

Reproduced with permission from Warell, Cox & Firth, *Oxford Textbook of Medicine*, Fifth Edition Oxford University Press, Oxford, UK, Copyright © 2012.

- thromboembolism (pulmonary/cerebral emboli), despite an increased bleeding risk
- hyperviscosity due to secondary erythrocytosis
- arrhythmias (supraventricular or ventricular)
- sudden cardiac death
- bacterial and viral infections (endocarditis, cerebral abscess, and pneumonia)
- gallstones and cholecystitis
- gout
- acne

Treatment includes avoiding dehydration, hypovolaemia, and nephrotoxic drugs. Avoid general anaesthesia and non-cardiac surgery, if possible, and any general anaesthesia should be performed by a cardiac anaesthetist. Consider pulmonary vasodilator therapy (e.g. non-selective endothelin receptor antagonists), once the patient has been referred to a pulmonary hypertension centre.

Ebstein's anomaly of the tricuspid valve

In Ebstein's anomaly, the tricuspid valve has an abnormal structure and position, with apical displacement of the valve. This leads to atrialization of the right ventricle, with a dilated right atrium, and a valve that may become severely regurgitant. Most cases are associated with an ASD or patent foramen ovale, which may result in some cyanosis; 25% of patients have associated Wolff–Parkinson–White syndrome.

Presentation of Ebstein's is variable, depending on the degree of leaflet displacement and the amount of right ventricle dysfunction and tricuspid regurgitation. Management should include closure of the atrial shunt, and tricuspid valve surgery, if very regurgitant, before the right ventricle starts to fail; but this operation is complex and requires specialist surgical input.

Cyanosis

Cyanosis occurs when there is a right-to-left shunt or decreased pulmonary blood flow and is clinically detectable when saturations drop below 85%. Cyanosis can be associated with low, normal, or high pulmonary vascular resistance.

Complications of cyanosis

The complications associated with cyanosis are:

- the development of secondary erythrocytosis, which is a physiological adaptation to hypoxia in order to increase oxygen-carrying capacity; it may cause hyperviscosity symptoms but is not associated with an increased risk of cerebrovascular accident; previously, venesection was recommended for therapy but now it is known that it causes iron deficiency and so is not beneficial
- thrombocytopenia
- coagulopathy (haemorrhage or thrombosis); often very difficult to manage
- renal impairment (due to glomerular proteinuria); can lead to iatrogenic renal decompensation if the patient is dehydrated or given nephrotoxic agents
- cerebrovascular accidents due to paradoxical emboli, and cerebral abscess
- acne
- gout
- pigment gallstones

Emergencies in adult congenital heart disease patients

Adult congenital heart disease patients are at risk from specific emergencies, including:

- haemoptysis:
 - This is a major cause of death, especially if pulmonary hypertension is present.
 - The patient will need resuscitation.
 - Lower the blood pressure, as pulmonary artery pressure is equivalent to systemic blood pressure—use beta blockade.
 - Intubate if the bleeding is uncontrolled.

- An urgent CT chest is needed to determine the source of the bleeding; causes can be in situ pulmonary artery thrombosis, bleeding from pulmonary arteriovenous malformations, or collaterals and infection.
- Management issues to consider include IV access with an air filter, due to risk of paradoxical embolism in cyanotic patients.
- tachyarrhythmias:
 - These can be either atrial or ventricular.
 - These are poorly tolerated and require cardioversion.
 - DC cardioversion is often safer than drug treatment.
- cerebral abscess

In addition, it is important to:

- avoid vasodilators, as these may increase cyanosis
- avoid iatrogenic renal dysfunction
- maintain haemoglobin post-operatively, to maintain adequate oxygen carrying capacity

Surgical procedures

Arterial switch

Arterial switch is an operation used to repair TGA, in which the great arteries are 'switched' (see 'TGA'). It involves moving the coronary arteries from the aortic root to the neo-aorta.

Blalock–Taussig shunt

In a classical Blalock–Taussig shunt, there is a direct end-to-side anastomosis of the subclavian artery to the pulmonary artery. In a modified Blalock–Taussig shunt, there is a graft from the subclavian artery to the pulmonary artery.

Glenn shunt

In a Glenn shunt, an anastomosis of the superior vena cava to the pulmonary artery is created.

Fontan procedure

This is a palliative operation for patients with single ventricle physiology, where blood from the systemic veins return to the lungs without passing through the subpulmonary ventricle (see 'Single ventricle circulation'). There are three versions of this operation:

Classic Fontan: in this version, a direct connection is made between the right atrium and the pulmonary artery

Björk modification: in this version, a valved conduit is made between the right atrium and the right ventricle

Total cavopulmonary connection: in this version, a connection is made from the inferior vena cava to the pulmonary artery via either a lateral tunnel or an extra cardiac conduit, with anastomosis of the superior vena cava to the pulmonary artery (Glenn shunt)

Mustard/Senning operation

The Mustard/Senning operation is an atrial switch, used to repair TGA (see 'TGA'). Venous blood is 'baffled' across to the contralateral ventricle by using synthetic material (Mustard) or fashioning an atrial wall (Senning).

Norwood operation

Divided into stages, the Norwood operation is used to repair a hypoplastic left heart and the associated hypoplastic aortic root and ascending aorta. Stage I, which is performed in neonates, involves the reconstruction of the aorta by using the pulmonary valve and trunk to create a neo-aorta, with the pulmonary blood supply being from a modified Blalock–Taussig shunt. In Stage II, which is performed in patients <1 year old, the Blalock–Taussig shunt is taken down and a bidirectional Glenn operation is performed. In Stage III, which is performed when the patient is <5 years old, the Fontan circulation is completed.

Rastelli operation

The Rastelli operation is used to repair TGA, VSD, and pulmonary stenosis (see 'TGA' and 'VSD'). The VSD is closed by a patch

connecting the left ventricle to the aorta, with a conduit from the right ventricle to the pulmonary artery.

89 Chronic stable angina

Cheerag Shirodaria and Sam Dawkins

Definition of the disease

Chronic stable angina is a condition where patients experience symptoms of chest pain of a particular character (e.g. angina pectoris; see 'Typical symptoms and less common symptoms') on effort only, due to atherosclerotic coronary artery disease. The hallmarks of stable angina are as follows:

- There must be stable atherosclerotic coronary artery disease (but see 'Other diagnoses that should be considered'), resulting in luminal narrowing(s) in one or more of the major epicardial coronary arteries. Such atheroma can be detected using appropriate technology (see "'Gold-standard" diagnostic test' and 'Acceptable alternatives to the gold standard'). Not all angina chest discomfort is due to atherosclerotic coronary disease—some is due to aortic stenosis, and some to hypertrophic cardiomyopathy; rarely, pulmonary hypertension is the cause.
- Symptoms must have been present for some time, say, arbitrarily, 2–3 months, as opposed to the case for angina of acute coronary syndromes, where symptoms have been present only for a few weeks at most—see Chapter 90. This time limit is important, as it allows the differentiation of symptoms from coronary obstruction due to coronary atheroma (generally a stable pathology, with a lower risk of infarction) from symptoms of coronary obstruction due to atheroma with superadded thrombus, which can be quite unstable and lead suddenly to total coronary obstruction with all its attendant risks.
- Symptoms must be stable, that is to say, from day to day, roughly similar levels of effort must be required for provocation. The pathological translation of this is that the degree of coronary obstruction is stable, as opposed to the rapidly changing coronary obstruction found in acute coronary syndromes.

Typical symptoms and less common symptoms

The hallmarks of angina are (1) its relationship with exercise, (2) the nature of the pain, and (3) its duration. All must be present for diagnosis; if they are not, atypical angina or non-cardiac chest pain is diagnosed, symptoms which have a lower chance of being due to obstructive coronary disease (see Chapter 10).

The relationship of the pain with exercise

Reliable provocation of symptoms by exercise and rapid relief by rest is the hallmark of angina. Symptoms are **never** present before exercise, build up during exercise, and are **fully relieved** by 2 minutes rest. Angina pectoris occurs when myocardial oxygen demand exceeds supply; atherosclerotic coronary obstruction, unless very severe, has no impact on resting coronary blood flow, but reduces the increase in coronary blood flow during exercise, explaining the effort dependence of symptoms. If oxygen demand exceeds supply, ischaemic metabolites build up, are sensed, and produce the feeling of angina. Angina can occur without exercise in situations with tachycardia, as tachycardia (1) increases myocardial oxygen demand and (2) reduces myocardial blood flow, as coronary blood flow occurs during diastole, and an increased heart rate reduces the proportion of time spent in diastole. Tachycardia due to an arrhythmia (e.g. atrial fibrillation, supraventricular tachycardia) is sufficiently profound to cause angina in those with less severe coronary disease. However, although the tachycardia associated with emotional stress can provoke angina, as the tachycardia and changes in myocardial oxygen demand and supply are relatively mild, patients need to have severe coronary disease for emotional

stress to provoke angina. Put another way, those with angina during emotional stress often have angina on fairly minimal effort, and one should have a low threshold for angiography in such patients.

The nature of the pain

Angina is often described as discomfort, pressure, or tightness in the chest, rather than as pain. It can radiate to the jaw, either arm, and less commonly to the back. Patients cannot usually localize the pain precisely and may diffusely rub their hand over the anterior chest wall, indicating the general area of discomfort; if they place a finger precisely at the site of pain, ischaemia is unlikely to be the cause. Two **atypical symptoms** may occur in some: (1) breathlessness, rather than angina (this is common in the elderly, and diabetics, and is termed 'angina equivalent'; the clues to angina are the effort dependence of symptoms, the rapid relief by rest, and the presence of coronary disease risk factors); and (2) effort intolerance without specific features (usually this is due to age, physical deconditioning, arthritis, or other factors; however, rarely, it relates to coronary disease—the clue is that the alternative diagnoses have usually reduced exercise capacity over years, whereas coronary disease can reduce exercise capacity over just a few months).

Some patients interpret the pain as being gastrointestinal in origin, and use phrases such as 'burning'; alternatively, they interpret it as being arthritis, particularly if symptoms are felt around the shoulder; as always, the clue to the real diagnosis is the effort dependence of symptoms, and relief with rest.

The duration of the pain

In chronic stable angina, pain does not last more than a few minutes. If it occurs during exercise, patients rest, or take glyceryl trinitrate, thus rapidly relieving symptoms. Pain that lasts longer is either due to an acute coronary syndrome (the clue is that the prolonged pain is similar in quality to previous angina, although longer lasting and may be more severe) or, conversely, not due to a coronary problem at all (random episodes of prolonged pain going back many months lasting ≥ 20 –30 minutes and never related to exercise). Far and away, the commonest cause of prolonged chest pain is non-cardiac pain.

Classification of angina severity

Angina severity is classified using a scale devised by the Canadian Cardiovascular Society (see Table 89.1).

Demographics and etiology of the disease

Stable angina in nearly all cases relates to atherosclerotic coronary artery disease, which in turn relates to the various risk factors for atheroma, including age (the most important factor), diabetes, obesity (especially centripetal), smoking, hypertension, poor genes (sometimes seen as an adverse family history of documented coronary disease in first-degree relatives ≤ 65 years old (coronary death or coronary revascularization only), male gender, psychosocial stress, and dyslipidaemia. A diet high in fruits and vegetables, moderate alcohol intake, and exercise are protective, and relevant on a population basis. The biology of atheroma is complex; in essence, cholesterol enters the vessel wall (this is a normal physiological process), is trapped (perhaps as it has been altered by smoke products), and excites an inflammatory response, resulting in the formation of scar tissue and the atheromatous plaque. This can build up by extension of this process, or by incorporation of super-added thrombus, so narrowing the lumen.

Table 89.1 Angina severity scale

Grade	Definition
I	Ordinary physical activity, such as walking or climbing stairs, does not cause angina. Angina occurs with strenuous, rapid, or prolonged exertion at work or recreation.
II	Slight limitation of ordinary activity. Angina occurs on walking or climbing stairs rapidly, walking uphill, walking or climbing stairs after meals, or in cold, in wind, or under emotional stress, or only during the few hours after awakening. Angina occurs on walking more than 2 blocks on the level and climbing more than 1 flight of ordinary stairs at a normal pace and in normal condition.
III	Marked limitations of ordinary physical activity. Angina occurs on walking 1 to 2 blocks on the level and climbing 1 flight of stairs in normal conditions and at a normal pace.
IV	Inability to perform any physical activity without discomfort—anginal symptoms may be present at rest.

Complications

The major complications in chronic stable angina are myocardial infarction and/or sudden death. On average, the annual incidence is 1% but prognosis varies widely. Factors associated with an adverse prognosis are (1) multiple risk factors for coronary disease, especially if they cannot be controlled (e.g. smoking; diabetes is strongly associated with a worse outcome); (2) symptoms on low levels of effort; (3) impaired left ventricular function, especially if the ejection fraction is <40%; (4) extensive coronary disease involving all three major coronary arteries; (5) proximal coronary disease affecting the left main stem or proximal left anterior descending coronary artery; and (6) increasing age.

A few patients develop the following complications:

Arrhythmias: The commonest is atrial fibrillation, which is serious due to its thromboembolic risk. Most patients presenting with atrial fibrillation in middle age and beyond need to have coronary disease excluded.

Heart failure: This is not rare in chronic coronary disease and has a number of different etiologies and treatments:

- Chronic coronary disease increases the fibrous content of the heart, making it stiffer and leading to diastolic heart failure—the clue is good left ventricular systolic function, absence of critical coronary disease, and a raised biomarker for heart failure, such as BNP.
- Chronic coronary disease, if severe, can lead to a reduction in resting coronary blood flow—often this results in myocardial infarction but, in a few, the reduction in blood flow can be compensated for by cells shutting down energy expensive functions, such as contractile functions; that is, the heart can hibernate. The heart then enlarges and systolic performance falls away. Patients usually present with a history of progressive breathlessness over several months; the clue is that, on echocardiography, left ventricular wall thickness remains good, the ECG does not show Q waves, and angiography shows critical coronary disease. It can be difficult, however, to fully determine whether the myocardium is hibernating or dead—cardiac magnetic resonance (lack of scar tissue) and a myocardial perfusion scan (tracer uptake) may distinguish between these two possibilities. Revascularization improves hibernating myocardium, but not a scarred heart.
- Critical proximal multivessel coronary disease can result in heart failure—such patients often present with life-threatening pulmonary oedema. When the acute episode has been treated, good left ventricular function is found echocardiographically and troponin levels are only minimally elevated, but angiography shows either left main or severe three-vessel coronary artery disease.
- There may be isolated disease affecting a papillary muscle; the commonest is disease in the circumflex coronary leading to ischaemia or infarction, papillary muscle dysfunction, and severe mitral regurgitation, presenting as pulmonary oedema. Outside the episode, there may be very little mitral regurgitation, and normal left ventricular function. Angiography usually shows disease limited to the circumflex coronary artery.

Approach to diagnosing the disease

The principle is one valid for most diseases: reach a diagnosis from the history, exclude other possible causes of angina from the physical

examination (particularly aortic stenosis and other causes of left ventricular outflow tract obstruction, and also, where possible, pulmonary hypertension), and confirm the diagnosis using an appropriate test (see ‘‘Gold-standard’’ diagnostic test’). Always in your own mind decide whether the patient is experiencing angina before you order tests—if you do not do so, you will not know what to do with the results! Once you have diagnosed chronic stable angina, assess left ventricular function (usually done echocardiographically), then make an assessment of the severity of the coronary disease—there are many ways to do this, and part of the skill of the clinician is to decide which test is appropriate for which patient. Once you know the diagnosis, how intrusive symptoms are, left ventricular function, and coronary extent, you can plan the best management, be it medical alone or revascularization also.

Other diagnoses that should be considered

The other causes of anginal chest pain include aortic stenosis, pulmonary hypertension, and cardiomyopathy with left ventricular outflow tract obstruction. Asthma and COPD can give rise to similar symptoms. Other causes of chronic chest pain include musculoskeletal pain, various gastrointestinal pains (including gastroesophageal reflux disease, oesophagitis, peptic ulcer disease, and dyspeptic syndromes; very rarely, biliary pain is felt predominantly in the chest), non-cardiac chest pain, and pain referred from the back, due to either degenerative back disease or entrapment neuropathy. Pain from metastatic deposits is a very rare cause of pain, occasionally seen.

‘Gold-standard’ diagnostic test

The gold standard for assessing coronary arteries is coronary angiography but this test is far from perfect. It is an anatomical test, assessing coronary artery luminal diameter in the resting artery, rather than a functional test measuring ischaemia. This is an important difference, as the anatomical appearances of the severity of the luminal narrowing only have a modest relationship with the impairment in coronary artery function. Most narrowings that are $\geq 90\%$ of the luminal diameter impair coronary blood flow, whereas most that are $\leq 50\%$ do not. However, in between, it is difficult to predict whether the arterial narrowing impedes blood flow or not. In other words, while as a generalization the more severe the narrow in an artery appears angiographically, the more likely it is to reduce peak blood flow, there are many exceptions—angiographically minor narrowings can have very major functional impacts and, perhaps surprisingly, angiographically severe narrowings can have very modest impacts on function. It is the degree of functional impairment that relates to symptoms and to prognosis—it is the functionally most damaged arteries that are most likely to have plaque rupture and so provoke a myocardial infarct. This means that, in chronic stable angina, it is more difficult to decide whether to undertake revascularization based on the angiogram than it is in an acute coronary syndrome, where the main aim of percutaneous coronary intervention is to stabilize an unstable segment of artery with plaque rupture and superadded thrombus—and usually the trouble with the artery has been diagnosed by the finding of an elevated troponin and ECG changes, allowing localization of the affected artery. In chronic stable angina, it is important to demonstrate ischaemia prior to revascularization, and this can be done by a variety of investigations.

Acceptable alternatives to the gold standard

For many patients, a non-invasive diagnostic strategy is appropriate. Those with a high pretest probability of coronary artery disease should undergo angiography as the first-line investigation, as should some with equivocal or conflicting results from non-invasive testing. A low threshold for angiography is appropriate in those with known coronary disease, previous acute coronary syndrome, or revascularization.

Exercise tolerance testing is a useful inexpensive means to assess suspected coronary disease. A treadmill or a bicycle is used for incremental exercise. Exclusions to exercise tolerance testing include the physical incapacity to exercise, left bundle branch block, and pre-excitation (e.g. Wolff–Parkinson–White syndrome). Ideally, the test should be carried out while the patient is off anti-anginal medication.

There are several endpoints: the patient reaching $\geq 85\%$ maximum heart rate (where, for men, the maximum heart rate is $220 - \text{age}$ and, for women, the maximum heart rate is $210 - \text{age}$) without symptoms (a negative test); limiting chest pain or diagnostic ECG changes (ST depression > 2 mm, ST elevation > 1 mm); or a sustained fall in systolic blood pressure (> 10 mm Hg). The duration of exercise, development of chest pain, and extent of ECG changes are used to risk stratify patients, for example, by using the Duke treadmill score.

Exercise testing is inaccurate in low risk or asymptomatic individuals, as false positives outweigh genuine positives, rendering the test poorly specific; in addition, false negatives are also common in this group, rendering the test poorly sensitive. Patients at high risk of having coronary artery disease (from the history and risk factors) should be referred for angiography, as exercise tolerance testing will not provide any further information.

Coronary CT angiography (CTA) is a non-invasive test currently undergoing rapid development and evaluation. High-resolution, three-dimensional pictures of the heart and great vessels are produced during coronary CTA, allowing demonstration of luminal architecture, and so the presence of coronary artery disease. It is particularly useful in evaluating the patency of coronary bypass grafts. In order to obtain optimal image quality, the subject's heart rate should be < 60 bpm, which is achieved by using either beta blockers or ivabradine.

Investigations useful for the demonstration of myocardial ischaemia

Dobutamine stress echocardiography (DSE) or a **myocardial perfusion scan (MPS)** is used if the exercise test is not possible or is inaccurate (resting ECG changes, left bundle branch block). They are also of particular use in asymptomatic patients with diabetes. The choice between these modalities generally depends on staff and equipment availability; their accuracy is comparable.

In DSE, baseline transthoracic echocardiography is carried out prior to starting a dobutamine infusion (which increases heart rate and contractility), and then echocardiography is repeated as the heart rate increases and during recovery. Myocardial contractility is impaired where there is coronary ischaemia (regional wall motion abnormality). Regional wall motion abnormalities at rest are likely to be due to infarcted muscle, which will not benefit from revascularization.

In an MPS, exercise or a coronary vasodilator (adenosine or dipyridamole) is used to increase myocardial blood flow; then, a radioactive isotope (technetium or thallium) is injected, which is taken up by the myocardium in proportion to myocardial blood flow. The heart is then imaged using a CT gamma camera, allowing reconstruction of a three-dimensional image of the heart. It is then possible to determine if there are differences in uptake between different areas of the heart, in other words, if areas of the heart are supplied by stenosed arteries. The scans are undertaken at rest (allowing diagnosis of previous myocardial infarction), and following stress, to determine areas of ischaemia.

A fractional flow reserve (FFR) technique, using pressure wires and adenosine vasodilatation, can also be used (see Chapter 97).

Other relevant investigations

A resting ECG should be performed in patients presenting with chronic chest pain; this is to provide evidence of previous infarction,

or left ventricular hypertrophy (associated with hypertension and coronary disease). Occasionally—though rarely—there is evidence of an acute coronary syndrome. The resting ECG is usually normal in chronic stable angina.

Resting transthoracic echocardiography is appropriate in chronic chest pain to exclude valve disease or cardiomyopathy, and to examine left ventricular function in breathless patients. Patients with ECG abnormalities such as left bundle branch block or ECG evidence of a previous myocardial infarction should also undergo echocardiography.

A chest X-ray should be undertaken in patients with angina, mainly to exclude other smoking- and age-related diseases that may impact on angina treatment, and, occasionally, suspected valve disease, heart failure, or suspected pulmonary disease.

Prognosis and how to estimate it

Prognosis in chronic stable angina is variable but overall annual mortality is 1%, as is risk of non-fatal myocardial infarction. Patients at higher risk are those with multiple cardiovascular risk factors, multi-vessel disease, proximal stenosis, severe angina, or reduced left ventricular function.

Treatment and its effectiveness

The aims for treating angina are to treat symptoms and improve prognosis. Beta blockers are the first-line treatment, and further agents should be added if anginal symptoms persist.

Drugs to improve symptoms

Drugs used to improve symptoms are:

- short-acting nitrates:
 - These relieve angina.
 - Glyceryl trinitrate spray and sublingual tablets have rapid onset (1–4 minutes) and last for 15–30 minutes.
 - They cause vascular smooth muscle relaxation, systemic vasodilatation (reducing afterload and cardiovascular work), and coronary vasodilatation (improving myocardial oxygen delivery) and reduce preload through venodilatation.
 - Side effects include flushing, headache, dizziness, and hypotension.
 - Nitrates taken prior to planned exertion can increase exercise capacity.
 - Patients should seek medical advice should angina not improve 5 minutes after one glyceryl trinitrate spray.
- longer-acting nitrates:
 - These can be used for patients with frequent symptoms.
 - Isosorbide dinitrate acts for 4–8 hours, and isosorbide mononitrate for 6–12 hours.
 - Nitrate tolerance develops quickly, and having a nitrate-free period each day prevents this.
- calcium channel blockers:
 - The longer-acting dihydropyridines (e.g. amlodipine) cause coronary and systemic vasodilatation through vascular smooth muscle relaxation.
 - These drugs, and more so the short-acting dihydropyridine nifedipine, cause a reflex tachycardia and so are often used in conjunction with beta blockers.
 - The non-selective calcium channel blockers (verapamil and diltiazem) also cause vascular smooth muscle relaxation and additionally have a negative effect on heart rate and myocardial contractility, which reduces myocardial oxygen demand still further.

Approaches used to improve the prognosis

Approaches used to improve the prognosis are:

- the use of aspirin
- aggressive risk factor modification:
 - Reduce blood pressure to $\leq 130/80$ mm Hg.
 - Use statins to achieve a target LDL cholesterol level of ≤ 2.6 mmol/l.
 - Offer patients assistance with smoking cessation and dietary advice.

- the use of angiotensin-converting enzyme (ACE) inhibitors (or angiotensin receptor blockers)
 - These should be considered in patients with a history of myocardial infarction, chronic kidney disease, diabetes, or heart failure.

Drugs that have an effect on both symptoms and prognosis

Drugs that have an effect on both symptoms and prognosis are:

Beta blockers: These reduce myocardial oxygen demand by reducing contractility, heart rate, and blood pressure; they also improve oxygen supply through a reduction in heart rate, thus lengthening diastole and therefore the time for myocardial perfusion. Regular use results in reduced frequency of anginal attacks and increased exercise tolerance. In patients who have had a previous myocardial infarction, or in systolic heart failure, beta blockers have prognostic benefit.

Nicorandil: This is a potassium-channel activator that causes venous and arterial vasodilatation. It also has a modest effect on prognosis.

Exercise

The importance of regular exercise in patients with chronic stable angina should not be underestimated. A regular exercise programme improves exercise tolerance and aids weight loss. In lower-risk patients, a programme of regular exercise can be as effective as

revascularization, both in terms of exercise capacity and event-free survival, at considerably lower cost.

Revascularization

Diagnostic angiography with a view to revascularization (percutaneous coronary intervention or coronary artery bypass grafting) should be considered in patients with severe angina which is significantly affecting quality of life despite medical therapy, or in those with high-risk markers.

Prevention

See Chapter 343.

90 Acute coronary syndromes

Cheerag Shirodaria and Sam Dawkins

Definition of the disease

The term 'acute coronary syndrome' (ACS) includes unstable angina, ST-elevation myocardial infarction (STEMI), and non-ST-elevation myocardial infarction (NSTEMI). The difference between these three syndromes is as follows:

- In STEMI and NSTEMI, there is evidence of myocardial necrosis, as evidenced by raised cardiac enzymes, specifically, the very sensitive cardiac biomarker troponin. STEMI is diagnosed when the ECG shows persisting ST elevation in an appropriate territory consistent with STEMI, whereas, in NSTEMI, there can be any or no ECG changes, or very transient self-limiting ST elevation.
- In unstable angina, there is no myocardial necrosis, and troponins are normal. The ECG is as for NSTEMI and often shows no change, ST depression, or T-wave inversion.

The prognoses in STEMI and NSTEMI are identical; unstable angina has a better prognosis than either STEMI or NSTEMI.

Typical symptoms and less common symptoms

A patient with an acute coronary syndrome usually presents with ischaemic chest pain. A careful history should establish the nature of pain. Ischaemic chest pain usually comes on over minutes, rather than second or hours, and is often described not as a pain but rather a pressure or tight band around the chest. The pain is usually poorly localized, and patients are unable to put a finger on the precise location. If there is radiation, it is classically to the throat and the left arm, although pain radiating to the right or both arms is more strongly predictive of myocardial ischaemia. Symptoms associated with the pain can be variable. Nausea, indigestion, and an unpleasant taste in the mouth are associated with gastro-oesophageal reflux but these can also be features of myocardial infarction. Equally, an improvement in the pain with glyceryl trinitrate spray does not necessarily indicate cardiac disease. Sweating is more strongly predictive of cardiac disease and is generally not associated with gastro-oesophageal disease.

Certain patients are more likely to have atypical symptoms. Those with diabetes mellitus tend to have less severe pain and may present with the complications of silent myocardial infarction (including heart failure or confusion). Female patients are more likely to use words such as 'sharp' or 'burning' to characterize their pain.

Demographics and etiology of the disease

Coronary artery disease remains the largest cause of mortality and morbidity in industrialized countries. Increasing age, positive family history, male gender, and smoking all increase the risk of atherosclerosis. Other risk factors include diabetes mellitus, dyslipidaemia, hypertension, lack of exercise, and obesity (especially centripetal 'abdominal' obesity), and psychosocial stress.

Natural history

The pathological process that leads to acute coronary syndrome begins with atherosclerosis, which is a disease of the vessel intima, due to cholesterol and lipid deposition and the infiltration of inflammatory cells. This leads, in mature lesions, to a lipid-rich core enclosed by a fibrous cap within the vessel intima. Plaques may occlude the vessel lumen, or may become 'unstable', when

increased inflammatory activity causes weakening of the fibrous cap. Plaque rupture may lead to mural thrombosis and acute vessel occlusion, or downstream showering of emboli to occlude the microvessels. These pathological events result in a continuous spectrum of clinical syndromes, from stable angina, to unstable angina, to myocardial infarction.

Complications of ACS

Complications associated with ACS are as follows:

Arrhythmias: Arrhythmias are common in ACS:

- Atrial fibrillation commonly complicates ACS, and is associated with more severe coronary disease.
- Ventricular tachycardia can complicate ACS, in which case it is often associated with remote myocardial infarction (producing an 'arrhythmogenic' scar) with new myocardial ischaemia—and it is the two together that are necessary for such ventricular arrhythmias.
- Ventricular fibrillation complicates ACS and, indeed, the commonest cause of sudden cardiac death is ventricular fibrillation related to myocardial ischaemia. It occurs in up to 30% of ACS, although, as this occurs usually very early on, it is now not common in patients once they reach hospital and receive modern therapy.
- Heart block can complicate myocardial ischaemia, especially when the right coronary artery is involved.

Myocardial rupture: Myocardial rupture was previously a relatively common cause of death in ACS. Traditional teaching was that this occurred 2–7 days post myocardial infarction, and could be either of the free wall, resulting in cardiac tamponade and immediate death, or internal, resulting in a ventricular septal defect; the low pressure in the right ventricle would result in blood shunting from the left ventricle into the right ventricle, so diminishing systemic cardiac output and resulting in prominent right heart failure. The clues to the development of a ventricular septal defect are a patient becoming less well, though happy to lie flat; peripheral oedema; and a loud pansystolic murmur along the left sternal edge. Cardiac ultrasound is diagnostic; angiography confirms the diagnosis and diagnoses the extent of coronary disease. Surgical repair can be life-saving. Mortality is high.

Heart failure: Heart failure can be due to several mechanisms:

- the death of contractile tissue, related to the size of the myocardial infarction
 - hibernation of contractile tissue (see Chapter 92)
 - papillary muscle dysfunction, usually due to circumflex territory ischaemia—this can result in torrential mitral regurgitation; severe pulmonary oedema, so that the patient automatically sits bolt upright; and profound hypoxaemia; the murmur of mitral regurgitation is usually absent or very quiet; cardiac ultrasound is usually diagnostic; treatment is immediate intubation, angiography, and surgery; even in the best units, mortality is high
- Pericarditis:* Pericarditis usually only complicates a full-thickness ('Q-wave') myocardial infarct rather than other forms of ACS.
- Dressler's syndrome:* Dressler's syndrome (see Chapter 109) is rare, and usually only with larger infarcts (full-thickness Q wave).

Some 30% of patients die during a myocardial infarct—of these deaths, some 70%–80% occur in the first few hours, usually before patients reach hospital. Put another way, patients who reach hospital are immediately in a better prognostic group, as they have survived

this early death rate. Treatments (see 'Treatment and its effectiveness') to improve the prognosis of those reaching hospital are vital, but perhaps overall of less importance than encouraging patients with possible ACS to come to hospital early.

Approach to diagnosing the disease

The general approach is to diagnose an ACS from the history, use the examination to exclude complications or other important possible diagnoses, and confirm the diagnosis with the ECG and biomarkers. See also Chapters 9 and 10.

History

About half of patients with an ACS have previous stable angina now complicated by an ACS. Diagnosis here is easy; they have had effort-related ischaemic chest pain, usually only on good levels of exercise, then often a period of symptoms on increasingly mild effort, culminating in rest pain, usually lasting >20 minutes and not responding to glyceryl trinitrate. Likewise, some patients have had a previous **proven ACS**; they present with symptoms similar to those for the last ACS. The diagnosis here is also easy. The difficulty arises when patients present 'out of the blue', and the diagnosis here can be difficult, as the pain may be atypical, or confused with gastrointestinal (or other) causes of pain, or masked by other symptoms (breathlessness, malaise, confusion, 'off legs') that have a very broad differential diagnosis. As an ACS is so common, it not infrequently presents in an atypical fashion or in the elderly, in whom dementia may render the history unreliable. It is important, therefore, to have a high index of suspicion in any adult presenting to hospital with appropriate risk factors and symptoms that are not immediately diagnosed as something else, and which just might represent an ACS. In these patients, undertake standard tests to exclude an ACS (sequential ECGs, biomarkers), always bearing in mind that the interpretation of these tests will require a much broader differential than in those presenting with typical symptoms.

Investigations

ECG

The ECG is the crucial investigation in suspected ACS. It should be carried out at presentation, every 2–3 hours, and whenever there is chest pain.

If the ECG remains resolutely normal despite prolonged rest pain, the chances of an ACS are significantly reduced—one diagnosis to beware of is circumflex coronary artery disease, which can present with an ACS with a normal ECG, as this part of the heart can be electrically quiet. However, many high-risk ACSs are excluded if the troponin remains negative despite repeated measurements. Put another way, most circumflex territory ACSs, despite possibly having normal or near normal ECGs, have abnormal troponins.

If the ECG shows fixed abnormalities (but see 'Other diagnoses that should be considered in possible ACS') that do not change, then the chance of an ACS is probably neither increased nor decreased. If the ECG shows signs classically associated with a high-grade coronary stenosis, such as pan-anterior (or inferior), **deep T-wave inversion**, the chances of an ACS have increased very substantially—however, even pan-anterior T-wave inversion (an ECG so highly correlated with a high-grade stenosis in the proximal portion of the left anterior descending (LAD) coronary artery that it has been termed a 'LAD-syndrome ECG') is not universally due to high-grade coronary disease, and similar ECGs can be seen with pulmonary emboli (quite commonly), takotsubo cardiomyopathy (much more common than once realized—see 'Other diagnoses that should be considered in possible ACS') and hypertrophic cardiomyopathy (a much less likely diagnosis). The basic principle, as in virtually all investigations, remains that one should use the investigation to increase or decrease the probability of the disease in question, and not absolutely rely on any one test to diagnose the illness, unless you know that test to be completely reliable.

If the ECG shows 'dynamic' ST changes (i.e. the ST segments go down—or up—over time), it is likely that there is an ACS and, in particular, a high-risk ACS (although there are many

exceptions—and, in particular, beware that hyperventilation can result in ST-segment shift).

Troponin (or other biomarkers)

Biochemical markers are both used in the diagnosis of myocardial infarction and also have prognostic value once the diagnosis has been made (from the degree of the elevation). Troponin is a regulatory enzyme that is found almost exclusively in cardiac muscle; there are two subtypes, T and I. Serum troponin rises with myocardial damage, and the extent of elevation correlates with the size of infarction. Troponin levels start to rise 3–4 hours post myocardial infarction, reach a peak over the next 12 hours, and return to undetectable levels after around 10 days. For this reason, a single negative troponin result does not exclude myocardial infarction and it is important to make sure a further sample is taken 6–12 hours after admission and after any subsequent episodes of chest pain.

There are many causes of a troponin rise, other than an ACS. Correlation with the clinical condition of the patient, in addition to serial troponin measurements and measurement of renal function, helps to correctly diagnose myocardial infarction as the cause of a troponin rise (see Table 90.1). As is true of most tests, minor deviations from normal are common and result in the most diagnostic doubt. You should be most aware that **small rises in troponin do not make the diagnosis of an ACS**. You must use all the clinical clues to determine whether patients with small increases in troponin have an ACS or some other condition. It is only when the troponin is very elevated that you can be reasonably sure the test is diagnostic of ACS.

If the ECG remains normal, troponin is not elevated, and symptoms settle, then patients fall into a low-risk category, even if they have unstable angina. Most such patients can be safely discharged and undergo expedited outpatient evaluation.

Other diagnoses that should be considered in possible ACS

Chest pain with positive troponin

See Table 90.1. Exclude **renal failure** as a cause of elevated troponin, in which case the differential is that of chest pain with negative troponin. The commonest alternative of chest pain with raised troponin is a **pulmonary embolus**, which remains in the differential even when the troponin is negative.

Stress (takotsubo) cardiomyopathy is an increasingly recognized cause of chest pain and raised troponin in women. The typical case involves a middle-aged woman who has had an emotional event (an argument, bad news, etc.). Ischaemic-sounding chest pain develops and patients present rapidly to hospital (perhaps as the vast majority of those affected are women—men with chest pain present late to hospital). The ECG sequentially develops changes that look like those for a proximal LAD lesion, that is to say, pan-anterior T-wave inversion, and the troponin is mildly raised. At angiography (which must happen as the differential diagnosis is an acute coronary event), the coronary arteries are shown to be smooth and unobstructed. However, a left ventriculogram demonstrates the classic abnormality of this condition, which is akinesis of the anteroapical and distal inferior wall of the left ventricle, a contractile abnormality beyond the distribution of a single coronary artery. The contractile abnormality can be profound, with overall left ventricular function sometimes being severely impaired (although contraction in the unaffected segments is normal or even hyperdynamic). Treatment is with angiotensin-converting enzyme (ACE) inhibitors, and beta blockers, to improve left ventricular function. Prognosis is generally good; even in the absence of treatment, left ventricular function returns to normal within a few months. Complications are rare, but the occasional patient does die during the acute episode, usually of arrhythmias. The exact pathophysiological mechanism remains obscure.

Chest pain with negative troponin

One cause of chest pain with negative troponin is unstable angina, the clues to which are in the history, and often from an abnormal

Table 90.1 Non-coronary conditions with troponin elevations		
	Frequency as a cause of troponin elevation	Notes
Renal failure (either acute or chronic)	Universal	The commonest cause of mild–moderate troponin elevations in acute medical admissions (commoner than ACS); very few have an ACS—the clue to an ACS is a changing troponin despite stable (albeit abnormal) renal function; if the renal function is changing, it is difficult to diagnose ACS from changing troponin—rely more on the history and ECG
Tachyarrhythmia	Common	Sustained (20–30 mins) of tachyarrhythmia very commonly results in elevated troponin in the absence of an ACS; this is very common with SVT (where heart rates are in 160–190 bpm), and not rare with AF; arrhythmias should be >140 bpm to result in raised troponin
Pulmonary embolus	Common	Troponin rises with a pulmonary embolus are very common; the extent of rise correlates to the severity of right ventricular strain, and so to the size of the pulmonary embolus, and the outcome
Acute left ventricular failure	Common	Any cause of acute left ventricular failure will give moderate elevations in troponin even when no ACS is present—diagnose an ACS here on the basis of the history (ischaemic chest pain), ECG changes, and if troponin rises are substantial
Inflammatory disease (e.g. myocarditis or myocardial extension of endocarditis/pericarditis)	Common	Very frequent in myocarditis—clues are tachycardia and heart failure; common in pericarditis, where it indicates some myocarditis (and has implications for recommending exercise restriction until the patient is better)
Acute neurological disease (e.g. stroke, subarachnoid haemorrhage)	Not rare	Like major ECG changes (e.g. pan-anterior T-wave inversion), troponin elevations are not rare in subarachnoid haemorrhage; their extent correlates with the severity of the neurological insult
Cardiac contusion (e.g. from deceleration injury (RTC), ablation, insertion of a new pacing lead, cardioversion, or endomyocardial biopsy)	Common	Usually easily diagnosed from the history
Critically ill patients (especially those with respiratory failure or with sepsis)	Common	Troponin rises (just like ECG changes) are common in critical illness, and it can be difficult to determine whether this reflects the illness, or a complicating ACS—if doubt exists and diagnosis alters treatment, coronary angiography may be necessary
Drug toxicity (e.g. Adriamycin, 5-fluorouracil, Herceptin)	Not common	Probably common in those suffering cardiac toxicity from these drugs, but rare in those not suffering cardiac toxicity
Aortic dissection Aortic valve disease Hypertrophic cardiomyopathy Infiltrative diseases (e.g. amyloidosis, haemochromatosis, sarcoidosis, scleroderma) Hypertensive crisis	Rare	These do occur, although usually the etiology is fairly clear
Hypothyroidism	Rare	Occurs, but very rarely seen in acute admissions

Abbreviations: ACS, acute coronary syndrome; AF, atrial fibrillation; bpm, beats per minute; ECG, electrocardiography; RTC, road traffic collision; SVT, supraventricular tachycardia.

ECG, either at presentation or over the next few hours. If patients are troponin negative, have **persistently** normal ECGs, their pain settles, and there is no other obvious alternative diagnosis, they fall into a very good prognostic group, even if they have unstable angina. However, many patients presenting with prolonged chest pain, normal ECGs, and negative troponin do not have any cardiac illness.

Aortic dissection, oesophageal rupture, and other causes

Additional diagnoses that should be considered include:

- aortic dissection; this rare, but still seen several times a year in most units (see Chapter 103)
- oesophageal rupture; this is usually obvious from a history of vomiting followed by severe chest pain
- causes that lead to raised troponin levels but do not relate to the heart (see Table 90.1)

'Gold-standard' diagnostic test

The diagnosis will often be settled by coronary angiography. The advantage of this technique is that it can be diagnostic and lead to the therapeutic procedure of percutaneous coronary intervention (PCI).

Acceptable diagnostic alternatives to the gold standard

In reality, coronary angiography is usually not required to make the diagnosis, as this can be made on the basis of clinical symptoms, ECG, and troponin:

STEMI: In STEMI, the history and ECG are sufficient to make the diagnosis. Coronary angiography is helpful, as it is the essential prelude to PCI, a procedure associated with marginally improved survival compared to thrombolysis.

The rest of the acute coronary syndrome spectrum: For the rest of the acute coronary syndrome spectrum, a combination of history, examination, ECG, and cardiac biomarkers can be used to make the diagnosis. If, despite this, the diagnosis remains in doubt, it can be clarified by using invasive or non-invasive tests. Not infrequently, however, patients have major comorbidities, and introducing empirical therapy is appropriate—an approach should always be guided by an experienced cardiologist, preferably an interventional cardiologist. Put another way, it is important that interventional cardiologists see all patients with possible ACS, regardless of the patient's age or comorbidity, to ensure that the largest number of patients benefit from appropriate medical therapy and, where relevant, targeted interventional therapy.

Imaging

It is also possible to diagnose an ACS using nuclear cardiology techniques—radioactive technetium is injected (at ≤ 2 hours of chest pain) and then the heart is imaged with a CT gamma-radiation-detecting camera. If the scans are normal, myocardial perfusion is normal and this excludes most high-risk ACS cases—provided ECGs and biomarkers remain negative, these patients can be safely discharged to return the following day for the stress component to evaluate any ischaemic burden. In other words, a normal post-chest-pain scan does not exclude coronary disease; it does, however, risk stratify the patient and exclude most immediately life-threatening forms of coronary disease.

Occasionally, cardiac magnetic resonance is used to diagnose infarction (by finding scar tissue in the distribution of a coronary artery) in situations where differentiation from myocarditis is important and cannot be made using traditional techniques. Likewise, cardiac ultrasound is used to look for evidence of regional wall motion abnormalities indicating coronary artery disease.

Other relevant investigations

The aim of additional investigation is to determine:

- the size of the myocardial infarct (troponin, and cardiac ultrasound)
- the presence of other illness impacting on cardiac management; renal function is important, as are general blood tests to exclude anaemia and determine if there is any ill health (diagnosed from low albumin), cancer (raised inflammatory markers/abnormal liver/bone function tests), or infection
- glucose and cholesterol

Prognosis and how to estimate it

The prognosis in ACS is determined by many factors, including age, renal function, comorbidity, extent of coronary disease, vessel affected by the acute lesion (left main and proximal left anterior descending artery lesions have higher risk), left ventricular function, presence of heart failure, and extent of biomarker release. These factors are combined in a number of widely available scoring systems, including TIMI (<http://www.mdcalc.com/timi-risk-score-ua-nstemi/>) and GRACE (http://www.outcomes-umassmed.org/grace/acs_risk/acs_risk_content.html).

Treatment and its effectiveness

The aims of treatment in ACS are to relieve symptoms and improve prognosis—however, the issue is complicated, as it is not always apparent who has an ACS, so the diagnostic process sometimes needs to run in parallel with the therapeutic process. Furthermore, angiography is not appropriate for all, most often on account of comorbidity, when the prognostic element may be removed from the equation. There also can be controversies about the best approach to revascularization in NSTEMI and unstable angina and, in particular, which patients should have PCI and which should have a coronary artery bypass graft (CABG).

Treatment for STEMI

All patients should receive immediate pain relief (morphine), aspirin (in the ambulance), and clopidogrel (or similar). Oxygen is commonly given. The occluded artery needs to be opened immediately. Thrombolysis with intravenous thrombolytics is effective but primary (i.e. first-line treatment, ≤ 30 minutes of presentation) PCI is slightly more so and thus is now the standard treatment. Following the opening of the occluded artery, any bystander disease may be treated by PCI or CABG, depending on the exact anatomy and patient preference. Bystander revascularization usually takes place after recovery from the initial infarct, although there is increasing evidence that this should be done as early as possible.

Treatment for NSTEMI

Provide pain relief, dual antiplatelet agents (see 'Drugs'; aspirin and clopidogrel), heparin (or similar), and beta blockers (or similar).

Angiography is used to risk stratify high-risk NSTEMI to determine which artery has an acute lesion, and the extent of the coronary disease. PCI to acute thrombotic lesions has been shown to reduce reinfarction and death rates (discussed in Chapter 97).

Drugs with an important role in ACS

Drugs with an important role in ACS include:

Aspirin: Aspirin causes the irreversible inhibition of the COX-1 enzyme, which inhibits production of thromboxane A₂, a powerful platelet aggregator released by activated platelets and leading to platelet activation. Aspirin in ACS reduces the risk of infarction and death. The first dose should be chewed or given in dispersible form to ensure a rapid onset of action. Unless contraindicated, aspirin should be continued for the rest of the patient's life.

Clopidogrel: Clopidogrel (a thienopyridine) prevents platelet aggregation via inhibition of an ADP receptor (P_{2Y₁₂}), and has an additive effect in combination with aspirin. It reduces the risk of death, further myocardial infarction, and urgent revascularization, but with an increased bleeding risk. Prognostic benefit is restricted to high-risk patients. Clopidogrel should be given for 1 year following an ACS. Newer thienopyridines such as prasugrel can also be used with particular benefit in patients undergoing primary PCI, due to its quick onset of action. However, prasugrel must be used with caution in patients over 65 or under 60 kg, due to an increased risk of bleeding.

Ticagrelor: Ticagrelor is more effective than clopidogrel and is increasingly used, especially in diabetic patients.

Anticoagulation drugs: Anticoagulation with low-molecular-weight heparin reduces the death rate and further myocardial infarction. Direct thrombin inhibitors and fondaparinux, a selective inhibitor of factor Xa, have similar actions. The low-molecular-weight heparins (e.g. enoxaparin, dalteparin) are the most commonly used anticoagulants in ACS. They reduce the risk of angina, myocardial infarction, and death. They do not require anticoagulant monitoring and have less risk of heparin-induced thrombocytopenia, compared with unfractionated heparin. There is no benefit to prolonged heparin treatment.

Beta blockers: Beta blockers are important in ACS, acting through several mechanisms. They are negatively chronotropic (so reducing myocardial oxygen demand) and prolong diastole, improving coronary artery perfusion. They reduce ventricular tachyarrhythmias and sudden death. In the long term, beta blockers have a role in ventricular remodelling and thus their use can lead to an improvement in ventricular function. In patients with COPD, beta blockers are often withheld because of a perceived risk of bronchospasm. The benefits of beta blockers outweigh this risk in the majority of COPD patients, as most have largely fixed airways obstruction; cardioselective beta blockers should be given in patients with mild-to-moderate airways disease.

Glycoprotein IIb/IIIa inhibitors: Glycoprotein IIb/IIIa inhibitors such as abciximab and tirofiban block the final common pathway of platelet activation by binding to fibrinogen and, under high shear conditions, to von Willebrand factor, thus inhibiting the bridging between activated platelets. In patients at intermediate to high risk, particularly patients with elevated troponins, ST depression, or diabetes, either eptifibatid or tirofiban for initial early treatment can be used in addition to oral antiplatelet agents. In high-risk patients not pretreated with glycoprotein IIb/IIIa inhibitors and proceeding to PCI, abciximab has been shown to reduce the combination of death and myocardial infarction or need for urgent revascularization at 30 days.

Angiotensin-converting enzyme (ACE) inhibitors: ACE inhibitors reduce the incidence of further myocardial infarction and sudden death post myocardial infarction. They also improve ventricular remodelling if ventricular function is impaired. They should be used in STEMI patients. In NSTEMI, an ACE inhibitor should be started in those with diabetes, chronic kidney disease, hypertension, or a left ventricular ejection fraction of $\leq 40\%$; it is not unreasonable to consider starting an ACE inhibitor in patients outside these groups. The drug should be started prior to hospital discharge. An angiotensin II receptor blocker should be started in patients who cannot tolerate an ACE inhibitor (usually due to cough).

Statins: Statins should be started in high dose in ACS (e.g. atorvastatin 80 mg every day) and continued for 1–2 years, after which time conventional-dose statins are used.

Hypoglycaemic drugs: patients with hyperglycaemia on admission have a worse outcome, whether they are known to have diabetes mellitus or not. Indeed, much type II diabetes mellitus is diagnosed during an admission for ACS. There is debate on how to manage hyperglycaemia here. Intensive glucose control, while controlling hyperglycaemia, may put the patient at risk of hypoglycaemia, which has a negative impact on outcome. The pragmatic approach is to institute insulin therapy in diabetic patients with an elevated blood glucose on admission, but to use oral agents in those patients with moderately raised blood glucose.

91 Acute heart failure

Kazem Rahimi

Definition of the disease

Heart failure is a clinical syndrome characterized by an inadequate cardiac output for the needs of the body in the absence of low filling pressures, and reflects abnormal cardiac structure or function. Although various definitions for acute heart failure (AHF) exist, here AHF is defined as new-onset heart failure or an acute exacerbation of chronic heart failure, requiring urgent therapy. Patients with AHF typically have clinical features of organ hypoperfusion, with or without pulmonary and peripheral oedema.

Aetiology of the disease

It is best to think of AHF in a two-stage manner: first, there is a cardiac substrate; second, there may be a cardiac or non-cardiac event provoking acute deterioration. Identifying and treating all underlying and contributory causes is central to the management of AHF.

Underlying cardiac causes

Underlying cardiac causes include:

- acute coronary syndromes
- hypertensive heart disease
- valvular disease (especially if acute, such as acute valvar regurgitation due to endocarditis)
- cardiomyopathies
- myocarditis
- pericardial diseases

Provoking causes

Provoking causes include:

- cardiac causes such as atrial fibrillation (which requires an underlying cardiac substrate to lead to heart failure, i.e. atrial fibrillation by itself does not cause heart failure)
- volume overload (e.g. from a rapid blood transfusion or excess intravenous fluid)
- severe anaemia, especially if acute (e.g. from a gastrointestinal bleed)
- hypoxia (e.g. caused by acute exacerbation of COPD)
- infection, especially if a sepsis syndrome is present (septicaemia)
- thyrotoxicosis
- medications (e.g. NSAIDs, glitazones)
- intoxications (e.g. from heroin, barbiturates, etc.)
- nutritional (thiamine deficiency)
- lack of adherence to chronic treatment (this is particularly common)

Typical symptoms of the disease and less common symptoms

Dyspnoea is the most common presenting symptom. Typically, this has been present on effort for some time, and now occurs at rest. However, in a minority of cases, AHF reflects the sudden deterioration of cardiac function (e.g. due to a myocardial infarct, or acute myocarditis). Such patients clearly may be completely well until an hour or two before their acute presentation with respiratory distress. A postural dependence to breathlessness (orthopnoea) is common. A small minority of patients present with symptoms from hypotension or frank shock. With acute coronary syndrome being a major cause for AHF, chest pain is commonly found at presentation. Other common symptoms and findings include cough, haemoptysis, agitation and, in severe cases, drowsiness (due to hypoxia, hypercapnia), and multi-organ failure. Symptoms often resemble those of acute

respiratory disorders due to pneumonia and asthma, especially if there is underlying chronic lung disease, and this clearly can pose a diagnostic challenge to clinicians.

Demographics of the disease

Accurate estimates of the prevalence of AHF are not available, partly because of reporting of the underlying causes of this syndrome. European data suggests that AHF accounts for at least 5% of all hospital admissions and complicates the admission of a much larger patient population. With the wide spectrum of the underlying causes, patient demographics are highly heterogeneous, but patients are usually elderly with considerable cardiovascular and non-cardiovascular comorbidities. In one European registry, the mean age of patients admitted to hospital for heart failure was 70 years, and half were women. The majority of people admitted to hospitals with AHF are known to have chronic heart failure and only 15%–20% are incident presentations of heart failure. About 25% of patients are hypertensive at presentation (systolic blood pressure >160 mm Hg) and <10% are hypotensive. Half of AHF patients have a relatively preserved left ventricular systolic function. These patients tend to be older, are more likely to be women, and are more likely to present with severe hypertension and atrial arrhythmias.

Natural history and complications of the disease

The clinical course of AHF is highly variable. On average, people improve rapidly and can be discharged after a short hospital stay (median hospital duration in the US registries is about 5 days). The average hospital mortality rate ranges from a low of 4% (with large regional variations) to up to 20% in the small subgroup of AHF patients who present with hypotension and renal failure (<5% of the AHF population). Those who are discharged from hospital are at substantial risk of readmission and death. Readmission rate is about 30% at 60 to 90 days after discharge, and mortality ranges from 5% to 15%. Post-discharge outcomes seem to be similar for those with preserved and reduced systolic function; however, the epidemiology of the former group is less well described.

Approach to diagnosing the disease

Diagnosis is based on the amalgamation of the presenting symptoms, the physical examination, and simple clinical findings, especially the chest X-ray, and BNP. In essence, to diagnose AHF, the combination of acute breathlessness (or equivalent) with the physical findings of left heart failure (pulmonary oedema), an abnormal ECG, a raised biomarker, and abnormal cardiac substrate is required. Accordingly, a number of investigations can help confirm the diagnosis and identify the underlying cause or precipitant.

Physical findings include the following:

General: General findings are obvious breathlessness with tachypnoea, cyanosis, pallor, sweating, and cold skin (due to sympathetic nervous system activation).

Cardiovascular: Cardiovascular findings are raised jugular venous pressure, tachycardia, gallop rhythm due to a third heart sound, murmurs (functional mitral regurgitation is very common; alternatively, the murmur of any underlying valvar lesion), hepatomegaly, peripheral oedema, and hyper- or hypotension.

Respiratory: Respiratory findings include wheeze, crackles, and pleural effusion.

Chest X-ray: Chest X-ray findings include dilated and prominent upper lobe vessels, alveolar oedema ('bat's wings'), interstitial oedema (Kerley B lines), and pleural effusion with or without cardiomegaly. Isolated right pleural effusion can be due to heart failure, whereas isolated left pleural effusion is not.

ECG: An ECG may show acute ischaemic changes, left ventricular hypertrophy, bradycardia or tachycardia, atrial fibrillation/flutter, ventricular arrhythmias, broad QRS complexes, or signs of pericardial tamponade. A normal ECG makes the diagnosis of heart failure, especially with systolic dysfunction, very unlikely.

Laboratory tests: Patients with AHF should have a full blood count, serum electrolytes, creatinine, glucose, liver function tests, and urine analysis. In people with untreated mild-to-moderate heart failure, marked abnormalities of the blood count or electrolytes are uncommon. However, mild hyponatraemia, hyperkalaemia, and abnormal renal function are commonly encountered. Natriuretic peptides (BNP/NT-pro-BNP) are raised as a biochemical correlate for increased myocardial wall stress and left ventricular filling pressures. Evidence for their use in the acute setting is less established, but average values are usually much higher than in patients with chronic heart failure. Despite their high negative predictive value, they may not be raised in AHF at the time of admission if blood samples are taken immediately after symptom onset (in particular during flash pulmonary oedema or acute mitral regurgitation). Mild elevations of cardiac troponin are common, even in the absence of coronary events or myocarditis. While raised troponin levels are almost always a marker of myocardial tissue damage, they may be difficult to interpret in the context of chronic renal impairment, where mild chronic elevations of troponin levels are common. Here, serial measurements might be useful.

Echocardiography: Echocardiography plays a central role in making the diagnosis. Lack of any evidence for structural or functional heart disease on cardiac ultrasound makes the diagnosis of heart failure extremely unlikely. It allows assessment of heart chamber sizes, left ventricular ejection fraction (LVEF) and regional wall motion abnormalities, diastolic function, myocardial thickness, pericardial effusion, valvular function, and pulmonary arterial pressure. Approximately 50% of AHF patients have a relatively preserved systolic function (LVEF > 45%–50%); there are a number of acronyms for this condition, a common one being heart failure with preserved ejection fraction.

Cardiac MRI may be an alternative to echocardiography in those with poor echocardiographic windows or when characterization of the tissue is particularly important, such as in suspected myocarditis or an infiltrative myocardial disease.

Arterial blood gas analysis: The usual finding is of hypoxaemia with hypocapnia due to hyperventilation; pCO₂ levels may be normal or elevated due to exhaustion (or in less severe cases). Metabolic alkalosis is often a sign of diuretic toxicity.

Other diagnoses that should be considered

AHF is a syndrome, and investigations should include tests for underlying causes. The differential diagnosis includes pulmonary infection, chronic obstructive pulmonary disease or asthma, chest sepsis, pulmonary infiltrative processes, and, very occasionally, fluid overload due to renal dysfunction. In people presenting with hypotension, alternative causes of shock should be considered (pulmonary emboli being a leading cause). Since multimorbidity is the rule rather than the exception in those with heart failure, the presence of alternative diagnoses usually does not definitely rule out heart failure, and sometimes assessment of response to empiric therapy might be useful.

'Gold-standard' diagnostic test

There is no single gold-standard diagnostic test. However, for a secure diagnosis, appropriate symptoms, a chest X-ray clearly showing pulmonary oedema, raised biomarkers, and a very abnormal cardiac ultrasound secure the diagnosis. The fewer of these features that are present, the less secure is the diagnosis.

Acceptable diagnostic alternatives to the gold standard

Appropriate symptoms responding rapidly to diuretics is sometimes regarded as diagnostic.

Other relevant investigations

Diagnostic investigations include BNP, cardiac ultrasound, and coronary angiography, if proximal/multivessel coronary artery disease is not unlikely; with ST-segment elevation myocardial infarction, angiography should be done immediately; for non-ST-segment elevation myocardial infarction, it should be done once the patient is stabilized. C-reactive protein is valuable in most patients as a pointer to underlying infection.

Investigations to assess the response to therapy, and the 'sickness' of the patient, include ECG monitoring, pulse oximeter measurements, urinary catheterization, arterial line, and central venous line. Daily assessment of patient weight is the most effective method for documenting effective diuresis. Insertion of a pulmonary artery catheter is unnecessary for the diagnosis and management of AHF and can be lethal. Tissue Doppler echocardiography offers an alternative non-invasive means of estimating the pulmonary capillary pressures and left ventricular filling pressures.

Prognosis and how to estimate it

Many scoring systems for the evaluation of the prognosis of patients admitted with AHF exist. The selection of the method will depend on the availability of data for risk estimation and the type of outcome to be predicted. In a US-based study, the strongest independent predictors of inhospital death were higher age, lower systolic blood pressure, and higher blood urea nitrogen levels. Other factors with some predictive value were a higher heart rate, lower blood sodium levels, presence of chronic obstructive pulmonary disease, and non-black race. Interestingly, the predictive value of the model was independent of the left ventricular systolic function. However, the model was based on total mortality, with no information on cause-specific mortality or long-term post discharge outcomes.

Treatment and its effectiveness

Treatment can be divided into three stages: the early stage, the intermediate stage, and the final stage.

Early stage

In the early stage, immediately after presentation, the goal is to achieve haemodynamic stability, relieve symptoms, and restore organ perfusion.

Intermediate stage

The intermediate stage is about identifying the underlying cause of heart failure with targeted intervention. In general, evidence for the immediate management of AHF is mostly empiric, with many recent trials showing disappointing results. Patient should undergo immediate airway and fluid status assessment, and intravenous access should be secured. Fluid removal with loop diuretics, and preload and afterload reduction with vasodilators, are the mainstay of therapy. The intensity and combination of vasodilator and diuretics depends on the patient's haemodynamic status (i.e. blood pressure and degree of fluid overload). In patients with new-onset AHF, an initial dose of furosemide is 40 mg IV, or bumetanide 1 mg IV may suffice. However, patients with chronic oral diuretic dose should be given double or at least equivalent dose to their usual therapy as an IV injection, and those with renal failure or large volume overload are also likely to need higher doses or a continuous infusion. The total dose of furosemide should, however, if possible, remain <120 mg in the first 6 hours, with monitoring of the urinary output. In non-responders, a combination of a loop diuretic with thiazide diuretics (e.g. metolazone 2.5 mg) is preferable to higher doses of loop diuretics alone (to increase response rate

and to avoid toxicity). Intravenous glyceryl trinitrate is the most widely used vasodilator. It should be avoided in AHF patients with a systolic blood pressure of <90 mm Hg.

Patients with hypotension and signs of organ hypoperfusion (reduced urinary output, liver dysfunction, somnolence, lactic acidosis) or those with congestion, despite vasodilators and diuretics, may need inotropes. Their use should be kept as brief as possible because of the potential risk of myocardial injury, despite acute improvement in the haemodynamic status. Vasodilating inotropes such as dobutamine, milrinone, and levosimendan are commonly used. Inotropes with a more prominent vasoconstricting effect are less commonly used. Current guidelines give preference to dopamine over alternative vasopressors (noradrenaline and adrenaline), with the recommendation that such agents should be reserved for special circumstances (sepsis and cardiac resuscitation). However, these recommendations have been challenged by recent trial evidence showing no significant difference between dopamine and noradrenaline.

Hypoxic patients should be given oxygen to maintain arterial oxygen saturation >95% (>90% in COPD patients). However, routine use of oxygen in people with normal oxygen saturations should be avoided because of the potential risk of aggravating ischaemia.

Non-invasive ventilation (NIV) may be required for people with respiratory failure (persistent respiratory distress or respiratory acidosis with or without hypoxia). Usual settings are a positive end expiratory pressure of 5–7.5 cm H₂O, with an FiO₂ of ≥40%. However, evidence for the efficacy of NIV is limited. Patients presenting in cardiogenic shock or severe pulmonary oedema may require intubation and mechanical ventilation. Indication for mechanical ventilation (usually more than one factor required) includes:

- exhaustion
- hypoxaemia (oxygen partial pressure <8 kPa, or arterial saturation <93%)
- hypercapnia (oxygen partial pressure >8 kPa)
- acidosis (pH <7.2)
- failure to respond to NIV

A number of new and old pharmacological treatments for AHF exist, with little evidence for their safety and efficacy. Notably, digoxin may have a role for the management of people with AHF and reduced systolic function, even in the absence of atrial fibrillation. In some patients, analgesia and sedation may be required. Intravenous morphine in boluses of 2.5–5.0 mg is usually administered to patients with severe AHF who present with restlessness, anxiety, or chest pain. Morphine should be combined with antiemetics (e.g. metoclopramide 5–10 mg).

Treatment in the intermediate stage includes treatments for the underlying cause of heart failure, such as antihypertensive

medication, rate control, coronary intervention, valve operation, and so on. Ultrafiltration may be used for those with excessive fluid overload and renal impairment. Intra-aortic balloon pump and left ventricular assist devices may be used in more severe cases as bridging or for a short period of time until recovery, although the evidence for their effectiveness is limited.

Final stage

The final pre-discharge stage aims to initiate long-term chronic therapy prior to discharge. The principle underlying chronic heart failure drug therapy is neuroendocrine blockade; in the early days of heart failure treatment, therapy was directed towards increasing the inotropic state of the heart, that is, its contractility. All these drugs (with the exception of digoxin) led to an increase in mortality when used chronically (i.e. they are harmful). Later work clarified that the neuroendocrine activation seen in chronic heart failure (i.e. increases in epinephrine, norepinephrine, and other vasoconstrictors, including endothelin, etc.) was deleterious, and neuroendocrine blockade with angiotensin-converting enzyme (ACE) inhibitors (or angiotensin-receptor blockers), beta blockers, or mineralocorticoid antagonists (spironolactone, eplerenone) improves outcome, especially if these agents are used in combination. Generally, it is recommended that patients with AHF who are already on medication for chronic heart failure should continue with these during the acute admission whenever possible and, if needed, at a reduced dose. Prior to discharge, the patient should have made a successful transition from intravenous to oral medication, with arrangements for early follow-up after discharge. Many patients will have a significant improvement of their symptoms, but acute treatment usually will not completely abolish symptoms. Plans should be in place for long-term intervention with complex pacing devices, such as an implantable cardioverter defibrillator or a cardiac resynchronization therapy device, if appropriate, and for longer-term lifestyle interventions, including exercise.

92 Chronic heart failure

Kazem Rahimi

Definition of the disease

The European Society of Cardiology defines heart failure as a clinical syndrome in which patients have all of the following features (see Table 92.1):

- symptoms typical of heart failure, such as:
 - breathlessness
 - fatigue
 - ankle swelling
- signs typical of heart failure, such as:
 - tachycardia
 - tachypnoea
 - pulmonary crackles
 - pleural effusion
 - raised jugular venous pressure
 - peripheral oedema
 - hepatomegaly
- objective evidence of a structural or functional abnormality of the heart at rest, such as:
 - cardiomegaly
 - third heart sound
 - cardiac murmurs
 - abnormality on the echocardiogram
 - raised natriuretic peptide concentration

Heart failure results in activation of the sympathetic nervous system and the renin–aldosterone–angiotensin system, and release of a number of hormones, such as natriuretic peptides and cytokines, including tumour necrosis factor amongst others. While neurohormone activation is initially compensatory and helps in the short term to maintain circulatory needs, ultimately, it has detrimental effects on the myocardium and compromises its function further. These mechanisms are, therefore, therapeutic targets to improve symptoms and lessen the risk of death.

Aetiology of the disease

Chronic heart failure is a clinical syndrome that is caused by a cardiac pathology, but may be acutely precipitated by a number of cardiac and/or non-cardiac conditions. For specific causes, see Chapter 91, 'Aetiology of the disease'. The major differences between acute and chronic heart failure are in:

Timing: Chronic heart failure is often present for months, whereas acute heart failure progresses rapidly over minutes to hours.

Severity: Acute heart failure causes symptoms at rest, whereas chronic heart failure usually does not.

Manifestation: Acute heart failure largely manifests as left heart failure (pulmonary oedema), whereas chronic heart failure generally manifests as peripheral oedema (right heart failure).

Typical symptoms of the disease, and less common symptoms

Breathlessness, tiredness, and fatigue are characteristic symptoms, but assessment of these, in particular in the elderly, requires skills and experience. Since many patients with chronic heart failure can present with rapidly worsening symptoms, many of the symptoms described in Chapter 91 also apply to chronic heart failure. However, a key difference is that the chronicity of long-standing heart failure leads to the other major complications that of cardiac cachexia, a complex syndrome driven by several pathophysiological mechanisms including cytokine activation (tumour necrosis factor, interleukins, etc.), which leads to muscle loss and, in turn, underlying fatigue and many other symptoms. Visible cachexia is a grim prognostic sign.

Demographics of the disease

Aging populations and the improved survival rates from acute cardiovascular events continue to contribute to a growing prevalence of heart failure in most high-income countries (data from low- and middle-income countries are very limited). In the UK, about 1% of the population suffers from chronic heart failure, but the prevalence increases rapidly with age, affecting about 7% of the population aged 75 years or more. Patient demographics are highly heterogeneous, but patients tend to be elderly with considerable cardiovascular and non-cardiovascular comorbidities, such as coronary artery disease, diabetes, renal dysfunction, depression, cognitive impairment, and respiratory diseases. In one community-based cohort study, the average age of people with heart failure was about 75 years, with similar distributions for men and women. However, women, the elderly, and those with hypertension or diabetes are more likely to have preserved systolic function (ejection fraction > 45%–50%).

Natural history and complications of the disease

Advances in diagnosis and management of heart failure have led to a steady decline in morbidity and mortality during recent years.

Table 92.1 Definition of heart failure with preserved (HFpEF), mid-range (HFmrEF), and reduced ejection fraction (HFrEF)

Type of HF	HFrEF	HFmrEF	HFpEF
CRITERIA	1	Symptoms ± Signs ^a	Symptoms ± Signs ^a
	2	LVEF <40%	LVEF ≥50%
	3	–	–
		1. Elevated levels of natriuretic peptides ^b ; 2. At least one additional criterion: a. relevant structural heart disease (LVH and/or LAE), b. diastolic dysfunction (for details see Section 4.3.2).	1. Elevated levels of natriuretic peptides ^b ; 2. At least one additional criterion: a. relevant structural heart disease (LVH and/or LAE), b. diastolic dysfunction (for details see Section 4.3.2).

Abbreviations: BNP, brain natriuretic peptide; HF, heart failure; HFmrEF, heart failure with mid-range ejection fraction; HFpEF, heart failure with preserved ejection fraction; HFrEF, heart failure with reduced ejection fraction; LAE, left atrial enlargement; LVEF, left ventricular ejection fraction; LVH, left ventricular hypertrophy; NT-pro-BNP, N-terminal brain natriuretic peptide.

^aSigns may not be present in the early stages of HF (especially in HFpEF) and in patients treated with diuretics.

^bBNP >35 pg/ml and/or NT-pro-BNP >125 pg/ml.

Reproduced with permission from Piotr Ponikowski et al., 2016 ESC Guidelines for the diagnosis and treatment of acute and chronic heart failure, *European Heart Journal*, May 2015, ehw128; DOI: 10.1093/eurheartj/ehw128 Copyright © 2015 Oxford University Press.

ECG makes chronic heart failure, in particular with systolic dysfunction, very unlikely (<10%). Chest X-ray allows assessment of pulmonary congestion and may demonstrate important pulmonary or thoracic causes of dyspnoea. Plasma concentrations of natriuretic peptides can help in establishing the diagnosis and may provide additional useful information for staging and guiding further management.

Other diagnoses that should be considered

The differential diagnosis includes pulmonary infection, COPD, or asthma and restrictive lung disease (e.g. caused by obesity); renal dysfunction and other causes of oedematous states such as chronic venous thromboembolism; and liver cirrhosis. Immobility and obesity by themselves can lead to profound peripheral oedema. Calcium channel blockers likewise underlie some oedematous states. Often, however, many of these other diseases/conditions coexist, and it can be difficult to determine how many of the symptoms are from heart failure and how many from the comorbidities, including depression and physical deconditioning, which themselves are therapeutic targets

'Gold-standard' diagnostic test

The confirmation of the diagnosis of chronic heart failure requires both clinical and objective evidence. While no gold standard exists, the triad of appropriate symptoms plus a raised biomarker (e.g. BNP) and a sufficiently abnormal echocardiography is commonly considered to meet diagnostic criteria.

Acceptable diagnostic alternatives to the gold standard

A suggestive clinical situation, with raised biomarkers but relatively normal cardiac ultrasound, may be acceptable (e.g. in the case of heart failure with preserved ejection fraction). For screening in primary care, the tactic is to exclude heart failure, by ECG and BNP; heart failure is very unlikely here and so echocardiography is not justified, unless either or both of these tests are abnormal, in which case echocardiography with or without specialist evaluation is appropriate.

Other relevant investigations

Other relevant investigations include:

Tests to investigate for myocardial ischaemia: All patients require ischaemia risk evaluation (this is done using the pretest probability; see Chapter 89). Given the typical demographics of heart failure, most patients require tests evaluating ischaemia (e.g. nuclear myocardial perfusion scans and/or coronary angiography). If severe, proximal, multivessel coronary disease is found, then tests for hibernating myocardium (viable heart muscle whose function improves after revascularization) are indicated; there are no perfect tests for hibernation, but nuclear isotope scanning (SPECT) using either technetium-99m or thallium, or, better still, 18F-labelled glucose analogues, imaged using PET, may be helpful. Cardiac MRI also has a role.

Tests to evaluate arrhythmia risk and presence: Arrhythmia risk is evaluated mainly by estimation of ejection fraction, and arrhythmia presence from symptoms, office ECGs, and 24-hour ECGs. Occasionally, implantable reveal devices are used.

Right heart catheterization: This is not uncommonly used, mainly to investigate the degree and site of pulmonary hypertension, but also to diagnose pericardial constriction and intracardiac shunts.

Cardiac MRI: This is used, independently of its role in evaluating hibernation, mainly to very accurately assess ventricular function (especially when there are poor echocardiographic windows), to diagnose subtle changes (e.g. right ventricular cardiomyopathy), to understand the pattern and mechanism of left ventricular hypertrophy further, and to distinguish cardiomyopathy from infarction.

Transoesophageal echocardiography: This may have some incremental value over transthoracic echocardiography (e.g. in people with inadequate transthoracic echocardiographic windows) and allows a more accurate assessment of valve dysfunction and morphology.

Exercise testing: Exercise testing, with or without measurement of gas exchange, is very useful in documenting exercise capacity and physical fitness, as some patients complain bitterly of symptoms which objective testing fails to confirm. It is also useful in evaluating whether exercise-induced arrhythmias, particularly ventricular arrhythmias, are present.

Pulmonary function tests: These are indicated to exclude lung disease and follow up patients on amiodarone.

Holter ECG: This is indicated as part of an arrhythmia workup, especially in hypertrophic cardiomyopathy.

Myocardial biopsy: This is usually only used when amyloid heart disease is under consideration.

Genetic testing: This may also be useful to gain further insight into causes of heart failure and to better plan further management.

Prognosis and how to estimate it

As a chronic condition, heart failure affects patients' quality of life and reduces their life expectancy. Several statistical tools for prediction of risk of death and readmissions have been reported. Most prognostic scores are based on readily available data such as age, severity of symptoms, ejection fraction, heart rate, blood pressure, BNP levels, and renal function. On average, patients are at high risk of death and hospitalization soon after the initial diagnosis, and about 50% of patients will die within four years of the initial diagnosis.

Treatment and its effectiveness

The goals of treatment are symptom relief, avoidance of hospitalization, and the prevention of premature death. Treatment of acute heart failure is described in Chapter 91. Pharmacological treatment is the cornerstone of heart failure in patients with left ventricular systolic function (evidence for effective therapy in patients with preserved systolic function is limited). Pharmacological treatment should be complemented by other measures, including lifestyle changes concentrating on physical fitness and ideal weight. In selected patients, device therapy and surgery have a role.

Therapy for systolic dysfunction

Therapy for patients with systolic dysfunction (left ventricular ejection fraction < 40%) includes the following:

Angiotensin-converting-enzyme (ACE) inhibitors: Use of ACE inhibitors is the first-line therapy in people with systolic heart failure. ACE inhibitors have been shown to be highly effective in reducing mortality (up to 40% relative risk reduction), have modest positive effects on quality of life, and reduce hospital admission due to worsening heart failure. Potential adverse effects include cough, worsening renal function, hyperkalaemia, and symptomatic hypotension. A certain rise in blood creatinine levels (up of 50% from baseline or about 250 $\mu\text{mol/l}$) is expected after the initiation of ACE-inhibitor use and is not an indication for treatment withdrawal.

Angiotensin-receptor blockers (ARBs): The efficacy of ARBs is similar to that of ACE inhibitors; however, because of higher costs, the use of ARBs is usually limited to patients intolerant of ACE inhibitors because of cough. ARBs can be used concomitantly with ACE inhibitors in patients who remain symptomatic despite optimal therapy with ACE inhibitors and beta blockers and who are unable to tolerate aldosterone antagonists.

Beta blockers: Beta blockers are also first-line therapy, together with ACE inhibitors, in patients with systolic dysfunction, regardless of the underlying cause. Treatment with beta blockers reduces mortality by about a third, improves symptoms, and prevents hospitalization. Beta blockers may need to be withdrawn in people presenting with severe systemic hypoperfusion, but many people admitted to hospital with heart failure can continue with a smaller dose of their usual beta-blocker therapy and it should be initiated in cautiously in people with no beta-blocker therapy at the time of admission to hospital. Unlike asthma, COPD is not a contraindication to beta-blocker use. The use of beta blockers should be avoided in people with high-degree heart block in the absence of a permanent pacemaker. Many patients with systolic heart failure

have chronic asymptomatic hypotension; beta blockers should not be withheld in these patients.

Aldosterone antagonists: Aldosterone antagonists are recommended in all patients who have severe systolic heart failure (ejection fraction $\leq 30\%$) but remain symptomatic (New York Heart Association (NYHA) Class II or IV) despite treatment with a diuretic, an ACE inhibitor (or ARB), and a beta blocker. However, triple therapy consisting of an ACE inhibitor, an ARB, and an aldosterone antagonist should be avoided because of the risk of renal dysfunction and hyperkalaemia. Breast tenderness and/or enlargement can occur with spironolactone treatment. In such cases, spironolactone should be replaced by eplerenone.

Hydralazine and isosorbide dinitrate (H-ISDN): In symptomatic patients, H-ISDN may be used as an alternative to ACE inhibitors or ARBs (e.g. because of intolerance), or in addition to them, if patients remain symptomatic despite treatment with an ACE inhibitor, a beta blocker, and an ARB or an aldosterone antagonist. The most common side effects of H-ISDN are headache, dizziness, and nausea. Arthralgia is less common (about 10%).

Sacubitril-valsartan: The combination of an angiotensin-receptor blocker and neprilysin inhibitor (ARNI), sacubitril-valsartan, can be used in place of an ACE-inhibitor or ARB in patients with heart failure due to LV systolic dysfunction (ejection fraction 35% or less) who remain symptomatic (in NYHA classes II-IV) despite a stable dose of one or other of these therapies. Adverse effects of sacubitril-valsartan include hypotension, hyperkalaemia, and renal failure.

Diuretics: Diuretics can provide rapid relief of dyspnoea and fluid retention. The lowest dose needed to achieve the dry weight is used. In severe cases of fluid retention, a loop diuretic may need to be combined with other classes of diuretics under close monitoring of blood electrolytes. Diuretics should be reduced in dose and, if possible, withdrawn in people without evidence of fluid retention, to avoid renal dysfunction and dehydration.

Other medications: Digoxin is usually recommended in patients with symptomatic heart failure or in those with fast atrial fibrillation. Digoxin has been shown to improve symptoms and to reduce hospital admission for worsening heart failure, but there is no evidence to suggest that digoxin has an impact on survival. It can be prescribed in addition to a beta blocker. Unlike studies in the general population, there is no evidence that antiplatelet agents and statins reduce cardiovascular events in people with heart failure.

Implantable cardioverter defibrillators (ICDs): ICDs are recommended for patients who survive an unprovoked episode of ventricular fibrillation or sustained ventricular arrhythmia, and for primary prevention in people who have been identified as NYHA Class II or III, have an ejection fraction that is persistently 35% or less despite optimal medical therapy, and who are expected to survive for at least 1 year with a reasonable quality of life.

Cardiac resynchronization therapy (CRT): CRT can improve quality of life and reduce admissions to hospital by achieving a more synchronous contraction of the left ventricle. Current European Society of Cardiology guidelines recommend CRT (Class I indication) for

symptomatic patients with heart failure in sinus rhythm with a QRS duration >130 ms, and LBBB morphology, and a LVEF $<35\%$ despite optimum medical therapy; CRT should be considered (Class IIa) for those with QRS duration >150 ms and non-LBBB morphology. Patients in permanent atrial fibrillation can also benefit from CRT, but in this group, it may be necessary to ablate the AV node to ensure biventricular pacing occurs most of the time. Most patients for whom CRT is indicated also qualify for an ICD. An ICD component can be added to CRT by using a right ventricular ICD lead and a CRT defibrillator generator (CRT-D) instead of a standard CRT pacemaker (CRT-P). However, the additional benefit of CRT-D over CRT-P is uncertain, and the best choice of device for the individual patient is the subject of current research. Cardiac device therapy is discussed in chapter 121.

Other interventions: The role of other interventions, such as coronary revascularization, cardiac transplantation, and left ventricular assist devices, is less straightforward and often requires a case-by-case decision. Lifestyle modifications, such as restriction of sodium intake, are often recommended, but with little evidence for their effectiveness. Aerobic physical activity, however, can improve functional capacity and quality of life, based on limited trial evidence.

Disease management strategies: Disease management strategies, such as patient education and nurse-led monitoring, can be effective, but the optimal content of such programmes is uncertain and is likely to depend on the availability of resources at the local level. Palliative care for patients with refractory symptoms despite optimal medical therapy is recommended.

Therapy for preserved left ventricular ejection fraction

No specific treatment has been shown equivocally to reduce morbidity and mortality in patients with preserved left ventricular ejection fraction (left ventricular ejection fraction $\geq 40\%$). Diuretics are commonly used for symptom control. There is some evidence to suggest that verapamil and nebivolol may have beneficial effects in this patient population. In clinical practice, treatment is commonly targeted at the underlying causes of heart failure, such as hypertension or atrial fibrillation.

93 Aortic stenosis

Patrick Davey and Jim Newton

Definition of the disease

Aortic stenosis is characterized by thickening and reduced mobility of the aortic valve leaflets and results in restriction to the blood flow from the left ventricle to the aorta, and secondary left ventricular hypertrophy (Figure 93.1).

Symptoms

A normal trileaflet aortic valve opens to an orifice area of 3 cm². Symptoms do not usually develop until the valve area is <1.0 cm², although they may occur earlier in the presence of common comorbidities, such as coronary artery disease (found in 25%–50% of patients with moderate or severe aortic stenosis). Stenotic valves with an orifice area <1 cm² allow sufficient cardiac output at rest, but do not allow normal arterial perfusion during exercise.

Exertional breathlessness is typically the first symptom, followed by effort angina. Syncope on exertion is an ominous symptom. Sudden death is a rare presentation of asymptomatic aortic stenosis, but becomes more prevalent as symptoms occur and the left ventricle fails.

The valve area and symptoms in aortic stenosis are given in Table 93.1.

Demographics and aetiology of aortic stenosis

The commonest cause of aortic stenosis is calcific degeneration of a structurally normal trileaflet valve. This is a disease process similar to atherosclerosis and is associated with hyperlipidaemia, diabetes, renal failure, and increasing age. Early inflammation due to endothelial damage leads to lipid deposition, which promotes fibrosis and calcification. Patients usually present around the seventh decade of life

Figure 93.1 Simultaneous measurement of the pressure in the left ventricle (LV) and that in the aortic root (AO), with the classic finding of aortic stenosis shown as the difference in pressure between the two in systole (normal individuals should have no pressure drop between the left ventricle and the aortic root in systole).

Classification	Symptoms	Valve area	Peak pressure drop (mm Hg)
Normal	–	>3.0 cm ²	0–10
Mild aortic stenosis	–	1.5–2.0 cm ²	10–40
Moderate aortic stenosis	– (+ if comorbidities)	1.0–1.5 cm ²	40–60
Severe aortic stenosis	++	<1.0 cm ²	>60
Critical aortic stenosis	+++	<0.8 cm ²	> 80

Note: The insidious onset of symptoms can be difficult to elicit in the elderly, as they reduce their daily activities to compensate; formal assessment of their exercise capacity may prove very useful.

and, overall, it is the most common form of valvular heart disease in the Western world.

Up to 2% of the population are born with a bicuspid aortic valve. Although not stenotic at birth, altered flow dynamics and shear stress promote premature leaflet degeneration, and patients present with stenosis around the fifth decade of life. Important associations include Turner's syndrome, aortic coarctation, and aortic root dilation. The latter is due to both altered post-stenosis flow and abnormal collagen with the aortic media; 10% of cases are genetic and related to NOTCH1 gene mutations.

Rheumatic fever can affect the aortic valve as well as the mitral valve, with a similar process involving leaflet thickening and commissural fusion, and subsequently significant stenosis, usually when the patient is in the third to fifth decades of life.

Natural history of the disease

Aortic stenosis is a slowly progressive disease with a long asymptomatic phase, as cardiac output is maintained by secondary left ventricular hypertrophy. The valve orifice area reduces by a mean of 0.12 cm²/year, and the pressure drop across the stenotic valve increases by 4–6 mm Hg per year—therefore it takes around 10 years to progress from mild to severe stenosis. Symptoms usually develop insidiously, although some patients present in established heart failure or with sudden syncope.

Complications of aortic stenosis

The principle complication of aortic stenosis is left ventricular failure occurring when the ventricle can no longer overcome the afterload, leading to myocyte apoptosis and fibrosis.

Patients with aortic stenosis are also at risk of:

- atrial fibrillation (can prompt sudden deterioration)
- atrioventricular conduction disease (due to calcific infiltration)
- infective endocarditis
- myocardial infarction (even with normal coronary arteries)
- sudden death (higher risk if symptoms or left ventricle dysfunction)
- Heyde's syndrome (colonic angiodysplasia and coagulation factor destruction)

Approach to diagnosing the disease (including diagnostic pitfalls)

The diagnosis should be suspected in patients with either typical symptoms or murmur, or both. The physical examination is usually diagnostic, and the most common signs are:

- a loud ejection systolic murmur heard at the base of the heart and radiating to the aortic area and carotids; the loudness of the murmur correlates with severity if left ventricular function is normal
- decreased intensity of the second heart sound (aortic valve closure) due to reduced valve compliance
- a slow-rising arterial pulse (may also be found in elderly patients with stiff vasculature)

The left ventricle hypertrophies in response to stenosis and usually leads to typical ECG changes with increased voltages and lateral T-wave inversion. These changes may regress as the ventricle

develops fibrosis and fails later in the disease. However a normal ECG is unusual in severe aortic stenosis.

Clinical examination is accurate in the majority of patients, but can be unreliable in patients with poor ventricular function and insufficient forward flow to generate an obvious murmur.

Other diagnoses that should be considered

The symptoms of effort dyspnoea, angina, or syncope have a broad differential diagnosis (see Table 93.2).

The murmur of aortic stenosis can be confused with other murmurs, usually those arising from the left ventricular outflow tract:

Innocent flow murmur: This is usually less intense and with a normal second heart sound and pulse character.

Hypertrophic obstructive cardiomyopathy: In this case, the murmur arises from the anterior mitral valve leaflet encroaching on the left ventricular outflow tract during systole. The murmur is more prominent in late systole, and the second heart sound is usually normal. An additional clue is that, during squatting, there is a reduction in the murmur, which increases immediately afterwards. Additional mitral regurgitation due to mitral valve distortion is common.

Subvalvar stenosis: This is due to a congenital membrane located below the aortic valve and which obstructs left ventricular outflow; it is rare and typically presents in childhood.

Eccentric mitral regurgitation: Eccentric mitral regurgitation can be directed onto the underside of the aortic root and mimic the radiation of aortic stenosis. However, the murmur is pansystolic, the quality of the carotid pulse is normal, and the second heart sound is preserved.

'Gold-standard' diagnostic test

The gold-standard test for aortic stenosis is invasive confirmation of a pressure difference between the left ventricle and the aortic root. This is achieved by passing a catheter retrogradely across the aortic valve into the left ventricle; the catheter is then withdrawn while recording pressure. The aortic valve area can be derived from the pressure drop across the valve. This test is rarely performed, as echocardiography is usually sufficient, and crossing a stenotic aortic valve carries a risk of provoking systemic emboli and stroke. The measurement of aortic root pressure is influenced by blood pressure and can underestimate the true pressure drop. It is now only used when the cardiac ultrasound is non-diagnostic, or has produced discordant data.

Acceptable diagnostic alternatives to the gold standard

Standard transthoracic echocardiography is diagnostic in the majority of cases. The structure of the aortic valve, the degree of calcification, and the degree of valve thickening are assessed with 2D imaging. Doppler echocardiography allows measurement of the velocity of blood in the left ventricular outflow tract and across the stenosis; from this measurement, the valve orifice area can be derived. In addition, the degree of adaptive left ventricular hypertrophy can be quantified, as can both systolic and diastolic function. Additional valve disease, such as mitral regurgitation, can be identified or excluded.

Table 93.2 Symptoms of effort dyspnoea, angina, or syncope

	Effort breathlessness	Effort angina	Effort syncope
In the young	Asthma	Syndrome X Pulmonary hypertension	Vasomotor (usually post-effort) Pulmonary hypertension
In the middle-aged or elderly	COPD Heart failure from any other cause Anaemia Physical deconditioning	Coronary disease	Arrhythmias; usually ventricular tachycardia, or supraventricular tachycardia + poor left ventricular function

The velocity of blood flow across the stenotic orifice is related not only to the degree of stenosis but also to the stroke volume and the force of ventricular contraction. In patients with a low stroke volume—due either to small body size, or poor ventricular function—the pressure drop measured by echocardiography may not be in the severe category even if severe aortic stenosis is present. This can be overcome by increasing the stroke volume by peripheral infusion of dobutamine and reassessing the Doppler data as stroke volume is normalized. An alternative scenario is when the valve appears to open poorly and severe stenosis is suspected but, when the stroke volume is improved, the increased force of flow opens the valve and non-severe aortic stenosis is confirmed—so-called pseudo-severe stenosis, where poor left ventricular function is the main issue.

Other relevant investigations

The similarity of the pathophysiology of aortic stenosis to that of atherosclerosis warrants an assessment of atherosclerosis risk factors in all patients, although interventions with statins and antihypertensives have not yet been shown to influence disease progression.

Many patients will claim to be asymptomatic, but in reality have reduced their physical activity in response to early symptoms. In such patients, exercise treadmill testing can be used to quantify effort capacity, heart rate, and blood pressure response to exertion and symptoms. Such testing is safe in severe aortic stenosis, if there are no unstable symptoms or heart failure.

In patients proceeding to surgical aortic valve replacement, coronary angiography is performed in almost all cases, to exclude significant coronary disease warranting concomitant coronary artery bypass grafting.

Plasma brain natriuretic peptide (BNP) can be measured in patients where symptoms are of uncertain aetiology, such as in patients with multiple comorbidities. A normal BNP should prompt screening for an alternative cause of dyspnoea.

If transthoracic imaging is insufficient, then the following alternative imaging investigations may be performed:

Transoesophageal echocardiography: This provides improved visualization of valve anatomy and disease but limited accuracy of Doppler assessment.

Computed tomography: This can identify valve anatomy and degree of calcification but cannot measure flow or easily assess left ventricular function.

Cardiac MRI: This can assess valve anatomy but not calcification, and is accurate for flow assessment and quantification of ventricular function.

Prognosis and how to estimate it

The prognosis is related to symptoms. Asymptomatic patients have a good prognosis with a low risk of sudden death or major complications. Patients with effort dyspnoea survive on average for 5 years without intervention; those with angina, only 3 years. Heart failure is an ominous symptom, with death by 12 months without definitive intervention. Prognosis after successful intervention is primarily related to the patient's age and additional comorbidities.

Treatment and its effectiveness

Patients who are genuinely asymptomatic and have normal left ventricular function can be reviewed intermittently after education on general cardiac health, the need to promptly report symptoms, and advice on reducing the risk of endocarditis. No medical therapy has yet been shown to influence disease progression.

Patients with symptoms and severe aortic stenosis must be referred for surgical aortic valve replacement, if this can be performed at acceptable risk. Even patients in their eighties can safely undergo aortic valve replacement if there are minimal comorbidities and good left ventricular function, although the recovery time will be prolonged. The overall operative death risk is 2%–4%, and patients afterwards return to a normal, age-matched life expectancy.

Patients with symptomatic, severe aortic stenosis and who are at high risk for surgical aortic valve replacement should be considered for transcatheter aortic valve implantation. The minimally invasive nature of the procedure promotes more rapid recovery, as formal sternotomy is avoided, although the procedural risks are similar to those for surgical valve replacement. Outcomes are excellent in selected patients with appropriate anatomy, compared to those for medical therapy or high-risk surgical valve replacement.

Balloon valvuloplasty can be performed as rescue therapy in patients with severe aortic stenosis, poor left ventricular function, and heart failure, if definitive intervention is likely to be feasible if cardiac function recovers.

94 Aortic regurgitation

Kazem Rahimi

Definition of the disease

Aortic regurgitation is the diastolic reflux of blood from the aorta into the left ventricle, across the aortic valve.

Aetiology of the disease

Aortic regurgitation can be caused by either damage to or dysfunction of the aortic valve leaflets or as a consequence of distortion or dilatation of the aortic root.

Disorders of the aortic valve leaflets

The following are disorders of the aortic valve leaflets:

- rheumatic heart disease
- infective endocarditis
- degenerative valve disease
- traumatic or iatrogenic leaflet rupture or paravalvular damage
- congenital abnormalities (e.g. bicuspid aortic valve, subarterial ventricular septal defect, subaortic stenosis)
- rheumatoid arthritis
- SLE (Libman–Sacks endocarditis)

Disorders of the aortic root

The following are disorders of the aortic root:

- aortic root dilatation (e.g. from Marfan syndrome, osteogenesis imperfecta, syphilis, ankylosing spondylitis, Reiter's syndrome)
- proximal aortic dissection
- systemic hypertension

Primary disorders of the aortic valve leaflets are falling in incidence. In developed countries, aortic regurgitation due to root pathology now accounts for >50% of cases in those undergoing surgery. Acute aortic regurgitation is usually caused by infective endocarditis or aortic dissection.

Typical symptoms of the disease, and less common symptoms

Chronic aortic regurgitation may remain asymptomatic for decades, owing to compensatory enlargement of the left ventricle. During this phase, patients may only report awareness of a pounding heart as a result of the increased left ventricular stroke volume. Failure of the heart's compensatory mechanisms over time leads to the development of dyspnoea and fatigue. Patients may also report palpitations (due to sinus tachycardia or extrasystoles) and non-specific chest discomfort. Typical angina is rare and is likely to reflect concomitant coronary artery disease.

Acute aortic regurgitation usually presents with acute severe dyspnoea due to pulmonary oedema.

Demographics of the disease

The prevalence of aortic regurgitation depends on age and the severity of the condition. Aortic regurgitation of any degree (even trace aortic regurgitation) is uncommon before age 50. In a population-based cohort of the Framingham Heart Study, the prevalence of moderate-to-severe aortic regurgitation was 0.5%, 0.6%, and 2.2% in men at ages 50–59, 60–69, and 70–83, respectively. The corresponding rates in women were 0.2%, 0.8%, and 2.3%.

Natural history, and complications of the disease

The prognosis of chronic aortic regurgitation is highly dependent on the presence of symptoms. The average annual rate of onset of symptoms is <6% in chronic asymptomatic patients. This may be somewhat higher in those with aortic root dilatation or bicuspid aortic valve. Without valve replacement, symptomatic patients are at substantial risk of death.

Approach to diagnosing the disease

The physical examination of patients with chronic severe aortic regurgitation is usually abnormal and establishes the diagnosis. The increased stroke volume results in abrupt distension of the peripheral arteries and an elevation in systolic blood pressure. Reflux of blood into the left ventricle then leads to a rapid fall in pressure, with quick collapse of the arteries and a low diastolic blood pressure, which may approach zero in severe disease. The net effect is a wide pulse pressure, which is manifested on examination as a 'water hammer' or Corrigan pulse. A number of eponymous signs related to the wide pulse pressure have been described.

The apex beat in chronic aortic regurgitation is laterally displaced and hyperdynamic. A high-pitched decrescendo diastolic murmur is usually present but can easily be missed unless the patient is examined sitting forward with breath held in end-expiration. In very severe regurgitation with ventricular decompensation, the murmur may become soft or even absent. While the intensity of the murmur does not correlate well with the severity of aortic regurgitation, its timing and duration may be useful for grading the severity. An early onset of the murmur with extension through most of the diastole suggests severe aortic regurgitation.

While the ECG and chest radiograph are usually abnormal in patients with severe aortic regurgitation, definitive diagnosis is achieved with echocardiography. Echocardiography allows assessment of aortic valve leaflet and aortic root structure, severity of aortic regurgitation, left ventricular size and function, and the presence of any other cardiac abnormalities. Serial measurements can be useful for evaluation of changes that may occur over time. The severity of aortic regurgitation is classified according to a combination of echocardiographic measures (see Table 94.1).

Transoesophageal echocardiography (TOE) affords better views of the valve and, in particular, of the aortic root. Real-time 3D TOE or cardiac MRI can be of further assistance in difficult cases. Cardiac catheterization is rarely required, although coronary angiography is usually performed in patients being considered for surgical treatment.

Since onset and progression of symptoms is usually gradual, patients may be sedentary and feel relatively asymptomatic. In such cases, exercise testing may be useful to assess effort tolerance.

Other diagnoses that should be considered

The bounding pulse and wide pulse pressure (without a diastolic murmur) may accompany other conditions, such as thyrotoxicosis, fever, anaemia, pregnancy, patent ductus arteriosus, liver cirrhosis, Paget's disease of the bone, multiple arteriovenous fistulae, and, in elderly patients, systolic hypertension due to increased stiffness of the aorta and major arteries.

Table 94.1 Echocardiographic measures used to classify the severity of aortic regurgitation

	Severity		
	Mild	Moderate	Severe
Vena contracta*	<0.3 cm	0.3–0.6 cm	>0.6 cm
Jet width in LVOT	<25% LVOT	25–65% LVOT	>65% LVOT
Descending aorta flow	Brief early diastolic flow	–	Holosystolic flow reversal
Pressure half time [^]	>500 ms	500–200 ms	<200 ms
Regurgitant volume	<30 ml	30–60 ml	>60 ml
Left ventricle size [#]	Normal		Moderate or severe dilatation with no other cause

*May be unreliable if jet is not circular.

[^] In chronic aortic regurgitation, equalization of pressure across the valve may lead to underestimation of aortic regurgitation severity.

[#]In acute aortic regurgitation, ventricle size is usually normal.

Note that the more abnormal the valve morphology, the broader the regurgitant jet on colour flow, and the louder the regurgitant Doppler signal, the more severe the regurgitation.

Abbreviations: LVOT, left ventricular outflow tract.

'Gold-standard' diagnostic test

Echocardiography confirms the diagnosis.

Acceptable diagnostic alternatives to the gold standard

Cardiac MRI and invasive aortography may be useful in quantifying the degree of aortic regurgitation when clinical and echocardiographic findings are discordant.

Other relevant investigations

Blood BNP and NT-pro-BNP levels show some correlation with severity of aortic regurgitation and presence of symptoms, and they may play a role for the assessment of progression of the disease.

Prognosis and how to estimate it

The prognosis of patients with aortic regurgitation is determined largely by symptom status and by left ventricular size and function (see Table 94.2).

More recent data suggest that quantification of aortic regurgitation fraction measured by cardiac MRI may be better at discrimination of clinical deterioration. Patients with a regurgitant fraction of >33% are highly likely to progress to surgery within <3 years.

Treatment and its effectiveness

Asymptomatic patients with mild or moderate chronic aortic regurgitation do not require treatment unless there is coexistent systemic hypertension. Asymptomatic patients with severe aortic regurgitation or progressive ventricular enlargement may benefit from vasodilator therapy (angiotensin-converting enzyme (ACE) inhibitors, hydralazine, or nifedipine), although supportive evidence is limited.

Table 94.2 The prognosis of patients with aortic regurgitation

	Prognosis (% per year)
Asymptomatic	
Preserved LV systolic function, LVESD <40 mm	0*
Preserved LV systolic function, LVESD 40–50 mm	6*
Preserved LV systolic function, LVESD >50 mm	19*
Impaired LV systolic function	>25 [†]
Symptomatic	
NYHA Class II	6 [‡]
NYHA Class III/IV	>25 [‡]

* Progression to symptoms, LV dysfunction, or death.

[†] Progression to symptoms.

[‡] Mortality.

Abbreviations: LV, left ventricular; LVESD, left ventricular end-systolic diameter; NYHA, New York Heart Association.

Data from The Joint Task Force on the Management of Valvular Heart Disease of the European Society of Cardiology (ESC) and the European Association for Cardio-Thoracic Surgery (EACTS), Guidelines on the management of valvular heart disease (version 2012), *European Heart Journal*, volume 33, pp.2451-2496 Copyright © 2012 Oxford University Press.

Diuretics may palliate symptoms, but should not be used to defer the need for valve surgery. Beta blockers are relatively contraindicated on theoretical grounds because their prolongation of diastole leads to an increased regurgitant volume. Asymptomatic patients require frequent clinical review to assess for symptoms, progression of aortic regurgitation, and left ventricular size and function. The frequency of follow-up depends on the cause of aortic regurgitation and its severity, and varies from every 3–5 years for mild aortic regurgitation, to every 3–6 months for asymptomatic severe aortic regurgitation.

Waiting for the patient to develop exercise intolerance or dyspnoea may result in some degree of irreversible left ventricular dysfunction, with an increased perioperative risk. Therefore, surgery is recommended, even in subgroups of asymptomatic patients presenting with (moderate or) severe aortic regurgitation. Indications for surgery in asymptomatic patients include:

- left ventricle ejection fraction < 50%, or left ventricular end-systolic diameter > 50 mm, or left ventricular end diastolic diameter > 70 mm
- aortic root dilatation > 55 mm (> 50 mm if bicuspid valve or Marfan syndrome; lower thresholds are recommended in those with Marfan and additional risk factors, such as strong family history of dissection, rapid increase in size, planned pregnancy)
- in those undergoing coronary artery bypass graft, aortic regurgitation is at least moderate, and progression is likely

Symptomatic patients should undergo surgery to repair or replace the aortic valve for both symptomatic and prognostic indication. Valve-sparing aortic root surgery is increasingly used in expert centres. This technique may be particularly suitable for younger patients with less valve calcification and no retraction of the cusps.

95 Mitral regurgitation

Kazem Rahimi

Definition of the disease

Mitral regurgitation (MR) is the reflux of blood from the left ventricle into the left atrium as a result of dysfunction of the mitral valve. MR can result from abnormalities of any part of the mitral valve apparatus (valve leaflets, annulus, chordae tendineae, and papillary muscles), or dilatation/disease of the left ventricle

Aetiology of the disease

In the developed world, rheumatic heart disease is now uncommon, and the major causes of MR are degenerative mitral valve disease and ischaemic heart disease. Mitral annular calcification is a common finding in the elderly. It is often associated with mild to moderate MR but is unlikely to cause severe MR.

Disorders of the mitral valve apparatus

Disorders of the mitral valve apparatus include:

- degenerative mitral valve disease (also called myxomatous mitral valve disease or mitral prolapse, defined as movement by one or both mitral leaflets of at least 2 mm beyond the long-axis annular plane); degenerative disease can lead to leaflet redundancy, thickening, or thinning, and to lengthening or rupture of the chordae
- rheumatic heart disease
- infective endocarditis
- papillary muscle rupture complicating acute myocardial infarction
- disorders caused by traumatic damage to the chordae or leaflets (e.g. via balloon valvotomy)
- congenital disorders (e.g. mitral valve cleft)
- drug-induced disorders (e.g. via ergotamine, cabergoline)
- disorders due to connective tissue disorders (e.g. Marfan syndrome, Ehlers–Danlos syndrome, osteogenesis imperfecta, pseudoxanthoma elasticum, psoriatic arthritis, SLE)

Diseases of the left ventricular myocardium

The following are the diseases of the left ventricular myocardium:

- dilatation of the left ventricle, due to ischaemic heart disease with previous myocardial infarction or dilated cardiomyopathy
- hypertrophic cardiomyopathy

Typical symptoms of the disease and less common symptoms

The development of symptoms in MR depends on a number of factors:

- severity of MR
- rate of progression
- degree of pulmonary hypertension
- heart rate and rhythm
- additional valve or ventricular disease

In isolated mild-to-moderate MR, forward cardiac output remains normal. Hence, patients are often asymptomatic. Even with chronic, severe MR, most patients remain asymptomatic until there is left ventricular failure, pulmonary hypertension, or atrial fibrillation. The most common symptoms are exertional dyspnoea and fatigue, due to the combination of an inadequate cardiac output, and pulmonary hypertension. Another common clinical presentation is intermittent or persistent atrial fibrillation.

Acute MR typically presents with acute severe dyspnoea due to pulmonary oedema.

Demographics of the disease

MR is the most common valve lesion, accounting for one-third of all cases of valve disease. Estimates of the prevalence of MR depend on the method of assessment. The widespread use of colour Doppler echocardiography, a sensitive technique for detecting valvular regurgitation, has increased the recognition of this lesion: trivial (physiological) MR is detectable in up to 70% of healthy adults. MR of greater than mild severity on colour Doppler echocardiography affects about 19% of men and women, while moderate or severe MR has been reported in 1.9% and 0.2% of the population, respectively. However, the prevalence increases with age, with moderate or severe MR being present in about 6% of people aged 75 years or more.

Natural history and complications of the disease

The principal complication of MR is left ventricular failure as a consequence of increased workload and cardiac dilatation. Pulmonary hypertension and right-sided heart failure in advanced stages is also common. This evolution generally occurs over many years, even decades, depending upon the severity of the regurgitant lesion and the cardiovascular response to the regurgitant volume. Other complications include atrial and ventricular ectopy, atrial fibrillation (about 5% per year), systemic embolism due to left atrial thrombus, infective endocarditis (<1% over 5 years), and sudden cardiac death (rare).

The heterogeneity of the underlying causes of MR makes the assessment of its natural history challenging. Most robust data are based on cohorts of patients with mitral valve prolapse, but they may be applicable to some other MR groups. Based on these data, the mortality risk increases with systolic dysfunction (ejection fraction < 50%), left atrial enlargement (>40 mm), atrial fibrillation, pulmonary hypertension, and age.

Approach to diagnosing the disease

MR is usually suspected from the clinical signs and confirmed by echocardiography. However, additional information may be helpful in the identification of complications and assessment of the risk.

Clinical signs

The following are clinical signs of MR:

Arterial pulse: It may be reduced in volume, but is usually brisk in upstroke, reflecting the decreased left ventricular ejection time. It may give the impression of a bounding pulse, similar to that seen with aortic regurgitation, but the pulse pressure is normal with MR.

Palpation: The apex beat may be laterally displaced due to cardiac enlargement. In severe MR, a thrill might be palpable.

Auscultation: The first heart sound is diminished (failure of the mitral leaflets to close properly), and the second heart sound is split (decrease in left ventricular ejection time leading to an early A2, and pulmonary artery hypertension leading to an increased and delayed P2). A third heart sound may be audible in severe MR. The characteristics of the systolic murmur of MR are variable and depend on the aetiology, severity, and direction of the

regurgitant jet. The classical murmur is a high-pitched, pansystolic murmur which is loudest at the apex and radiates to the axilla and back.

ECG

ECG may show signs of left atrial enlargement (broad P wave in Lead II, biphasic in V1), left ventricular hypertrophy, or right ventricular hypertrophy in the presence of pulmonary hypertension. Atrial fibrillation is common in chronic severe MR.

Chest X-ray

The commonest finding in chronic severe MR is enlargement of the cardiac silhouette due to left ventricular dilatation. Other abnormalities, such as mitral annular calcification, displaced left main bronchus, pulmonary arterial enlargement, or pulmonary oedema, may be present.

Echocardiography

Echocardiography is essential for identifying the aetiology of MR and grading its severity. Other important echocardiographic features are left atrial size, left ventricle size and systolic function, and pulmonary artery pressures. Left atrial size is usually increased. Left ventricular size and systolic function are normal early in the disease course, but progressive ventricular dilation and a decline in ejection fraction occur with chronic severe MR. Serial studies permit measurement of changes in ventricular dimensions or left ventricular ejection fraction. Standard transthoracic imaging is usually diagnostic, but 3D echocardiography or transoesophageal imaging may offer additional insight when information from transthoracic imaging is limited. The severity of MR is classified according to a combination of echocardiographic measures (many of which have their potential pitfalls mandating a combined assessment; see Table 95.1).

Other diagnoses that should be considered

Differential diagnosis includes other causes of heart failure. The following additional causes of pansystolic murmur should be considered:

- tricuspid regurgitation: murmur increases on inspiration, abnormal jugular venous pressure
- ventricular septum defect: murmur radiated to the right sternal edge

'Gold-standard' diagnostic test

Echocardiography confirms the diagnosis.

Acceptable diagnostic alternatives to the gold standard

Cardiac MRI and cardiac catheterization may have some value in some cases, for example, when the clinical and echocardiographic features are discordant.

Other relevant investigations

The complex relationship between the valve leaflets, annulus, papillary muscle system, and ventricular wall mean that the regurgitant volume can vary significantly with heart rate, loading conditions, and ischaemia. Consequently, the true extent of mitral regurgitation is difficult to assess and quantify during a resting study. Exercise echocardiography may allow assessment of MR and pulmonary artery pressure during stress.

Prognosis and how to estimate it

The prognosis of patients with MR depends on severity of the lesion, the presence or absence of systems, underlying aetiology, and degree of left ventricular dysfunction. The prognosis of patients with chronic severe MR can be estimated by the left ventricular size. When the end-diastolic dimension is less than 60 mm, and the end-systolic dimension is less than 40 mm (as measured by echocardiography), patients have a benign prognosis. Patients with a left ventricular end-diastolic dimension greater than 70 mm, end-systolic dimension greater than 45–47 mm, or a left ventricular ejection fraction less than 50%–55% are commonly classified as decompensated, and have a poor long-term prognosis, even with surgical treatment. Measurement of regurgitant fraction by cardiac MRI may provide another useful risk marker. People who are in the transitional status from compensated to decompensated have a good outcome with surgical treatment.

Treatment and its effectiveness

Medical management

Surgery is the mainstay of management of severe MR associated with symptoms and/or left ventricular impairment, and should be considered in all patients. Medical therapy should not be used to defer the need for surgery, but may be applicable for temporary symptomatic relief or palliation in those unsuitable for intervention. Diuretics are commonly used to reduce fluid overload. Angiotensin-converting enzyme (ACE) inhibitors, beta blockers, and aldosterone antagonists are indicated in those with left ventricular systolic dysfunction. Other antihypertensives may be required in those with a high blood pressure. Oral anticoagulation may be indicated if patient is in atrial fibrillation.

Surgical management

Evidence for the best timing of the surgery is limited to observational studies. Based on these studies, it is generally believed that corrective surgery (valve repair or replacement) should be performed in people with chronic MR before reaching the decompensated status stage where the myocardium is unlikely to recover and the operative risk is substantial.

In asymptomatic severe MR, therefore, surgery should be considered if there is:

- evidence of left ventricular dysfunction (ejection fraction < 60% and/or end-systolic volume > 45 mm)
- normal left ventricular systolic function with pulmonary hypertension (systolic pulmonary artery pressure greater than 50 mm Hg)

Table 95.1 Echocardiographic measures

	Severity		
	Mild	Moderate	Severe
Vena contracta*	<0.3 cm	0.3–0.6 cm	>0.6 cm
Jet area (Nyquist 50–60 cm/s) [#]	<4 cm ² or <20% left atrium	Variable	>10cm ² or >40% left atrium
PISA radius (Nyquist 40 cm/s) [*]	<0.4 cm	0.4–1 cm	>1 cm
Pulmonary vein flow [~]	Systolic dominant	Systolic blunting	Systolic flow reversal
Mitral inflow [§]	A wave dominant	Variable	E wave dominant and >1.2 m/s
Continuous wave Doppler [#]	Soft, mild density, parabolic	Variable	Dense and triangular shape
Regurgitant fraction [^]	<30%	30%–50%	>50%
EROA (via PISA) [^]	0–20 mm ²	20–40 mm ²	>40 mm ²

* May be unreliable if jet is not circular or patient in atrial fibrillation.

[#] Multiple or eccentric jets and enlarged atrium may lead to underestimation of severity.

[^] Severity may be underestimated in eccentric jets.

Severity may be overestimated if jet directed towards pulmonary vein.

[§] Depends on preload and can be affected by other factors, such as mitral stenosis. They can all vary with the volume status, heart rate, and blood pressure. Note that the more abnormal the valve morphology, the broader the regurgitant jet on colour flow, and the louder the regurgitant Doppler signal, the more severe the regurgitation.

Abbreviations: EROA, effective regurgitant orifice area; PISA, proximal isovelocity surface area.

Reproduced with permission from Patrizio Lancellotti et al., European Association of Echocardiography recommendations for the assessment of valvular regurgitation. Part 2: mitral and tricuspid regurgitation (native valve disease), *European Heart Journal*, Volume 11, pp.307–332, Copyright © 2010 Oxford University Press.

- normal left ventricular systolic function and new-onset atrial fibrillation.

Surgery is also indicated in chronic severe MR if symptomatic and if the ejection fraction > 30% and the end-systolic diameter < 55 mm. In people with severe left ventricular dysfunction and/or a dilated left ventricle, however, surgery should be considered if symptoms are refractory to medical therapy and the likelihood of valve repair is high.

People with acute symptomatic severe MR should undergo immediate surgical intervention.

Weighing the benefits or early surgery (before the development of left ventricular dysfunction) against the small operative risks in individual patients is often difficult. In the absence of robust evidence, approaches commonly depend on local expertise and the likelihood of valve repair.

Whenever possible, valve repair techniques such as annuloplasty, resection of prolapsing segments, or the use of adjunctive artificial chord replacement, are preferred to traditional valve replacement. Valve repair preserves all of the functional components of the native valve and avoids the use of a prosthetic heart valve with its attendant complications. In certain groups of patients, such as those with severe calcification or degeneration of the mitral valve or those with

widespread prolapse of both leaflets, mitral valve repair is not an option. In such cases, valve replacement with preservation of the subvalvular apparatus is usually performed. Emerging technologies such as percutaneous valve implantation or clipping may offer an alternative to those at high risk of surgery in the future.

Valve surgery may be accompanied by other surgical procedures, such as ablation therapy for atrial fibrillation or removal of the left atrial appendage to remove a potential source of embolism. Cardiac resynchronization therapy may be beneficial to patients with severe functional MR.

96 Miscellaneous valvar pathology: Mitral stenosis, pulmonary stenosis, and tricuspid regurgitation

Kazem Rahimi

Mitral stenosis

Definition of mitral stenosis

Mitral stenosis is obstruction to inflow of blood from left atrium to left ventricle at the level of the mitral valve. Non-valvar causes of left ventricular inflow obstruction include left atrial tumours and cor triatriatum.

Aetiology of mitral stenosis

Mitral stenosis usually due to rheumatic disease, although a positive history cannot be elicited in over 40% of such patients. Other systemic inflammatory conditions (e.g. SLE and endomyocardial fibrosis) can lead to mitral stenosis. Congenital mitral stenosis is rare.

Typical symptoms of mitral stenosis, and less common symptoms

The symptoms are primarily related to the severity of the valvular stenosis. The normal mitral valve orifice has a cross-sectional area of about 5.0 cm². Mitral valve area has to fall by around a half before the onset of symptoms. However, many patients with severe mitral stenosis (valve area < 1 cm²) deny symptoms because they adapt and reduce their level of activity as the stenosis slowly progresses. Typical symptoms are (exertional) dyspnoea and fatigue. If right heart failure ensues, it may be accompanied by oedema and ascites. In many patients, pregnancy, emotional stress, tachycardia, or infection may trigger the initial symptoms and lead to pulmonary oedema. Patients may also present with other symptoms, such as haemoptysis (rupture of anastomosis between pulmonary and systemic veins), dysphagia, thromboembolism, or hoarseness (due to atrial enlargement).

Demographics of mitral stenosis

Mitral stenosis is now rare in Western societies due to the declining incidence of rheumatic fever. Worldwide, it remains an important cause of cardiovascular morbidity and mortality due to the higher prevalence of rheumatic fever in developing countries. The incidence and prevalence of mitral stenosis is therefore geographically highly variable, with the prevalence ranging from 100 cases per 100 000 population in India to 1 case per 1 000 000 in the US. Women are 2–3 times more likely to present with mitral stenosis (despite similar rates of rheumatic fever among men and women).

Natural history and complications of mitral stenosis

The natural history of mitral stenosis is largely based on cohorts of patients with rheumatic heart disease. Rheumatic mitral stenosis has an asymptomatic latent period of 16–40 years from the initial episode of rheumatic fever to the onset of symptoms. The mean age of presentation is between 40 and 50 years. A long asymptomatic period is associated with good prognosis. Prognosis deteriorates dramatically once symptoms develop:

- New York Heart Association (NYHA) Class I–II: 10-year survival > 80%

- NYHA Class III: 10-year survival = 40%
- NYHA Class IV: 5-year survival < 20%

Serial assessment in such patients suggests a gradual narrowing of the valve area of 0.1–0.3 cm²/year. Left untreated, severe mitral stenosis typically leads to death from pulmonary hypertension and heart failure (65%), systemic embolism (20%), pulmonary embolism (10%), or infection and endocarditis.

Approach to diagnosing mitral stenosis

Physical examination gives clues to the diagnosis, which is then usually confirmed with echocardiography. However, additional investigations may be helpful in the identification of complications and assessment of the risk.

Clinical signs of mitral stenosis

The clinical signs of mitral stenosis are as follows:

General findings: General findings may include malar flush (mitral facies), small volume pulse, atrial fibrillation, V wave in jugular venous pressure, tapping apex beat, palpable first heart sound, apical diastolic thrill, and left parasternal heave (indicating right ventricular hypertrophy).

Auscultation: There is a loud S1 (if in sinus rhythm), accentuated P2, opening snap (maximal in expiration at the apex and only if leaflets still mobile and not heavily calcified), low-pitched rumbling mid-diastolic murmur, and early diastolic murmur of pulmonary regurgitation. Signs of coexistent other valvular diseases are likely to be present.

ECG in mitral stenosis

ECG may show bifid P waves (left atrial enlargement), tall, peaked P waves (pulmonary hypertension), or atrial fibrillation. Right axis deviation and right bundle branch block indicative of right ventricular enlargement may also be present.

Chest X-ray in mitral stenosis

The most likely abnormalities on a chest X-ray are left atrial enlargement (double silhouette along the right heart border and horizontal left bronchus) and pulmonary congestion.

Echocardiography in mitral stenosis

Transthoracic echocardiography is diagnostic. Classical findings in mitral stenosis are restricted opening of the mitral valve leaflets, with the doming of the anterior leaflet leading to a typical 'hockey stick' configuration in the parasternal long-axis view. The severity of mitral stenosis is assessed by measurement of valve area, either directly or indirectly using Doppler flow measurements (see Table 96.1).

Other diagnoses that should be considered aside from mitral stenosis

The differential diagnosis for the symptoms is broad, and includes many forms of heart and lung disease. For the signs, the murmur of left ventricular inflow obstruction can also be caused by an atrial myxoma, a left atrial thrombus causing ball-valve obstruction, or a tumour. These are all rare.

Table 96.1 Doppler flow measurements

	Severity		
	Mild	Moderate	Severe
Mean pressure gradient*	<5 mm Hg	5–10 mm Hg	>10 mm Hg
Systolic pulmonary artery pressure	<30 mm Hg	30–50 mm Hg	>50 mm Hg
Valve area [†]	1.5–2.5 cm ²	1.1–1.5 cm ²	<1.0 cm ²

* Useful in patients in sinus rhythm and a heart rate of 60–80 bpm.

[†] Valve area is usually overestimated if calculated with the pressure half-time (PHT) equation. A PHT >220 should be interpreted as severe mitral stenosis, irrespective of the calculated valve area. Severe tricuspid regurgitation leads to underestimation of severity, and severe mitral regurgitation to its overestimation. In atrial fibrillation, an average of 2–3 cycles should be used.

European Journal of Echocardiography (2009) 10, 1–25 doi:10.1093/ejehocard/jen303
EAE/ASE RECOMMENDATIONS Echocardiographic assessment of valve stenosis:
EAE/ASE recommendations for clinical practice.

'Gold-standard' diagnostic test for mitral stenosis

Echocardiography is the main diagnostic test to diagnose and assess the severity of mitral stenosis.

Acceptable diagnostic alternatives to the gold standard test for mitral stenosis

Transoesophageal echocardiography is often performed for the assessment of the suitability of the valve for balloon valvuloplasty (Wilkins score) and to rule out intracardiac thrombus. Cardiac catheterization allows accurate assessment of the haemodynamics and is often used when echocardiographic findings are inconclusive, or prior to balloon valvuloplasty.

Other relevant investigations for mitral stenosis

Cardiac MRI may have some merit in cases of diagnostic uncertainty.

Prognosis for mitral stenosis, and how to estimate it

Prognosis is associated with the severity of disease and presence of symptoms (see 'Natural history and complications of the disease'). There are no validated prognostic tools for discrimination of future risk.

Treatment of mitral stenosis, and its effectiveness

Medical management of mitral stenosis

Patients who are asymptomatic with respect to sinus rhythm and normal pulmonary artery pressures require no specific treatment. In those patients with mild symptoms, diuretics can lower left arterial pressure and relieve pulmonary congestion. Control of heart rate with beta blockers, calcium channel blockers, or digoxin, particularly in those who develop atrial fibrillation, is crucial. Electrical cardioversion may also be useful to restore sinus rhythm. Afterload reduction with angiotensin-converting enzyme (ACE) inhibitors is relatively contraindicated. Patients with atrial fibrillation, pulmonary hypertension, or a history of an embolic event require anticoagulation with warfarin. The risk of stroke approaches 10% per year. Thus, anticoagulation to an international normalized ratio of 2.5–3.5 is mandatory unless a major contraindication exists.

Interventional or surgical management of mitral stenosis

If symptoms cannot be controlled easily medically or if asymptomatic pulmonary hypertension develops, mechanical relief of the stenosis should be considered. Typical indications include:

- symptomatic patients with moderate or severe mitral stenosis (<1.5 cm²)
- asymptomatic patients with moderate or severe mitral stenosis (<1.5 cm²), and pulmonary hypertension (>50 mm Hg at rest or >60 mm Hg during exercise)

Indications may be expanded to other groups, such as those with previous thromboembolism, paroxysmal atrial fibrillation, need

for non-cardiac surgery, and early or intended pregnancy. The preferred option is percutaneous balloon valvuloplasty (commisurotomy). The suitability for balloon valvuloplasty depends on (i) valve mobility, (ii) subvalvular thickening, (iii) leaflet thickening, and (iv) degree of valvular calcification; the values for these are combined to give a single score (Wilkins score) for evaluation. In addition to a favourable anatomy, absence of severe mitral regurgitation and absence of thrombus in the left atrium are prerequisites for balloon valvuloplasty. Patients with an unfavourable anatomy or the presence of a thrombus or severe mitral regurgitation should undergo surgical valve repair or replacement.

Tricuspid regurgitation

Definition of tricuspid regurgitation

Tricuspid regurgitation is the reflux of blood from the right ventricle into the right atrium as a result of dysfunction of the tricuspid valve. It can arise from abnormalities of any part of the tricuspid valve apparatus, or dilatation/disease of the right ventricle.

Aetiology of tricuspid regurgitation

Tricuspid regurgitation is commonly functional, that is, it is secondary to non-valvular pathologies leading to dilatation of the right ventricle and annular ring (90%). A primary valve pathology is less common (10%).

Secondary or functional tricuspid regurgitation is usually due to pulmonary hypertension (e.g. caused by mitral valve disease or pulmonary embolism) or right ventricular dilatation and diastolic hypertension with malcoaptation of the tricuspid valve (e.g. atrial septal defect).

Primary tricuspid regurgitation is caused by infective endocarditis, Ebstein's anomaly, carcinoid syndrome, trauma, rheumatic heart disease, ischaemic heart disease with papillary muscle dysfunction, or connective tissue disorders (e.g. Marfan syndrome).

Typical symptoms of tricuspid regurgitation, and less common symptoms

There are no specific symptoms with tricuspid regurgitation alone and usually the symptoms of the underlying cause dominate. Many patients with isolated severe tricuspid regurgitation remain asymptomatic for many years. If symptoms develop, they are usually related to the raised atrial and venous pressures manifesting as pulsation in the neck, and right-sided heart failure with abdominal distension, jaundice, and peripheral oedema.

Demographics of tricuspid regurgitation

A small degree of (physiological) tricuspid regurgitation is present in approximately 70% of normal adults. Physiological tricuspid regurgitation is short in duration and often does not extend throughout systole. Moderate-to-severe tricuspid regurgitation was reported in 15% of adults undergoing echocardiography.

Natural history and complications of tricuspid regurgitation

Information on the natural history of tricuspid regurgitation is limited because of the heterogeneity of its underlying causes which usually dominate the long-term outcome. Severe tricuspid regurgitation can lead to cachexia, cyanosis, jaundice, ascites, and peripheral oedema.

Approach to diagnosing tricuspid regurgitation

Typical clinical findings include signs of right-sided heart failure (raised jugular venous pressure, hepatosplenomegaly, ascites, peripheral oedema) and a characteristic murmur (pansystolic murmur best heard at the right or left midsternal border or at the subxiphoid area, with accentuation during inspiration). The jugular veins may show a distinct 'c-v wave' due to systolic regurgitation into the right atrium. The venous pressure is usually pulsatile and may be confused with the

carotid arterial pulse. A murmur may be absent in severe tricuspid regurgitation.

ECG and chest X-ray may give clues to the underlying causes of tricuspid regurgitation (e.g. pulmonary hypertension).

Echocardiography confirms diagnosis and identifies possible aetiology. The right ventricle is usually dilated as is the valve annulus. Doppler colour flow shows the regurgitant jet. A vena contracta width >0.7 cm and systolic flow reversal in the hepatic veins suggest severe tricuspid regurgitation. Other criteria are a dilated inferior vena cava with severely reduced respiratory variation; a dense, triangular-shaped Doppler signal with an early peak; and dilated right heart chambers.

Invasive evaluation via cardiac catheterization may be performed to determine pulmonary vascular resistance or to investigate causes of functional tricuspid regurgitation.

Other diagnoses that should be considered aside from tricuspid regurgitation

Other diagnoses that should be considered in this case are mitral regurgitation and ventricular septal defect.

'Gold-standard' diagnostic test for tricuspid regurgitation

Echocardiography is the 'gold-standard' diagnostic test for tricuspid regurgitation.

Acceptable diagnostic alternatives to the gold-standard test for tricuspid regurgitation

Cardiac MRI is an acceptable diagnostic alternative to echocardiography when diagnosing tricuspid regurgitation.

Other relevant investigations for tricuspid regurgitation

Another relevant investigation for tricuspid regurgitation is right heart catheterization.

Prognosis for tricuspid regurgitation, and how to estimate it

Prognosis depends on the underlying cause of tricuspid regurgitation and its severity. In one study, the survival rates at 1 year for patients with no, mild, moderate, or severe tricuspid regurgitation were 92%, 90%, 79%, and 64%, respectively. Among the subsets of patients without pulmonary hypertension and without left ventricular dysfunction, the association of tricuspid regurgitation with decreased survival was still significant.

Treatment for tricuspid regurgitation, and its effectiveness

There is no established medical therapy for primary tricuspid regurgitation. Diuretics may improve symptoms by reducing the right ventricular volume overload and hepatic congestion. Treatment of pulmonary hypertension (e.g. balloon valvuloplasty for mitral stenosis; pulmonary thromboembolectomy; or the use of vasodilators such as sildenafil or bosentan) can be useful. The value of valve repair (mainly annuloplasty for functional tricuspid regurgitation) is controversial. Generally, in people who have severe tricuspid regurgitation and undergo surgery of left-sided heart disease, annuloplasty is recommended. In mild-to-moderate tricuspid regurgitation, such procedures have not been shown to be beneficial unless there is mitral valve prolapse as, in such patients, myxomatous changes of the tricuspid valve are common and may progress over time.

Pulmonary stenosis

Definition of pulmonary stenosis

Pulmonary stenosis is the thickening and immobility of the pulmonary valve leaflets and leads to the obstruction of blood flow from the

right ventricle to the lungs. As a result, there is an increase in pressure within the right heart.

Aetiology of pulmonary stenosis

Pulmonary stenosis almost always congenital in nature. Associations with sub- or supravulvar stenosis should be considered, and more complex congenital lesions such as Fallot's tetralogy may be present.

Typical symptoms of pulmonary stenosis, and less common symptoms

Pulmonary stenosis may remain asymptomatic over many years as the right ventricle hypertrophies in response to the increased pressure. Once compensatory mechanisms fail, symptoms of dyspnoea, fatigue, and exertional syncope may develop.

Demographics of pulmonary stenosis

Up to 10% of children will have pulmonary stenosis, with a slightly higher rate in females.

Natural history, and complications of pulmonary stenosis

Most patients present in childhood. Isolated pulmonary stenosis has a benign prognosis, for which the survival rate is not significantly different from that of the general population.

Approach to diagnosing pulmonary stenosis

An ejection systolic murmur in the pulmonary area, together with a split-second heart sound and a quiet P₂, is usually present. Patients may have a parasternal heave due to right ventricular hypertrophy. In more advanced stages, signs of right-sided heart failure (elevated venous pressure, jaundice, peripheral oedema) may be present.

ECG may reveal signs of right-heart enlargement (P pulmonale, right-axis deviation, right ventricular hypertrophy). A chest X-ray may demonstrate dilated pulmonary arteries due to poststenotic dilatation.

Echocardiography confirms the diagnosis and can identify associated abnormalities. Cardiac MRI may provide a more accurate assessment of the valve and its severity, together with right ventricular volume and function. A right-heart catheter is rarely required for making the diagnosis unless intervention is planned or complex heart disease is present.

Other diagnoses that should be considered aside from pulmonary stenosis

It is more common to miss pulmonary stenosis than to mistake it for an alternative diagnosis. However, the murmur may be misinterpreted as indicating aortic stenosis or a ventricular septal defect.

'Gold-standard' diagnostic test for pulmonary stenosis

The 'gold-standard' diagnostic test for pulmonary stenosis is right-heart catheterization.

Acceptable diagnostic alternatives to the gold-standard test for pulmonary stenosis

Echocardiography is an acceptable diagnostic alternative to right-heart catheterization when diagnosing pulmonary stenosis.

Other relevant investigations for pulmonary stenosis.

Another relevant investigation for pulmonary stenosis is cardiac MRI.

Prognosis for pulmonary stenosis, and how to estimate it

Patients with mild pulmonary stenosis have a benign disease that rarely progresses. Overall, patients' long-term outcome is unlikely to be affected by an isolated pulmonary stenosis.

Treatment for pulmonary stenosis, and its effectiveness

There is no established medical therapy for pulmonary stenosis. Balloon valvuloplasty is commonly performed to relieve symptoms and to prevent right heart failure. Alternatively, surgical valvotomy, valve repair, or valve replacement is performed in more complex cases. Balloon valvuloplasty is recommended in symptomatic patients with a peak systolic gradient >30 mm Hg and in asymptomatic patients with peak systolic gradient >40 mm Hg (moderate-to-severe disease). Although the evidence is less well established, because of the excellent outcome of balloon valvuloplasty, this procedure may also be considered in asymptomatic patients with a peak systolic gradient of 30–39 mm Hg.

97 Percutaneous coronary intervention

Cheerag Shirodaria and Sam Dawkins

Cardiac catheterization

Cardiac catheterization is a procedure by which **information** is obtained from the heart by passing fine plastic tubes (occasionally other instruments) either near to or within the heart, to introduce contrast to cardiac structures to understand their anatomy and function better, to measure pressures, and/or to measure oxygen saturations in different cardiac chambers. It is an extraordinarily useful **diagnostic** procedure. Percutaneous coronary intervention (PCI) is the modern term for an **intervention** on a coronary artery that relieves narrowing. It includes balloon angioplasty and stent insertion. It is a **therapeutic** procedure.

Cardiac catheterization comprises a number of different procedures:

- **coronary angiography**, where dye is injected into coronary arteries, allowing an understanding of their lumen to be made, and the diagnosis of the severity and extent of coronary narrowings
- **left ventricular cine-angiography**, where dye is injected directly into the left ventricle; used to measure left ventricular systolic function and the severity of mitral regurgitation
- **aortography**, where dye is injected into the aortic root, allowing determination of the aortic root size, the severity of aortic regurgitation, and the presence or absence of aortic dissection (this role is now largely superseded by CT aortography)
- **right-heart saturation measurements**, used to determine intra-cardiac shunt location and magnitude
- **pressure measurements of the cardiac chambers**, which give information about left ventricular performance, pulmonary artery pressure, and pulmonary vascular resistance; **simultaneous right- and left-heart pressure measurements** can be used to diagnose pericardial constriction

Cardiac catheterization is an extraordinarily useful technique; however, it is now largely used for coronary angiography in patients with chest pain and who are suspected of having severe coronary disease. The technique allows the operator to visualize the coronary arteries and identify any narrowings (stenosis). If stenoses are identified, a therapeutic intervention, such as balloon angioplasty or deployment of a coronary artery stent (collectively known as PCI), can be carried out.

The procedure is minimally invasive; access is gained to the arterial system via the femoral artery (one-third of procedures), the radial artery (two-thirds of procedures), or brachial arteries (arterial cutdown; rare these days). A fine catheter is passed to the ostium of the left and then the right coronary artery. Once the catheter is in the ostium, an iodine-based contrast agent is injected and X-rays are taken; as X-ray radiation can pass through thoracic structures but not through the contrast agent in the coronary arteries, a negative image of the coronary lumen is obtained. X-rays are taken in multiple projections to delineate the entire length of the coronary arteries.

Interpretation of coronary angiogram

A knowledge of how to interpret the data obtained from coronary angiography is important. The aim of angiography is to delineate anatomy so as to guide treatment, and in particular, to determine how many coronary stenosis are present and their severity.

Coronary lesion severity

Previously, in chronic stable angina, coronary disease severity was classified by the reduction in transluminal diameter caused by atheroma seen angiographically, although debate arose as to whether a $\geq 50\%$ or a $\geq 70\%$ reduction was significant. This debate has been settled by invasive studies of coronary function obtained using the fractional flow reserve technique (see 'Other invasive techniques to evaluate coronary arteries'). Not surprisingly, it turns out that achieving symptomatic relief from coronary intervention depends on whether the coronary obstruction interferes with coronary artery function; perhaps more surprisingly, it turns out that functional impairment of coronary flow does not relate precisely to anatomic appearance. One-third of narrowings of 50%–70% severity interfere with function, and two-thirds of narrowings of 70%–90% severity interfere with function. About 96% of stenoses $\geq 90\%$ interfere with function. Put another way, in some patients, surprisingly mild narrowings can interfere with function and, conversely in others, surprisingly severe narrowings may not. If functionally unimportant narrowings are treated by PCI or coronary artery bypass graft (CABG), then patients are exposed to risk and not benefit. Unless the narrowing is severe, information beyond that obtained from angiography is needed to plan optimal treatment in chronic stable angina. Such functional data on the extent of ischaemia can be obtained non-invasively prior to angiography (via nuclear, MRI, or stress echocardiography studies) or by fractional flow reserve at angiography. In acute coronary syndrome (ACS), the severity of the stenosis in the artery with the ruptured plaque is important, as the natural history of tighter narrowings is worse; however, as relatively mild untreated narrowings can still lead to abrupt vessel closure, most operators also treat by PCI angiographic lesions **at the site of the ruptured plaque** of 50%–70%. Increasing evidence suggests that 'bystander' disease (i.e. anatomically significant lesions found at the time of angiography undertaken for an ACS, but themselves not directly responsible for the ACS) should also be treated in ACS patients.

Coronary disease location and extent

Different patterns of coronary disease are seen; these are traditionally classified by the number of major epicardial vessels involved and their location, particularly, whether the left main coronary artery or the proximal portion of the left anterior descending (LAD) artery is involved. Major epicardial vessel involvement is regarded as narrowings within the main epicardial arteries but not in their side branches. Patients may therefore have single-, two-, or three-vessel coronary disease, with or without left main or proximal LAD involvement. The extent of prognostic benefit from CABG relates to the severity of the coronary disease, and patients with left main disease, or proximal LAD or three-vessel coronary disease benefit prognostically from early CABG, a benefit magnified in those with diabetes or impaired left ventricular function. Coronary disease can be classified from the perspective of PCI lesion complexity by using **the Syntax Score** (<http://www.syntaxscore.com>) derived from a major trial. This takes data from the lesion distribution and outputs a number, with a high score indicating technical complexity for PCI (and thus favouring CABG), and a low score indicating technical ease during PCI (so favouring PCI).

Other invasive techniques used to evaluate coronary arteries

While coronary angiography is by far the most common means of invasively assessing coronary artery disease, there are other complementary techniques available:

Fractional flow reserve: This is used to determine whether narrowings within coronary arteries impede coronary blood flow. In it, a small pressure probe built into a coronary guide wire is passed into a coronary artery, allowing pressure to be measured simultaneously both within the coronary artery beyond the possible narrowing and, using the standard catheter pressure measurement, at the ostium of the coronary artery. The pressure fall over the narrowing is obtained with the artery in its resting state. The artery is then dilated using the coronary vasodilator adenosine, so increasing blood flow. If the lesion is flow limiting, the increase in coronary flow results in an increased pressure drop over the coronary segment being interrogated. A ratio of ≤ 0.75 in the ratio of proximal to distal pressure indicates a flow limiting lesion; a ratio of ≥ 0.80 indicates no flow limitation; and a ratio of $0.75\text{--}0.80$ indicates possible flow limitation.

Intravascular ultrasound (IVUS): In IVUS, a small ultrasound probe is inserted into the coronary artery over a standard guide wire. Ultrasound emissions (20–40 MHz) are made at 90° to the wire to obtain a two-dimensional, cross-sectional image of the artery. The IVUS probe is then withdrawn with a motorized device at the speed of 0.5 mm/s, so imaging a length of coronary artery. IVUS is extremely good at looking at vessel and luminal diameter (to determine how large a stent is needed), plaque burden (to determine whether intervention is needed), and, perhaps its most important use, how well deployed a stent is. The use of IVUS is sometimes limited by vessel calcification.

Optical coherence tomography (OCT): OCT is an emerging technology that uses light rather than ultrasound to image coronary arteries, obtaining a very high resolution; indeed, so much so that it has been called 'virtual histology'. It has yet to find a clinical role, but its scientific role is fast developing.

Percutaneous coronary intervention (PCI)

Early in its development, PCI consisted of percutaneous transluminal coronary angioplasty (PTCA), a procedure in which a balloon was passed over a thin wire ('a guide wire') to the stenosis and inflated to squeeze the material comprising the blockage to the side of the artery, thereby removing luminal obstruction. There were two limitations to this technique:

- high rates of coronary dissection, resulting in acute vessel closure, myocardial infarction, and the need for emergency CABG
- high rates of restenosis following the procedure (up to 25%–40%); the PTCA balloon injures the vessel wall and, as in all tissues injured, scar tissue (neo-intimal proliferation) results. In the case of the coronary artery, such scar tissue results in luminal obstruction, recurrent symptoms, and, in a few cases, myocardial infarction

These issues have largely been dealt with by using **coronary stents**; these are alloy steel slotted metal tubes, deployed within a coronary artery. They seal dissections and substantially reduce the risk of restenosis. Stents used in PCI can either be **bare metal or drug eluting**, in which case the stent is coated with a drug that reduces neointimal proliferation. Stents are thrombogenic and require moderately intense antiplatelet therapy until they are endothelialized (4 weeks for bare-metal stents, 1 year for drug-eluting stents).

Drug-eluting stents are associated with a small increase in the risk of in-stent thrombosis; the risk can be minimized by giving the patient a second antiplatelet agent (e.g. clopidogrel) with aspirin for the first year post-PCI. The coatings most widely used for drug-eluting stents are paclitaxel (an anti-mitotic agent used in cancer chemotherapy) and sirolimus/everolimus (used for immunosuppression in transplant patients). Drug-eluting stents are of greatest benefit in long (>15 mm), narrow (<3 mm), or proximal lesions (left main, proximal LAD), especially in diabetics. They are also commonly used in

high-risk PCI. They should only be used in patients who are able to comply with antiplatelet therapy and should be avoided if the patient may undergo major surgery within the year, as post-surgical bleeding is considerably higher in those taking dual antiplatelet agents.

Types of PCI

Primary PCI is now used as a slightly better alternative to thrombolysis and refers to PCI that is carried out as an emergency (<1 hour from hospital presentation) for patients with ST-elevation myocardial infarction (STEMI). **Rescue (salvage) PCI** is PCI carried out in patients who have had thrombolysis but in whom there is clinical evidence of continuing occlusion, such as ongoing pain, or failure of ECG resolution. **Facilitated PCI** is primary PCI carried out soon after thrombolysis, and is most often used when a patient cannot undergo primary PCI within the target time (usually because the patient presents to a hospital that does not offer primary PCI) and so receives thrombolytic therapy first, either in the referring hospital or, increasingly, in the ambulance, and then undergoes primary PCI on arrival at the primary PCI centre.

Drugs used in PCI

All patients undergoing PCI should be on aspirin (or another antiplatelet agent) for life. The use of a thienopyridine agent, such as clopidogrel, greatly reduces the risk of stent thrombosis and is used for most PCI. Ideally, clopidogrel starts ≥ 5 days before PCI; if PCI is carried out the same day, a large (600 mg) loading dose is used. Clopidogrel is given for 1 month for bare-metal stents, and for 1 year for drug-eluting stents. There are several new inhibitors of platelet aggregation available, such as prasugrel and ticagrelor, and their use will become more commonplace. Prasugrel acts more quickly and inhibits platelet function more reliably than clopidogrel, and is therefore widely used in primary PCI, where quick, reliable antiplatelet therapy is vital. Ticagrelor is superior to clopidogrel in risk reduction following ACS and may become standard therapy whether or not PCI is used.

Glycoprotein IIb/IIIa antagonists, such as abciximab, tirofiban, or eptifibatid, block the final common pathway of platelet aggregation. They are used in high-risk PCI, such as primary PCI for STEMI, or PCI in non-STEMI with a major troponin rise indicating a large thrombin-rich clot within the coronary artery, as the clot may generate a substantial additional thrombus and acute vessel closure when squeezed with a balloon. It is also used if a PCI procedure has not gone well and arterial occlusion due to thrombus formation has occurred.

Anticoagulation is used in PCI. Unfractionated heparin is the standard; the degree of anticoagulation is monitored from serial activated clotting time (ACT) measurements. The target ACT is 250–350 seconds, and 200–250 seconds if a glycoprotein IIb/IIIa antagonist is used. In patients on low-molecular-weight heparin (LMWH), the amount of unfractionated heparin used depends on the time since the last dose of LMWH and procedure complexity. Post-procedure heparin confers no advantage. Bivalirudin is a direct thrombin inhibitor (in part derived from hirudin, a chemical found in the medicinal leech *Hirudo medicinalis*) which gives predictable, although short-acting, anticoagulation and, in primary PCI, improves outcome, compared to heparin.

Indications for PCI

Stable coronary disease

PCI is a useful adjunct to medical therapy in stable angina. Its main use is symptom relief, not prognostic improvement. Patients have different views on the degree of angina that is tolerable; for many, angina on strenuous exertion may be acceptable, but others prefer to be symptom-free. Comorbidity is another consideration prior to PCI. In the few patients where a large area of ischaemic myocardium is identified by non-invasive testing (e.g. myocardial perfusion scanning), PCI is associated with a prognostic benefit. The amount of myocardium that needs to be ischaemic to yield prognostic benefit from PCI depends on the technique measuring ischaemia—for myocardial perfusion scanning, it is $\geq 10\%$ of the myocardium.

CABG improves prognosis, compared to PCI, in patients with severe coronary disease (e.g. left main stem disease, triple-vessel disease, proximal LAD disease). However, recent advances in

stent technology and better angiographic risk stratification (e.g. Syntax score) according to disease pattern have identified patients in whom outcomes with PCI are equivalent to those with CABG. There are institutional issues about selecting the best means of revascularization for an individual patient, with cardiologists being biased towards PCI, and surgeons to CABG. To ensure that patients receive the best evidence-driven treatment, all revascularization decisions (unless obvious) should be made by a multi-disciplinary team including a cardiologist and surgeons. Whether revascularization is being considered or not, risk factor modification should be aggressively pursued in all, with the implementation of lifestyle changes (those concerning exercise, weight, smoking, and alcohol being the most important), and the use of statins, an angiotensin-converting enzyme (ACE) inhibitor, and, for many, a beta blocker.

STEMI

Primary PCI is superior to thrombolysis in reducing mortality, stroke, and non-fatal reinfarction in STEMI. It requires significant infrastructure both in-hospital (24-hour access to a fully staffed catheterization laboratory) and prehospital (ambulance crews trained to interpret ECGs and/or transmit them to the hospital). The role of PCI in patients with STEMI depends on the local availability of facilities: if primary PCI cannot be delivered within ≤ 2 hours of first contact (usually for geographical reasons) then thrombolysis, alone or as a bridge to facilitated PCI, is the preferred option. Most ambulance services now record an ECG on initial assessment, and, if an STEMI is identified, transfer the patient directly to the nearest primary PCI centre, reducing the time from first medical contact to coronary reperfusion. In the UK, primary PCI is offered to almost all patients with STEMI.

ACS

Most patients with ACS require angiography and PCI if a suitable target lesion is identified. Determining the urgency (and necessity) of PCI depends on risk, and risk-scoring systems such as GRACE and TIMI (both available as web-based calculators) can aid decision-making. There is evidence to suggest that higher-risk patients benefit from invasive management instead of a conservative strategy; this benefit is greatest in the elderly, so these patients particularly should be considered for early referral for PCI. Patients with haemodynamic instability, severe left ventricular dysfunction, angina despite medical therapy (such as morphine and vasodilators), or sustained ventricular arrhythmias should be referred for immediate angiography and treated with the same urgency as those referred for primary PCI. Patients fulfilling the following criteria should be referred for **early** (≤ 72 hours) angiography \pm PCI: raised troponin, dynamic ST- or T-wave changes, impaired left ventricular function, diabetes mellitus, ongoing angina, previous myocardial infarction or CABG, or PCI within the last 6 months. Patients with no further chest pain, no clinical features of heart failure, no new ECG changes, and no troponin rise are low risk and may be suitable for elective rather than urgent PCI and, in some cases, PCI may not be necessary.

Post-procedure management of PCI

PCI can be carried out as a day-case procedure in patients with stable angina, but must be carried out as an inpatient stay for those with ACS. Post-PCI care is generally straightforward, with most patients requiring observation only. Secondary prevention should always be addressed (or readdressed) during an admission for PCI, and this is a good opportunity to check fasting glucose and lipids, and optimize medication.

Complications of PCI

The mortality rate in all PCI is less than 1%; this risk is considerably lower in elective PCI in patients with stable disease (around 0.1%) and higher in primary PCI (4%). Mortality increases with age. The rate of emergency surgery is 0.07%, and that of stroke is 0.08%, for all PCI.

As patients who receive PCI have undergone an arterial puncture while taking high-dose antiplatelet agents and will usually also be anticoagulated, bleeding is the most common initial complication post-PCI. This can occur at the puncture site, demonstrated by an enlarging haematoma or continued bleeding. This can be treated by applying manual pressure to the site or by using one of the various mechanical devices available for this purpose. In patients who have undergone PCI using femoral access, retroperitoneal haematoma is a possibility and should be considered in patients who are haemodynamically compromised or have a falling haemoglobin post-PCI. This is usually managed conservatively with blood transfusion and reversal of anticoagulation, if appropriate. If a large haematoma forms in continuity with the arterial puncture site, a pseudoaneurysm can form. This is usually detected as a swelling at the puncture site, and diagnosis is confirmed using ultrasound. They can be managed by using ultrasound-guided injection of thrombin. Ensuring an adequate period of manual compression post-procedure can reduce the risk of pseudoaneurysm formation. A haematoma adjacent to arterial and venous puncture sites can lead to arteriovenous fistula formation and can be detected clinically by the presence of a bruit. It is diagnosed using ultrasound and usually requires surgical management.

The contrast agent used in angiography and PCI causes a small rise in the serum creatinine in most patients, and a period of hypotension in the acutely unwell patient can accentuate this rise. In some patients, this can be significant and, in $<1\%$, overt renal failure can be precipitated. Patients at risk of contrast nephropathy are those with preexisting renal disease and diabetes. For this reason, in these patients, the contrast dose should be minimized and the patients should be adequately hydrated before and after the procedure to minimize the risk. If the procedure is not urgent, N-acetylcysteine can be administered in the 48 hours before the procedure to reduce the risk further.

Stent complications

There are two major complications seen with intracoronary stents: thrombosis and restenosis. Broadly speaking, stent thrombosis occurs early (<1 month post-procedure) and restenosis later (>6 months).

The highest incidence of stent thrombosis is in the first 30 days post procedure, usually during the first 48 hours. For this reason, a patient with chest pain in the month following PCI should be evaluated very carefully. Taking clopidogrel dramatically reduces thrombosis risk, and the patient should be carefully counselled on the importance of taking clopidogrel regularly and for the prescribed duration. The current guidance is for patients with bare metal stents to take clopidogrel for 1 month, and those with drug-eluting stents should take it for 1 year. The reason for this difference is that the coating on drug-eluting stents impairs the process of endothelialization of the stent struts and thus increases thrombosis risk. There is an increased risk of very late stent thrombosis (>9 months post-procedure) with drug-eluting stents but this risk is small ($<1\%$). Other factors that increase the risk of stent thrombosis include the use of long stents; stenting a narrow lesion; the presence of bifurcations; and patients having ACS (rather than stable angina).

The other major complication, stent restenosis, is highest with balloon angioplasty. The use of bare metal stents reduces this risk, and the use of drug-eluting stents reduces it further still. Risk factors for stent restenosis are similar to those for thrombosis, and also include preexisting chronic kidney disease and diabetes mellitus.

98 Heart surgery

David Taggart and Yasir Abu-Omar

History

Cardiac surgery is still a relatively young specialty, having developed only in the latter half of the twentieth century with the introduction of extracorporeal circulation or 'cardiopulmonary bypass' (CPB). This initiated the era of open heart surgery, initially allowing the repair of congenital heart defects, then valve replacements, coronary artery bypass grafting (CABG), and, finally, heart transplantation. Over the last two decades, improvements in medical, anaesthetic, and surgical management of patients, allied to refinements in extracorporeal perfusion technology, have resulted in a decreasing mortality and morbidity from heart surgery despite the advanced age and significant comorbidity of many patients. Today, heart surgery continues to improve the prognosis and quality of lives of patients around the world. Surgical techniques and technologies continue to evolve and recent years have witnessed the emergence of, amongst others, the use of long-lasting conduits for CABG procedures, beating-heart ('off-pump') surgery, the use of minimally invasive and robotic techniques, and long-term mechanical circulatory support.

CPB

Although perfusion technology has evolved, the principles of CPB have remained consistent since the earliest clinical application by Gibbon in 1953. By diverting blood from the right atrium to the ascending aorta via a perfusion machine where blood is oxygenated and, if required, cooled, CPB supports the systemic circulation while bypassing the heart and lungs. The heart can then be temporarily paralysed, using biochemical solutions containing a high concentration of potassium, allowing surgery on a still, bloodless operating field. Numerous technological advances have resulted in highly sophisticated perfusion machines and biocompatible circuits, but systemic anticoagulation is still mandatory to prevent blood coagulation on exposure to the extracorporeal circuit. Use of CPB, however, has some drawbacks. Contact of blood with the extracorporeal circuit results in activation of a systemic inflammatory response syndrome which, although usually subclinical, can (rarely) result in end-organ dysfunction or failure. Other limitations include systemic hypoperfusion and microembolization, which may further contribute to end-organ injury.

Surgery for ischaemic heart disease

Despite significant advances in its treatment over the last two decades, including ever-improving medical therapy and interventions where appropriate, coronary artery disease (CAD) remains a major health burden in the developed world. Annually, it accounts for around 95 000 deaths in the UK, making it the most common cause of death (20% of men and 14% of women still die as a consequence of CAD).

CABG is the most common surgical procedure performed on the heart, with over half a million operations carried out worldwide every year. It is the most extensively studied surgical procedure ever undertaken with follow-up data extending to over four decades.

For the last three decades, CABG has remained the 'gold-standard' treatment for patients with multivessel and left main CAD. Despite advances in percutaneous coronary intervention (PCI) with drug-eluting stents, CABG still remains the best therapy in terms of prognosis and relief of symptoms in patients with more extensive CAD. CABG is highly effective in relieving the symptoms of CAD and improving life expectancy in certain anatomic patterns of disease;

these benefits are magnified in diabetic patients as well as those with the most severe disease, demonstrable ischaemia, and especially in the presence of impaired left ventricular function. Furthermore, CABG is a remarkably safe therapy. Improvements in medical, anaesthetic, and surgical management have ensured that its mortality has remained static (below 2% overall and 1% for elective patients) over the last decade, despite being applied in an ever-increasing, ageing, and sicker patient population.

The principle of CABG is to bypass diseased segments of the coronary arteries by using arterial and venous conduits. The most frequently used conduits are the left internal mammary artery (LIMA) and the long saphenous vein. The main drawback of CABG over the long term is vein graft failure, occurring in up to 50% of vein grafts at 10 years, and 75% at 15 years, leading to recurrent angina, myocardial infarction, and death. Whether the widespread use of antiplatelet agents and statins may improve graft longevity and subsequent outcome is unknown.

While the mammary artery is the conduit of first choice, several other conduits have been used with varying results. Performance of conduits is judged on the basis of patency, which ultimately affects clinical outcome. Patient factors, including coronary anatomy, also play an important part in the decision-making process. Figure 98.1 shows some of the graft configurations that may be used in CABG.

Conduits used in CABG

LIMA

The LIMA became the established graft of first choice when its superiority to saphenous vein grafts, with respect to patency rates and improved patient survival, was reported in 1986. The patency rate of the LIMA to the left anterior descending coronary artery, functionally the largest and most important coronary artery, is in excess of 90% at 10 years, in comparison to 50% for vein grafts. This improves survival by around 10% at 10 years, as well as reducing the incidence of recurrent angina, myocardial infarction, and the need for repeat intervention.

Bilateral internal mammary artery

Intuitively, the superior patency rate of the LIMA suggests that use of bilateral internal mammary artery (BIMA) would lead to even greater clinical benefits. To date, the most powerful evidence supporting this comes from a systematic review of observational studies by Taggart and colleagues of over 15 000 patients (Wijns et al., 2010). However, the use of BIMA should be weighed against its potential drawbacks, which include devascularization of the sternum (and hence an increased risk of wound complications, especially in obese diabetic patients), the increased operation time, and the technical challenges associated with its use. A randomized trial involving over 3000 patients (the Arterial Revascularisation Trial) on the use of BIMA versus single internal mammary artery has been completed and is due to be reported in the near future.

Long saphenous vein

The long saphenous vein was first used as a conduit for CABG in the 1960s and, to date, remains the most commonly used conduit. It is usually harvested using an open technique, but minimally invasive approaches are being increasingly utilized with the aim of reducing leg wound morbidity. Its main limitation is a continuing attrition due to the development of atherosclerosis leading to poorer patency rates over the longer term (only 50% at 10 years, and 25% at 15 years) but this may improve with increased use of secondary preventative measures such as antiplatelets and statins.

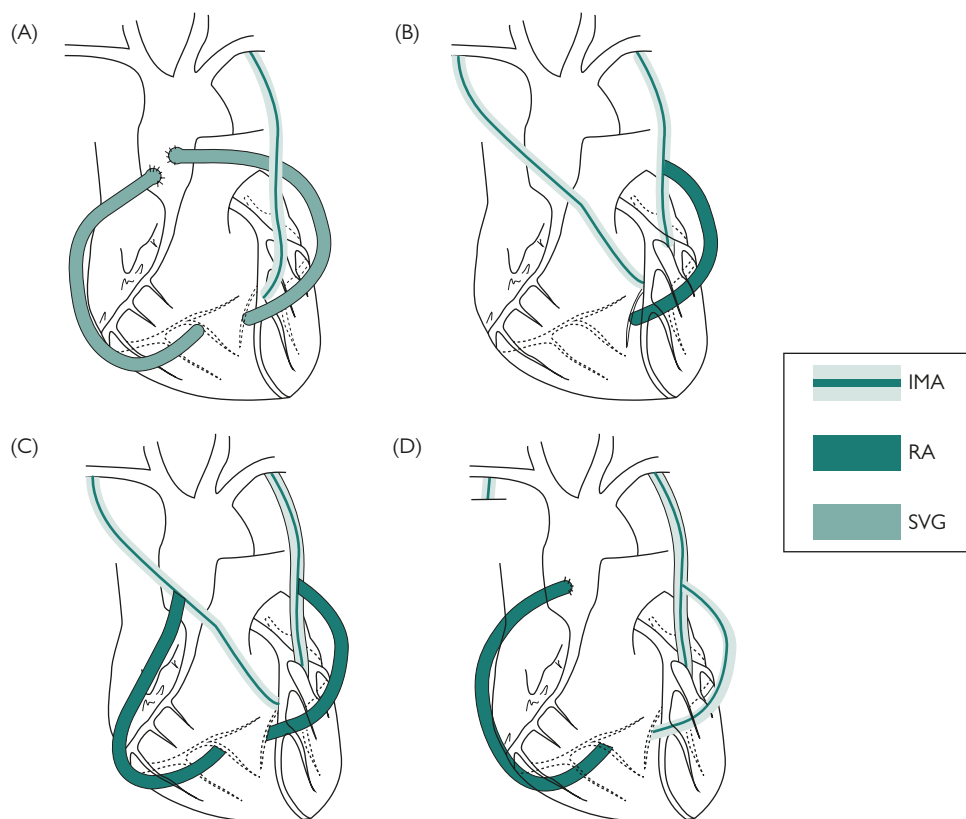

Figure 98.1 (A–D) Various graft configurations that can be used in coronary artery bypass surgery; IMA, internal mammary artery; RA, radial artery; SVG, saphenous vein graft.

Reprinted from *Medicine*, Volume 42, edition 9, Yasir Abu-Omar, David P. Taggart. Coronary artery bypass surgery, pp. 527–531. Copyright © 2014), with permission from Elsevier.

Radial artery

This conduit was first used in the 1970s but soon abandoned due to an observed increased risk of morbidity as a consequence of arterial spasm. Improved harvesting techniques, the use of antispasmodics to prevent vasospasm, and the demonstration of the radial artery's superior patency rate, as compared to those for vein grafts, has led to a resurgence of interest in its use as a conduit. Advantages include the low morbidity associated with radial artery harvesting, and avoidance of the need for leg incisions, thus encouraging early post-operative mobilization.

Other conduits

Other conduits, such as the short saphenous and cephalic veins or the inferior epigastric and gastroepiploic arteries, are only rarely used, when other conduits are not available, because of inferior patency rates.

Off-pump coronary artery bypass (beating-heart surgery)

CABG using CPB remains the gold-standard treatment for CAD. Over the past decade, techniques of revascularization on the beating heart without the use of CPB ('off-pump' surgery) have evolved, with an attempt to reduce the potential deleterious effects of extracorporeal circulation.

Around 20% of CABG procedures are currently performed off pump in the Western world but a far higher proportion is performed in the Far East. There is conflicting evidence about the efficacy of off-pump CABG in reducing mortality and/or morbidity, in comparison to that of conventional CABG with CPB. Several but not all trials have reported a significant reduction in morbidity following off-pump surgery in lower-risk patients, while large observational studies in higher risk patients have also reported a reduction in mortality. Furthermore, off-pump surgery potentially allows complete

avoidance of aortic manipulation, especially in patients with severe aortic atherosclerosis, thus reducing the incidence of stroke.

Off-pump surgery is technically more challenging than conventional CABG, and concerns have been expressed about inferior-quality anastomoses leading to reduced graft patency. Off-pump surgery, however, remains a safe and efficacious alternative to conventional CABG in experienced hands and may have the additional advantage of reducing mortality, morbidity, and, particularly, the risk of stroke in older, sicker patients

Surgery for valvular heart disease

Surgery remains the treatment of choice for symptomatic patients with valvular heart disease and results in significant improvements in prognosis and quality of life. The majority of valve lesions are diagnosed using echocardiography to precisely define the valvular lesion (stenosis, regurgitation, or mixed) and identify associated abnormalities (e.g. left ventricular impairment). Indications for surgery in the management of valve disease are discussed elsewhere. In general terms, valve surgery is recommended for all symptomatic patients with severe valve lesions, provided the risk of surgery (as assessed by scoring systems such as EuroSCORE) is not prohibitive. In asymptomatic patients with severe valve lesions, surgery may be advised in specific circumstances (e.g. when valve disease has resulted in left ventricular systolic dysfunction or severe pulmonary hypertension).

Surgical techniques used for valvular heart disease

Techniques to treat aortic valve disease

The mainstay treatment of aortic valve disease is valve replacement using a prosthetic valve. This is a frequently performed procedure with a low mortality (around 2%) and morbidity, and results in a remarkable improvement in prognosis and quality of life. Recent developments include the use of percutaneous aortic valve implantation

techniques, but developments are ongoing. Open surgical valve replacement remains the gold standard for many patients. However, Transcatheter Aortic Valve Implantation (TAVI) is a rapidly evolving field, and increasing numbers of patients are undergoing this procedure. Current UK criteria are extremes of age, or co-morbidity rendering the risks of cardiac surgery prohibitively high. However, as technology improves, these criteria are being progressively relaxed, and some patients at lower risk for conventional surgery now undergo TAVI. All patients for aortic valve surgery should be reviewed by a multidisciplinary team prior to intervention to ensure that they receive the best procedure for them.

Techniques to treat mitral valve disease

In mitral valve disease, valve repair rather than replacement is the first-line treatment, particularly in patients with mitral regurgitation. Around 90% of regurgitant valves can be repaired with low mortality (around 1%) and morbidity, and excellent clinical outcome. The technique of repair depends on the underlying pathology and may involve surgery on the leaflets, chordae, or mitral valve annulus. Use of minimally invasive techniques in mitral valve surgery is rapidly gaining in popularity and reduces morbidity by reducing surgical trauma and hospital stay while hastening patient recovery.

Choice of valve prosthesis

When valve replacement is necessary, several prostheses are available, broadly divided into mechanical and biological valves. Choice is dictated by several factors that include patient age and preference and longevity of the valve substitute. Mechanical valves are virtually indestructible and are reserved for the younger age group, but their main disadvantage is the need for lifelong anticoagulation (with around a 1% annual risk of serious bleeding). In contrast, biological valves have a limited lifespan, compared to mechanical valves, but do not necessarily require anticoagulation unless indicated by patient factors, such as the presence of atrial fibrillation. Biological valves are therefore usually reserved for patients over 65–70 years of age and especially because structural deterioration is much faster in these patients than in younger patients. In patients over the age of 70 years, the life expectancy of current biological valves would be expected to be in excess of 90% at 10 years. Infrequent but major complications following valve replacement include haemorrhage (secondary to anticoagulation), thromboembolism, and infection.

Surgery of the thoracic aorta

Surgery of the thoracic aorta has evolved over the last three decades, with improved preoperative assessment, surgical techniques, and perioperative management. It does, however, remain particularly challenging, with a higher risk of mortality and major morbidity particularly affecting the CNS.

Surgery for aortic dissection

Aortic dissection is the commonest thoracic aortic emergency and arises when a tear in the intima allows blood to be directed from the aortic lumen into the media, resulting in the formation of true and false lumens. The dissection may extend distally and compromise perfusion of the aortic side branches, resulting in end-organ ischaemia. It may also extend proximally and result in coronary ischaemia by compromising coronary blood flow. If the false lumen penetrates the adventitia of the aortic wall, it usually results in rupture and immediate death.

Patients present with acute onset chest or back pain, and there may be additional signs of end-organ ischaemia (e.g. stroke, renal failure, bowel infarction, leg ischaemia). Risk factors for aortic dissection include long-standing hypertension, atherosclerosis, connective tissue disorders (e.g. Marfan syndrome), trauma, and iatrogenic factors.

The most commonly used classification of aortic dissection is the following, called the Stanford system:

- Type A: dissection involving the ascending aorta
- Type B: dissection sparing the ascending aorta

The classification of an aortic dissection has very important implications for its treatment. An acute Type A aortic dissection is a surgical emergency with a mortality of up to 90% in the first 48 hours

(many of the patients die before reaching hospital). Prompt resuscitation and blood pressure control is followed by immediate surgical repair, which involves replacement of the ascending aorta with a prosthetic graft to prevent progression and rupture. This procedure may require systemic cooling (usually to 18°C–20°C) and circulatory arrest to construct the distal anastomosis to the arch of the aorta. Type A dissection carries an immediate mortality of around 20% and a high risk of cerebral injury.

Type B aortic dissection is usually managed medically with rigorous blood pressure control and regular follow-up. Intervention is indicated in the presence of life-threatening complications such as imminent rupture or malperfusion. The conventional approach is with surgery, but this is associated with a high risk of mortality and paraplegia secondary to spinal cord ischaemia. There is an increasing trend towards minimally invasive approaches using endovascular grafts which significantly reduce the immediate operative risk and major complications, but with a less durable outcome over the longer term.

Some patients present with chronic dissection of the aorta. Surgery is only indicated in these cases in the presence of persistent symptoms, malperfusion, or aneurysm formation.

Surgery for thoracic aortic aneurysm

Aneurysms of the thoracic aorta have a significant male preponderance and are classed as follows according to the part of the aorta involved:

- ascending
- arch
- descending thoracic
- thoracoabdominal

The aetiology of aortic aneurysms may be degenerative (atherosclerosis), congenital (associated with bicuspid aortic valve disease), due to connective tissue disorders (Marfan and Ehlers–Danlos syndromes), associated with aortic dissection, infective (mycotic), inflammatory (aortitis), or traumatic.

Surgery is indicated for:

- dissection
- rupture
- associated aortic valve disease
- large aneurysms:
 - >5.5 cm for the ascending aorta
 - >6.5 cm for the descending aorta
 - >4.5 cm in patients undergoing concomitant surgery
- aneurysms with a rate of growth of >1 cm/year

Imaging (using contrast CT) is essential in the preoperative evaluation and in planning the operative strategy. The surgical technique depends on the part of the aorta affected and involves replacing the aneurysmal segment of the aorta with a prosthetic graft.

Surgery for heart failure

End-stage heart failure is increasingly prevalent in the Western world, and ischaemic heart disease is the primary cause, affecting over half of all cases. Despite improvement in medical therapy for heart failure, prognosis remains very poor, with a mortality of 30% at 1 year. Surgical techniques continue to evolve in the management of heart failure and include revascularization; mitral valve surgery; mechanical circulatory support and the total artificial heart; and heart transplantation.

Revascularization

Coronary revascularization is a high-risk procedure in this group of patients and is indicated only in those with evidence of significant ischaemia and myocardial viability.

Mitral valve surgery

Left ventricular dilatation may result in significant mitral regurgitation, which is associated with a significant reduction in survival. Mitral valve surgery in selected patient groups has been shown to improve long-term outcome.

Mechanical circulatory support and the total artificial heart

Mechanical support may provide assistance to the failing heart by supporting the left and/or the right ventricles. It is increasingly used in view of limited donor organ availability for heart transplantation. These devices may be used to provide temporary support of the myocardium in acute myocarditis until recovery occurs (bridge to recovery), or until transplantation can be performed (bridge to transplant). Alternatively, these devices may be used for permanent support of patients with end-stage heart failure who are not candidates for transplantation (destination therapy). The technology associated with these devices continues to evolve rapidly, and in the future they will become viable alternatives to heart transplantation.

Heart transplantation

This is the best treatment for suitable patients with end-stage heart failure. Survival following successful transplantation is over 50% at 10 years. It is however limited by donor-organ shortage in an era with increased demand for transplantation.

Summary

Heart surgery offers highly cost-effective symptomatic and prognostic benefits to a broad range of patients with cardiovascular disease. Advances in technology, and scrutiny of results, have allowed for the evolution of cardiac surgical techniques which have translated into direct clinical benefits. Most adult cardiac surgical practice currently centres on the treatment of ischaemic heart disease and valvular disease, but in the future is likely to increasingly focus on mechanical support in patients with heart failure.

99 Circulatory support therapy

Kazem Rahimi

Introduction

A broad range of acute and chronic conditions reaching from hypovolaemic shock to ventricular tachycardia can present with circulatory failure. Hence, the approach for management of circulatory failure can vary considerably. This chapter focuses on circulatory failure due to pump failure of the heart and builds on general treatment strategies discussed in Chapters 91 and 92. Three major circulatory support therapies are discussed further: pharmacological therapy, balloon pumping, and surgically inserted devices. Treatment of circulatory failure unrelated to pump failure, and general measures such as fluid resuscitation, are beyond the scope of this chapter.

Pharmacological therapy

Pharmacological therapy aims to support myocardial function by increasing myocardial contractility. Currently, three major classes of inotropic agents are described:

- beta agonists: dobutamine, dopamine, adrenaline, noradrenaline
- phosphodiesterase inhibitors (increase contractility by increasing intracellular calcium concentration): amrinone, milrinone, vesnarinone, enoximone
- calcium sensitizers (increase the sensitivity of calcium receptors without increasing the intracellular calcium concentration): levosimendan, pimobendan

These agents differ in many pharmacological respects, both within and among classes. Beta agonists are the oldest and most widely used, albeit least well-studied, inotropic agents. On the basis of some distinctive pharmacological properties, many experts have traditionally given preference to the combination of dobutamine and dopamine over other beta agonists for treatment of systolic heart failure. However, there is little evidence to support such a choice. In fact, in the SOFA-II trial, which compared dopamine with noradrenaline for the treatment of shock (including cardiogenic shock), the use of dopamine was associated with a higher rate of arrhythmic complications, compared to noradrenaline. Similarly, many other promising pharmacological properties of inotropes have failed to translate into measurable clinical benefits. Current recommendations are, therefore, largely based on expert opinion and can be summarized as follows:

- The use of inotropes should be restricted to patients with persistent hypotension (systolic blood pressure <80–90 mm Hg) despite adequate fluid resuscitation and who have evidence of organ dysfunction (somnolence, oliguria, lactic acidosis, worsening renal or liver function) due to systolic heart failure.
- Patients with persistent fluid overload despite intensive diuretic therapy may also benefit from inotropic therapy.
- The use of inotropes should be limited to a minimum to avoid some of their common risks, such as arrhythmia.
- Treatment with inotropes can be used as a bridge to more definitive therapy, such as insertion of assist devices, or heart transplantation, or until circulatory recovery.
- Dobutamine (2–20 µg/kg min⁻¹) is the first choice in low-output states, often in combination with dopamine (1–10 µg/kg min⁻¹).
- The phosphodiesterase inhibitors milrinone and enoximone may have an advantage over beta agonists in patients in whom beta blocker use is maintained. However, they can worsen hypotension due to their significant vasodilating effect, and trial evidence (e.g. from OPTIME-CHF, PROMISE) for many phosphodiesterase inhibitors has been disappointing.

- Calcium sensitizers are considered experimental in the US. Levosimendan has not been shown to be superior to dobutamine in terms of reduction in risk of mortality (SURVIVE trial). The European Society of Cardiology recommends its use as an alternative to other inotropes, in particular if patients are already on a beta-blocker therapy.
- The vasoconstricting beta agonist noradrenaline is usually used in cardiogenic shock (in combination with dobutamine). Adrenaline's use is restricted to cardiac arrest.

The disappointing findings from many trials testing the efficacy and safety of inotropes, despite promising haemodynamic improvement, have challenged the whole concept of improved contractility without modification of energy metabolism, and have led to the hypothesis that the mismatch between energy consumption and energy production may be responsible for the harms caused by these agents. Emerging therapies such as ranolazine or perhexiline improve cardiac performance by modifying substrate utilization from free fatty acids to more efficient fuels like glucose and lactate, and thus provide energy to a myocardium that has run out of fuel. Whether such improvements in the utilization of myocardial energy can translate into clinical benefits is subject to a number of ongoing and planned trials.

Balloon pumping

The intra-aortic balloon pump (IABP), or balloon pumping, is a percutaneously inserted balloon in the descending aorta distal to the left subclavian artery; it inflates in the early diastole (filled with helium gas and triggered by ECG) and deflates in the late systole. IABP is currently the most widely used circulatory assist device. The counterpulsation of the balloon in the diastole has two main desired effects:

- It leads to augmentation of blood pressure during early diastole and hence improved coronary perfusion.
- The rapid deflating of the balloon in late diastole leads to reduced afterload through a vacuum effect and increases myocardial contractility at a lower myocardial energy consumption level.

Measurable haemodynamic effects in the individual patient are highly variable and depend on the exact timing of the balloon inflation and deflation, the volume of the balloon, its position in the aorta, heart rate, rhythm, the compliance of the aorta, and systemic resistance. On average, patients with cardiogenic shock may be expected to show the following haemodynamic changes:

- a decrease in systolic pressure by 20%
- an increase in diastolic pressure by 30%
- a reduction of the heart rate by less than 20%
- a decrease in the mean pulmonary capillary wedge pressure by 20%
- an elevation in the cardiac output by 20%

The evidence for the balance of efficacy and safety of IABP is tenuous. Randomized clinical trials for many of the currently recommended and widely used indications are lacking. Indeed, a meta-analysis of all trials that compared IABP with no IABP showed no difference in 30-day mortality but an increased 6% and 2% risk of bleeding and stroke, respectively, in the 500 patients in the IABP group as compared to the 500 patients in the control group (Sjauw et al., 2009). Planned trials may shed some light on the clinical value of IABP. Guidelines predating this meta-analysis acknowledge the gap in evidence but make recommendations for IABP use for the following indications:

- persistent hypotension (<90 mm Hg) unresponsive to other measures and with signs of end-organ dysfunction

- cardiogenic shock
- pre- and post-complex percutaneous coronary intervention/coronary artery bypass graft in haemodynamically unstable patients or patients with intractable angina
- acute mitral regurgitation or ventricular septal defect, as a bridge to more definitive therapy

IABP should not be used in patients with:

- significant aortic regurgitation
- aortic dissection
- severe peripheral arterial disease
- a high risk of bleeding

As many as 7% of patients experience complications related to IABP, of which a third can be considered as major. Complications include:

- stroke
- limb ischaemia
- perforation of the femoro-iliac arteries
- aortic dissection
- cholesterol emboli (e.g. leading to renal failure)

The use of IABP requires anticoagulation, usually with unfractionated heparin. IABP use should be kept to a minimum. Stepwise weaning, with reduction of the assisted counterpulsations from 1:1 to 1:3 every 3–4 hours, is recommended. After haemodynamic stability for about 4 hours without support (usually after initiation of vasodilators and/or beta blockers), the use of IABP can be withdrawn.

Surgically inserted devices

Surgical devices for mechanical cardiac support are commonly called ventricular assist devices (VADs). They are based on the principle of a parallel 'artificial heart' which bypasses the blood flow away from the ventricle(s) with the use of an extracardiac mechanical pump and improves forward circulatory output and cardiac filling pressures. On the basis of the ventricle(s) being supported, three types of VADs can be differentiated:

- left ventricular assist device (LVAD): this channels blood from the left ventricle or left atrium to the pump and then from the pump to the ascending aorta
- right ventricular assist device (RVAD): this channels blood from the right ventricle or right atrium to the pump and then from the pump to the pulmonary artery
- biventricular assist device: this is a combination of an LVAD and an RVAD

The newer, third-generation VADs (e.g. Heart Ware HVAD, Duraheart, Levacor) are becoming increasingly smaller in size and have continuous-flow centrifugal pumps that are magnetically or hydrodynamically levitated with minimal risk of bearing failure, which was seen with older-generation VADs. The net beneficial effect of these rapidly developing devices, however, has not yet been shown in randomized trials, and current recommendations are largely based on expert opinion. VADs are most commonly used as a bridge to transplantation in people with severe heart failure despite optimal medical therapy, or as bridge to recovery in people with severe myocarditis (although the ability to wean off VADs is usually poor). The increased longevity of the devices, reduced post-operative morbidity, and the greater likelihood of patient acceptance have led to some enthusiasm for the use of VADs as destination devices in people with severe left ventricular dysfunction and severe symptomatic heart failure but who are not candidates for transplantation. However, supporting evidence for such an expansion in indication is currently awaited.

Contraindications for VAD support usually include high surgical risk for device implantation, recent or evolving stroke, conditions impairing the ability to manage the device, a coexistent terminal condition, an abdominal aortic aneurysm >5 cm, active systemic infection, fixed pulmonary or portal hypertension, severe pulmonary dysfunction, multisystem failure, inability to tolerate anticoagulation, bleeding disorder, and pregnancy.

Common adverse events include surgical mortality, bleeding, right ventricular failure, infections, thrombosis, device malfunction, and neurological events.

100 Pulmonary hypertension

Robert MacKenzie-Ross, Karen K. K. Sheares, and Joanna Pepke-Zaba

Definition of the disease

Pulmonary hypertension (PH) is a haemodynamic and pathophysiological condition defined as mean pulmonary artery pressure ≥ 25 mm Hg at rest, assessed by right-heart catheterization (8–20 mm Hg is considered normal). A pulmonary capillary wedge pressure measurement of >15 mm Hg indicates a significant pulmonary venous component.

PH is associated with a variety of causes. The current PH classification is helpful in understanding the different etiological, pathological, and treatment approaches (see Box 100.1).

Box 100.1 Updated clinical classification of pulmonary hypertension (Nice, 2013)

1. Pulmonary arterial hypertension
 - idiopathic
 - heritable
 - BMPR2
 - ALK-1, ENG, SMAD9, CAV1, KCNK3
 - drug and toxin induced
 - associated with:
 - connective tissue diseases
 - HIV infection
 - portal hypertension
 - congenital heart diseases
 - schistosomiasis
 - persistent pulmonary hypertension of the newborn
 - pulmonary veno-occlusive disease and/or pulmonary capillary haemangiomatosis
2. Pulmonary hypertension owing to left heart disease
 - Left ventricular systolic dysfunction
 - Left ventricular diastolic dysfunction
 - Valvular disease
 - Congenital/acquired left heart inflow/outflow tract obstruction and congenital cardiomyopathies
3. Pulmonary hypertension owing to lung diseases and/or hypoxaemia
 - COPD
 - interstitial lung disease
 - other pulmonary diseases with mixed restrictive and obstructive pattern
 - sleep-disordered breathing
 - alveolar hypoventilation disorders
 - chronic exposure to high altitude
 - developmental abnormalities
4. Chronic thromboembolic pulmonary hypertension
5. Pulmonary hypertension with unclear multifactorial mechanisms
 - haematologic disorders:
 - splenectomy
 - chronic haemolytic anaemia, myeloproliferative disorders
 - systemic disorders:
 - sarcoidosis
 - pulmonary histiocytosis
 - lymphangioleiomatosis
 - metabolic disorders:
 - thyroid disorders
 - glycogen storage disease
 - Gaucher's disease

- others:
 - tumoural obstruction
 - chronic renal failure on dialysis
 - fibrosing mediastinitis

Aetiology of the disease

Different pathological features characterize the diverse clinical PH groups.

Group 1 (pulmonary arterial hypertension (PAH)) displays characteristic changes in the pulmonary artery, including medial hypertrophy, intimal proliferation, adventitial thickening, and plexiform and thrombotic lesions. This reduces the vessel calibre, changing its compliance and diffusion properties.

Group 2 (pulmonary hypertension owing to left heart disease) pathological changes are characterized by enlarged pulmonary veins, pulmonary capillary dilatation, and interstitial oedema.

Group 3 (pulmonary hypertension owing to lung diseases and/or hypoxia) pathological changes predominantly involve medial hypertrophy and intimal obstructive proliferation of the distal pulmonary arteries.

Group 4 (chronic thromboembolic pulmonary hypertension (CTEPH)) is characterized by organized thrombi attached to the pulmonary arterial medial layer, replacing the normal intima. These may completely occlude the lumen or form different grades of stenosis, webs, and bands. In the non-occluded areas, a pulmonary arteriopathy, indistinguishable from changes seen in Group 1 (including plexiform lesions), develops.

Group 5 (pulmonary hypertension with unclear multifactorial mechanisms) includes heterogeneous conditions with different pathological pictures.

In all cases, there is increased pulmonary artery pressure and increased pulmonary vascular resistance affecting the right ventricular workload.

Typical symptoms of the disease, and less common symptoms

Symptoms are nonspecific and often attributed to another cause, leading to late diagnosis. Symptoms start with breathlessness on exertion, progressing to breathlessness on minimal exertion, and ultimately at rest. Other symptoms include fatigue, weakness, angina, presyncope, abdominal distension, and, in advanced cases, peripheral oedema, syncope, arrhythmias, chest pain, and ascites.

If PH is associated with another disease, there will also be symptoms related to this condition.

Demographics of the disease

The aetiology of the PH will determine the demographics. The most frequent causes of PH are common medical diseases (e.g. left heart disease, COPD).

Group 1

The demographics of Group 1 PH are as follows:

Idiopathic PAH: incidence 1 to 3.3 cases per million per year; female predominance

PAH associated with connective tissue disease: predominantly seen with scleroderma (8%–22% prevalence in this group)

PAH associated with HIV: ~0.5% prevalence in the HIV population

Portopulmonary hypertension: prevalence 1%–6% in patients with portal hypertension

Group 2

The prevalence of PH associated with left heart dysfunction is up to 70% in patients with isolated left ventricular diastolic dysfunction, and up to 60% in patients with severe left ventricular systolic dysfunction.

Group 3

The demographics of Group 3 PH are as follows:

PH in patients with COPD: in patients screened for lung volume reduction surgery/lung transplantation (mean FEV₁ 24% of predicted), the prevalence is estimated at 40%

PH associated with interstitial lung disease: prevalence is estimated at between 8% and 34%

Group 4

Between 1% and 5% of patients with acute pulmonary embolism progress to CTEPH. However, 25% of patients with CTEPH do not give a history of acute pulmonary embolism.

Natural history, and complications of the disease

Hypoxic vasoconstriction and remodelling of the arterial or venous components of pulmonary circulations will initially increase pulmonary artery pressure and pulmonary vascular resistance. As the disease progresses, cardiac output will fall, leading to right-heart failure, which is the cause of the death in the majority of cases.

Increased right atrial pressure can re-open a foramen ovale, thereby helping to offload the right-heart chambers.

For PH associated with other conditions, the symptoms will intertwine with any symptoms related to the underlying disease process.

Approach to diagnosing the disease

Medical history

The main symptom is progressive exertional breathlessness. Ask about other symptoms (see 'Typical symptoms of the disease, and less common symptoms'). A diagnosis of idiopathic PAH should only be made after excluding other conditions which could contribute to PH.

Important risk factors are:

- use of dieting drugs (aminorex, fenfluramine, dexfenfluramine, benfluorex)
- history of DVT or pulmonary embolism
- history of splenectomy
- childhood murmurs
- Raynaud's phenomenon, or skin changes

Examination

Depending on the severity, there may be clinical signs of right-heart failure: raised jugular venous pressure (JVP), loud second heart sound, systolic murmur of tricuspid regurgitation, right ventricular heave, peripheral oedema, enlarged pulsatile liver, and/or ascites. The rest of the examination is directed towards the search for underlying causes.

Diagnostic tests

ECG

ECG will be normal in the early disease stage or will show a right ventricular strain pattern: right-axis deviation, a dominant R wave in V1, T-wave inversion in the anterior chest leads, right bundle branch block, or an enlarged P wave in Lead II (P pulmonale).

Chest X-ray

The chest X-ray may be normal, but often shows enlarged central pulmonary vessels, attenuation of the peripheral vessels, and a prominent right-heart border (right atrial enlargement). Look for causes of PH (e.g. lung parenchymal diseases, pulmonary infarcts).

Blood tests

The following blood tests may be used:

- full blood count: this is often normal; polycythaemia suggests congenital heart disease or hypoxic lung disease
- urea and electrolytes, and liver function test: these are often normal; the liver function test could be abnormal from liver cirrhosis or hepatic congestion from right heart failure
- thyroid function testing, hepatitis serology, and HIV testing: these can identify conditions associated with PH
- autoantibody testing: antinuclear antibodies for connective tissue disease (anticentromere for limited scleroderma); up to 40% of patients with idiopathic PAH have elevated antinuclear antibodies
- antiphospholipid antibody testing: this is performed if there is a history of DVT or pulmonary embolism

Arterial blood gases

Arterial blood gases can give an indication of hypoventilation or hypoxia from associated lung diseases.

Other tests

Other useful tests in approaching the diagnosis are lung function testing, echocardiography, ventilation/perfusion scanning, pulmonary angiography, CT, and cardiac MRI (see 'Other relevant investigations').

Other diagnoses that should be considered

Pulmonary valve stenosis and tricuspid valve abnormalities could mimic PH (symptoms of right-heart failure in the absence of pulmonary vasculopathy). A restrictive cardio myopathy or pericardial effusion can cause breathlessness with a raised JVP.

'Gold-standard' diagnostic test

Right-heart catheterization is mandatory for establishing the diagnosis. This test measures the pressure in the pulmonary artery and right heart chambers; cardiac output; and blood oxygen saturations. Blood oxygen saturations can identify left-to-right intra-cardiac shunts.

A vasoreactive challenge (using inhaled nitric oxide, or IV epoprostenol) during right-heart catheterization in patients with idiopathic PAH, heritable PAH, or PAH associated with anorexigen use will identify patients who may benefit from treatment with calcium channel blockers. A positive response is defined by a decrease in the mean pulmonary artery pressure of ≥ 10 mm Hg, reaching a mean pulmonary artery pressure of ≤ 40 mm Hg, and having an unchanged/increased cardiac output.

The data from right-heart catheterization gives information required to assess prognosis and to establish a management plan.

Acceptable diagnostic alternatives to the gold standard

Transthoracic echocardiography provides several variables which correlate with right-heart haemodynamics, including pulmonary artery systolic pressure, and should always be performed if PH is suspected. Echocardiographic estimation of pulmonary artery pressure from the tricuspid regurgitant jet is well correlated with right-heart catheterization measurements, but also does give false positive and negative results. The echocardiogram can evaluate the presence of congenital, valvular, or other cardiac conditions.

Other relevant investigations

Blood testing

BNP and N-terminal pro-BNP are useful blood markers of right-heart distension, giving prognostic information. Poor renal function will cause erroneously high results.

Serum uric acid is a marker of impaired oxidative metabolism of ischaemic peripheral tissue. High levels can be a marker of poor survival.

Lung function testing

Full lung function testing in PAH might be within normal range. In advanced cases, it can show a reduced gas transfer with otherwise normal lung volumes. Other lung function changes will suggest other causes for PH (e.g. an obstructive pattern in COPD or an increased transfer factor in left-to-right congenital heart shunts).

V/Q scanning

Normal perfusion in ventilation/perfusion scintigraphy, (V/Q scan), will rule out chronic thromboembolic disease.

CT scanning

High-resolution CT imaging of the thorax can screen for lung parenchymal causes of PH (e.g. fibrosis or emphysema). Interlobular septal thickening is characteristic of left-heart failure, pulmonary veno-occlusive disease. Mosaic perfusion of CTEPH. Contrast CT pulmonary angiography can distinguish pulmonary emboli and cardiac septal defects. CTEPH changes can present as filling defects, webs, bands, and vessel amputation or pruning.

MRI

Cardiac MRI is useful in assessing cardiac function and detecting congenital defects. Magnetic resonance pulmonary angiography can be used as a means of imaging the pulmonary arteries in the evaluation of CTEPH.

Conventional pulmonary angiography

Conventional pulmonary angiography remains the gold standard in imaging the pulmonary circulation in chronic thromboembolic disease.

Exercise testing

The 6-minute walk test is an objective assessment of exercise capacity. This is a submaximal cardiopulmonary exercise test used to monitor exercise capacity and disease progression. Cardiopulmonary exercise testing assessment of peak VO₂ and VE/VCO₂ has some correlation with pulmonary pressures.

Prognosis and how to estimate it

Historical series give a median survival of 2.8 years for untreated idiopathic PAH. Disease-modifying therapies for PAH have improved survival. Prior to disease-specific therapies, 1-year survival was 68% and 5-year survival was 34%, for patients with idiopathic PAH. With targeted therapies, these rates have improved to 87% at 1 year and to 47%–55% at 5 years, depending on the published series. Scleroderma-associated PAH has a worse prognosis, even with treatment: 3-year survival estimates are 47% without pulmonary fibrosis, and 28% with pulmonary fibrosis. PH in conjunction with COPD is associated with an increased mortality, compared to COPD alone. Survival in PH associated with Eisenmenger syndrome is considerably better.

The following factors are associated with a poor patient prognosis at first presentation:

- PH classified as WHO Functional Class III or IV
- poor performance on a 6-minute walk test (distance <380 m)
- raised BNP or N-terminal pro-BNP level
- enlarged right atrium or a pericardial effusion on echocardiography
- right-heart catheterization showing a reduced cardiac index or low mixed venous oxygen saturations

Medical intervention aims to improve these parameters, with an optimal condition being the PH is classified as WHO

Functional Class I or II, and the patient can walk >500 m and has normal BNP/N-terminal pro-BNP levels and echocardiography parameters.

Treatment and its effectiveness

Standard supportive treatments

Supportive treatment is with diuretics, to control oedema from right-heart failure, and oxygen, to correct hypoxia. Anticoagulation has some evidence to support its use, in idiopathic and heritable PAH. Anticoagulation is vitally important in CTEPH.

Calcium-channel blockers (CCBs) have some benefit in patients with idiopathic PAH who have a positive vasoreactive response (<10%; hence, CCBs should not be used except by specialist PH centres). There is no good evidence to support the use of CCBs in other forms of PH.

Specific Group 1 (PAH) drug therapy

Three main drug classes are currently used for specific Group 1 drug therapy: prostanoids (epoprostenol, iloprost, treprostinil sodium), prostenoid receptor agonists (selexipag) endothelin receptor antagonists (bosentan, ambrisentan, macitentan), phosphodiesterase-5 inhibitors (sildenafil, tadalafil), and guanylate cyclase stimulators (riociguat). They have been subject to randomized controlled trials (predominantly in idiopathic PAH, and PAH associated with connective tissue disease), and generally demonstrate improvement in exercise capacity and pulmonary haemodynamics. These study results have been extrapolated to all patients with PAH. These drug therapies have vasoremodelling properties, giving symptomatic improvement, delay disease progression, and improve survival.

It is recommended that these drugs are only prescribed and managed by PH specialist centres. Some combinations of drug therapies have been shown to be beneficial. At present, available therapies are not curative, and new therapeutic targets are actively researched.

Common side effects from these drugs are flushing, headaches, gastrointestinal disturbance, and hypotension. Endothelin-receptor antagonists require monthly liver function monitoring because of liver toxicity. Prostanoids can be delivered by intravenous, nebulized, or subcutaneous routes.

Specific PAH therapies are not recommended for patients in Groups 2, 3, and 5. The current best treatment for these groups is considered optimal treatment of their associated left heart or lung condition.

In Group 4, when possible pulmonary endarterectomy surgery is the treatment of choice. For patients unsuitable for pulmonary endarterectomy surgery (due to surgical inaccessibility or due to significant comorbidities) and patients who still have residual PH following pulmonary endarterectomy surgery riociguat is the only licensed therapy. There is increasing evidence for the role of balloon pulmonary angioplasty playing a role in treatment of CTEPH.

Invasive and surgical treatments

Balloon atrial septostomy

Balloon atrial septostomy is a palliative treatment, performed to offload a failing right ventricle and improve symptoms at the expense of decreased systemic arterial oxygen saturations.

Pulmonary endarterectomy

Pulmonary endarterectomy surgery is considered the treatment of choice for CTEPH. All patients must be carefully screened for surgical suitability. Success is dependent on the extent and location of the organized thrombus and pulmonary haemodynamic severity. After an effective intervention, a dramatic drop in the pulmonary vascular resistance can be expected with a near normalization of pulmonary haemodynamics. The result is improved exercise capacity, pulmonary haemodynamics, and survival.

Lung transplantation

If medical therapy has failed to halt symptom progression, bilateral lung/heart–lung transplantation should be considered. Transplantation offers a potential ‘cure’ for many forms of PH. The

5-year survival after lung transplantation for PH is similar to survival for all indications for lung transplant.

101 Venous thrombosis and pulmonary embolism

Karen Sheares and Joanna Pepke-Zaba

Definition of the disease

Venous thromboembolism (VTE) is a condition in which a thrombus forms in a vein, commonly in the deep veins of the leg, causing deep vein thrombosis (DVT). The thrombus may dislodge from the site of origin and be carried into the pulmonary vasculature, causing pulmonary embolism (PE). DVT and PE share similar predisposing factors; however, mortality is greater in those who present with PE than in those who present with DVT. Thrombi may form in other parts of the vasculature; this is covered in Chapter 285.

Aetiology of the disease

The three primary risk factors for development of venous thrombosis are venous stasis, vascular damage, and hypercoagulability (these factors are also known as Virchow's triad). Predisposing factors may be temporary or permanent and include reduced mobility (e.g. neurological disability, hospitalization, or institutional care), medical comorbidity (e.g. chronic cardiac or respiratory failure), surgery (particularly orthopaedic surgery), active cancer or cancer treatment, previous VTE, use of hormone replacement therapy or oestrogen-containing contraception, pregnancy, the presence of indwelling central venous lines, thrombophilias (see Chapter 285), obesity, and varicose veins. In approximately 20%, idiopathic or unprovoked PE may occur.

Typical symptoms of the disease, and less common symptoms

The symptoms of DVT include unilateral leg swelling, calf pain, redness, and warmth. The symptoms in PE are not specific and include dyspnoea, pleuritic chest pain (caused by pleural irritation in pulmonary infarction), retrosternal chest pain (due to right ventricular ischaemia), cough, and haemoptysis. The classic triad of dyspnoea, pleuritic chest pain, and haemoptysis is only seen in a minority.

Patients with PE may be tachypnoeic, tachycardic, and hypoxic, with an elevated jugular venous pressure, a gallop rhythm, a widely split second heart sound due to delayed right ventricular ejection, a tricuspid regurgitation murmur, and possible flow murmurs around the embolic obstructions. With pulmonary infarction, there may be a pleural rub and pyrexia. In severe cases, the right ventricle is unable to match the increase in afterload and so fails, leading to systemic hypotension and shock.

Demographics of the disease

Community studies have reported an annual incidence rate for VTE of 1.4–1.8 per 1000, with that for DVT approximately 1 per 1000, and that for PE about 0.5 per 1000. The incidence of venous thromboembolism rises markedly with increasing age for both sexes; over the age of 75, the annual incidence reached 1 per 100 population. VTE is uncommon in the paediatric population.

Natural history, and complications of the disease

Untreated VTE carries significant morbidity and mortality. In 2005, it was estimated that 25 000 people in the UK die of preventable, hospital-acquired VTE every year.

Proximal DVTs resolve slowly during treatment with anticoagulation, and thrombi remain detectable in 50% after a year, particularly in those with a large initial thrombus or cancer. About 10%–20% of patients with symptomatic DVTs develop severe post-thrombotic syndrome characterized by chronic pain, swelling, and skin ulceration. An estimated 40%–50% of patients with symptomatic proximal DVT develop PE which may be asymptomatic.

About 10% of PEs are rapidly fatal (most clinically unrecognized), and an additional 5% cause death later, despite diagnosis and treatment. There is approximately 50% resolution of PE after 1 month of treatment, and perfusion eventually returns to normal in two-thirds of patients. Between 0.5% and 5.0% of treated patients with PE develop chronic thromboembolic pulmonary hypertension due to poor resolution and/or the development of a distal pulmonary arteriopathy. Untreated patients with chronic thromboembolic pulmonary hypertension have a poor prognosis, with a 3-year survival as low as 10% in patients with a mean pulmonary artery pressure of greater than 30 mm Hg. This is covered in further detail in Chapter 100.

In both DVT and PE, there is a 6%–15% chance of recurrence after a course of anticoagulation. The risk of recurrent thrombosis is higher (i.e. approximately 10% per patient-year) in patients with permanent risk factors, active cancer, and acquired or hereditary thrombophilia.

Approach to diagnosing the disease

The symptoms and signs in acute VTE are not sensitive or specific, and therefore cannot be used to rule in or rule out DVT or PE. However, a key step in all diagnostic algorithms is an assessment of the clinical probability of these disorders.

Several clinical prediction models incorporating predisposing factors, symptoms, and clinical signs have been developed. The Wells prediction models for suspected DVT (see Table 101.1) and PE

Table 101.1 Wells clinical prediction model for DVT

Clinical Characteristic	Score
Active cancer (patient receiving treatment for cancer within the previous 6 mo or currently receiving palliative treatment)	1
Paralysis, paresis, or recent plaster immobilization of the lower extremities	1
Recently bedridden for 3 days or more, or major surgery within the previous 12 wk requiring general or regional anesthesia	1
Localized tenderness along the distribution of the deep venous system	1
Entire leg swollen	1
Calf swelling at least 3 cm larger than that on the asymptomatic side (measured 10 cm below tibial tuberosity)	1
Pitting edema confined to the symptomatic leg	1
Collateral superficial veins (nonvaricose)	1
Previously documented deep-vein thrombosis	1
Alternative diagnosis at least as likely as deep-vein thrombosis	-2

* A score of 2 or higher indicates that the probability of deep-vein thrombosis is likely; a score of less than 2 indicates that the probability of deep-vein thrombosis is unlikely. In patients with symptoms in both legs, the more symptomatic leg is used. Reprinted from *The Lancet*, Volume 350, issue 9094, Philip S Wells et al., Value of assessment of pretest probability of deep-vein thrombosis in clinical management, pp. 1795–1798, Copyright 199, with permission from Elsevier.

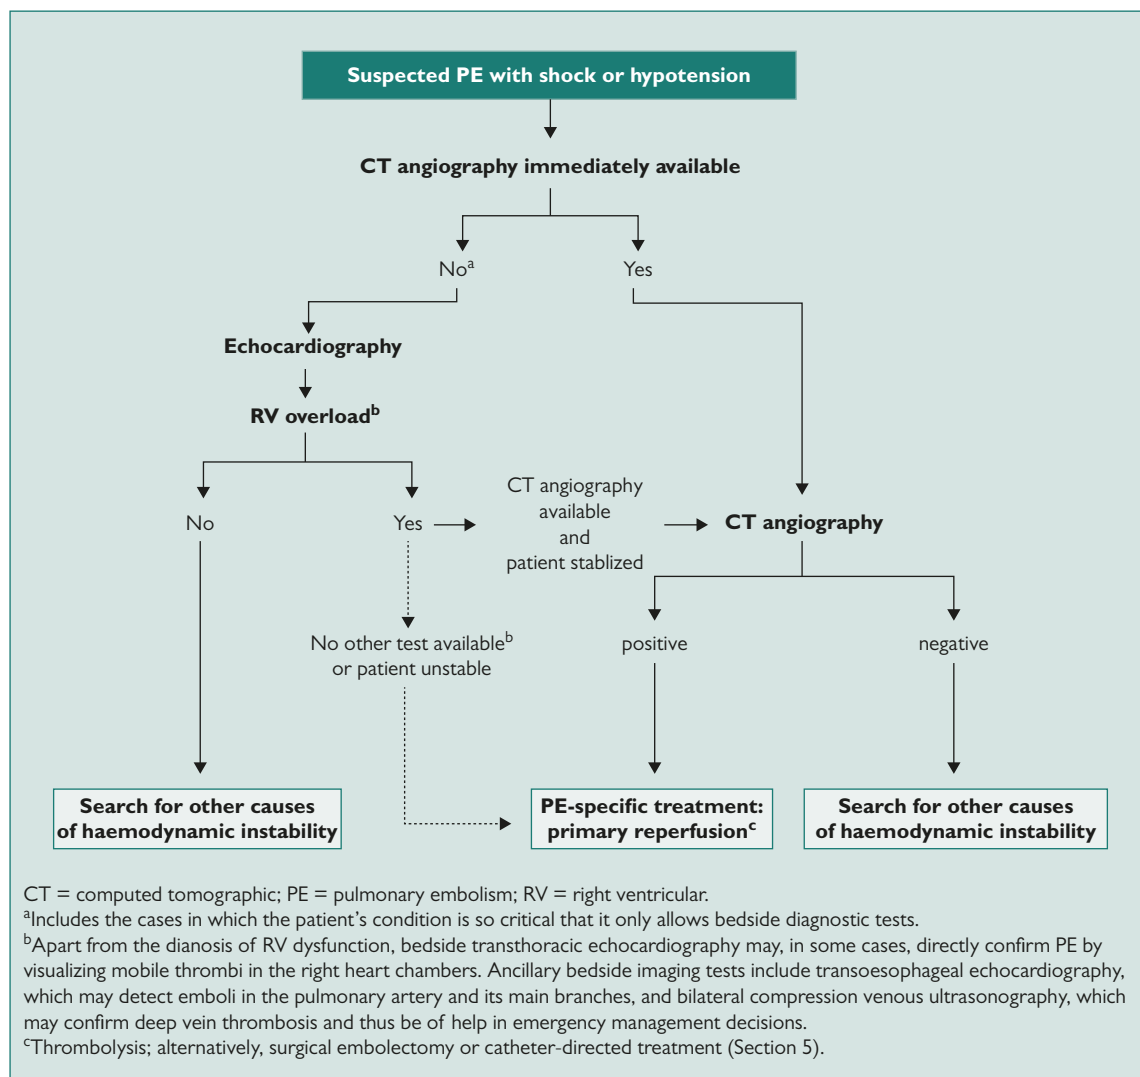

Figure 101.1 Proposed diagnostic algorithm for patients with suspected high-risk pulmonary embolism (i.e. presenting with shock or hypotension). Reproduced with permission from Authors/Task Force Members, Stavros Konstantinides et al., 2014 ESC Guidelines on the diagnosis and management of acute pulmonary embolism, *European Heart Journal*, Aug 2014, DOI: 10.1093/eurheartj/ehu283

(see Figures 101.1 and 101.2) have been validated extensively and are the most frequently used.

Each hospital should have a diagnostic algorithm for the investigation of patients with suspected DVT and/or PE; this algorithm will depend on local resources, expertise, and patient population. The National Institute for Health and Care Excellence has proposed algorithms as shown in Figures 101.3 and 101.4. VTE can be safely excluded in patients who have a low pretest clinical probability of VTE and a negative D-dimer, without further diagnostic imaging.

Other diagnoses that should be considered

In the case of a swollen painful leg, cellulitis, myositis, ruptured Baker's cyst, or haematoma may be alternative diagnoses. The differential diagnosis in suspected PE may be wide, including pneumonia; exacerbation of asthma or COPD; acute coronary syndrome; aortic dissection; lung cancer; pneumothorax; fractured ribs; costochondritis, or musculoskeletal pain.

'Gold-standard' diagnostic test

The gold-standard diagnostic test for DVT of the leg is contrast venography. Venography can detect both distal thrombi (in the calf

veins) and proximal thrombi (in the popliteal, femoral, and iliac veins). Venography is invasive, requiring pedal vein cannulation, which may be difficult with swollen legs, and the use of intravenous contrast.

Selective pulmonary angiography is the gold-standard test for PE, showing direct evidence of a thrombus either as a filling defect or as amputation of a pulmonary arterial branch. However, this invasive test has been increasingly replaced by CT pulmonary angiography (CTPA).

Acceptable diagnostic alternatives to the gold standard

The inability to compress the vein lumen during compression venous ultrasonography of the lower limb is diagnostic of DVT and an alternative to venography. DVT usually starts in the calf, and distal emboli that do not extend into proximal veins rarely lead to clinically significant emboli. This has guided the rationale for using serial ultrasonography and it is considered safe to withhold anticoagulation treatment from patients with clinically suspected DVT but who have normal results on compression ultrasonography at the time of presentation and at 1 week later.

CT venography has been used to diagnose DVT in patients with suspected PE, as it can be combined with chest CT angiography. However, it increases the overall detection rate only marginally in patients with suspected PE and adds a significant amount of radiation.

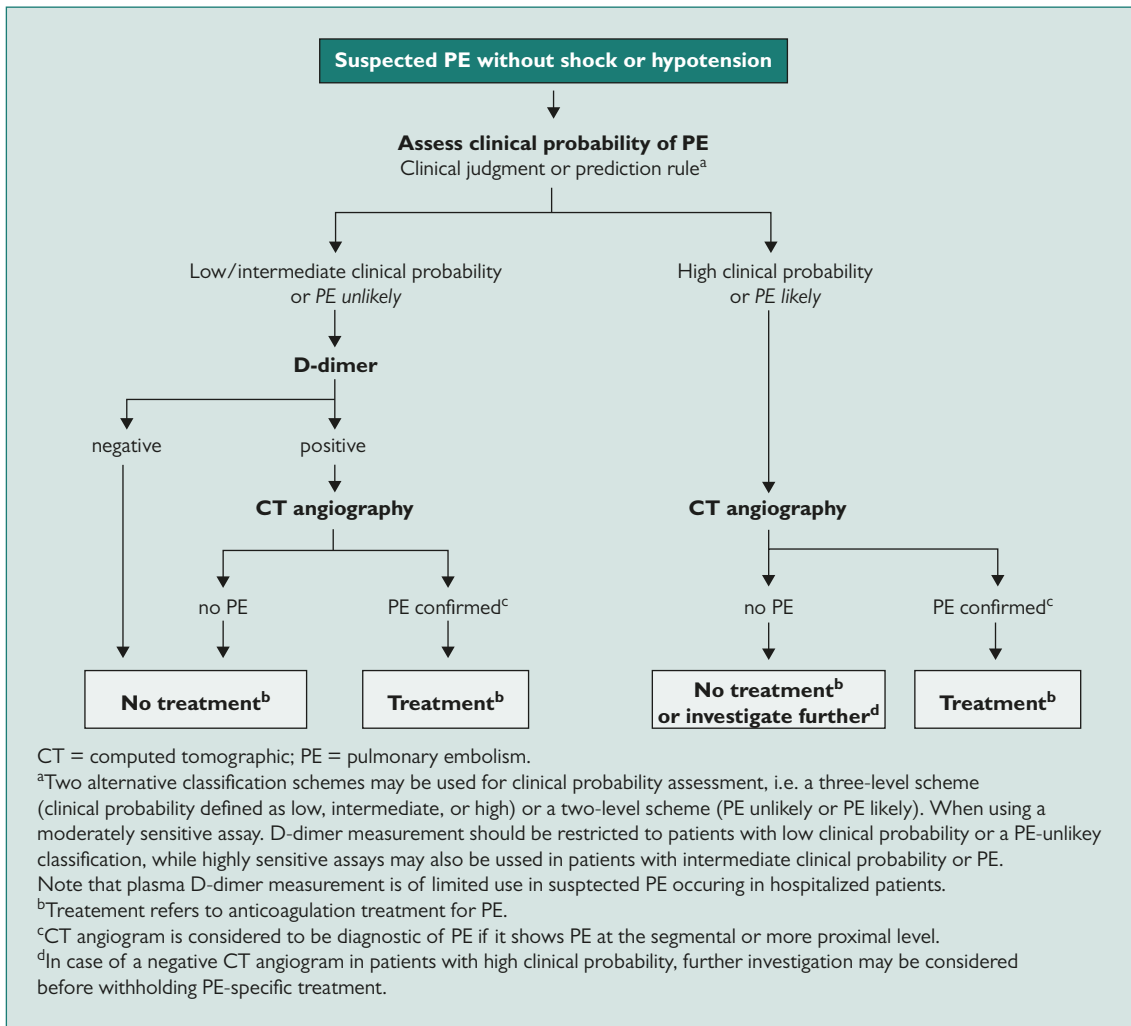

Figure 101.2 Proposed diagnostic algorithm for patients with suspected not high-risk pulmonary embolism.

Reproduced with permission from Authors/Task Force Members, Stavros Konstantinides et al., 2014 ESC Guidelines on the diagnosis and management of acute pulmonary embolism, *European Heart Journal*, Aug 2014, DOI: 10.1093/eurheartj/ehu283

Planar ventilation–perfusion scintigraphy is a well-tolerated and established diagnostic test for suspected PE in patients with normal chest X-rays. It allows identification of hypoperfused segments with normal ventilation, so-called mismatched defects, in PE. A normal test reliably excludes a PE; however, patients with indeterminate results require further investigation. Ventilation–perfusion single-photon emission CT offers three-dimensional views with potentially improved sensitivity and lower non-diagnostic rates.

Multidetector-row CTPA, with its high spatial and temporal resolution and quality of arterial opacification, has improved the sensitivity and specificity of CT in the diagnosis of PE. It allows adequate visualization of the pulmonary arteries up to at least the segmental level and allows assessment of the secondary effects, for example, dilatation of the right-heart chambers, dilatation of the main pulmonary artery, and tricuspid regurgitation. It has become the main thoracic imaging test for investigating suspected PE and also allows the identification of alternative diagnoses. The disadvantages are that the intravenous contrast is nephrotoxic and best avoided in renal failure; some patients are allergic to the contrast; and the radiation burden is approximately 2–6 mSv, compared to 1.1 mSv for perfusion scintigraphy.

Other relevant investigations

Plasma D-dimer is a degradation product of cross-linked fibrin and gives a measure of endogenous fibrinolysis. It has a good negative

predictive value and is useful in excluding DVT or PE. Unfortunately, it has a low specificity and is elevated in a wide range of conditions, for example, infection, inflammation, trauma, surgery, and pregnancy. Hence, an elevated D-dimer is not diagnostic of DVT or PE. It should not be measured in patients with a high clinical pretest probability, as it has a low negative predictive value in this population. A variety of different assays are available, each with different sensitivities, specificities, and predictive values. Generally, enzyme-linked immunosorbent assays (ELISA) are more sensitive than latex-agglutination techniques.

The chest X-ray may be normal or show atelectasis, pleural effusion, hypovascularity (Westermark's sign), or wedge-shaped peripheral infarct (Hampton's hump). It is also useful in excluding other causes of dyspnoea and chest pain.

ECG may show signs of right-ventricular strain, such as inversion of T waves in Leads V1–V4, a QR pattern in Lead V1, an S1Q3T3 pattern, and incomplete or complete right bundle branch block. This is useful, but of limited sensitivity. The ECG will exclude myocardial infarction or pericarditis.

Echocardiography may show signs of right-ventricular overload or dysfunction in at least 25% of patients with PE and may be helpful in excluding other diagnoses such as cardiac tamponade, acute valvular dysfunction, and acute myocardial infarction. It rarely enables direct visualization of PE but may reveal thrombus in the right atrium or right ventricle. It has an important role in prognostic stratification.

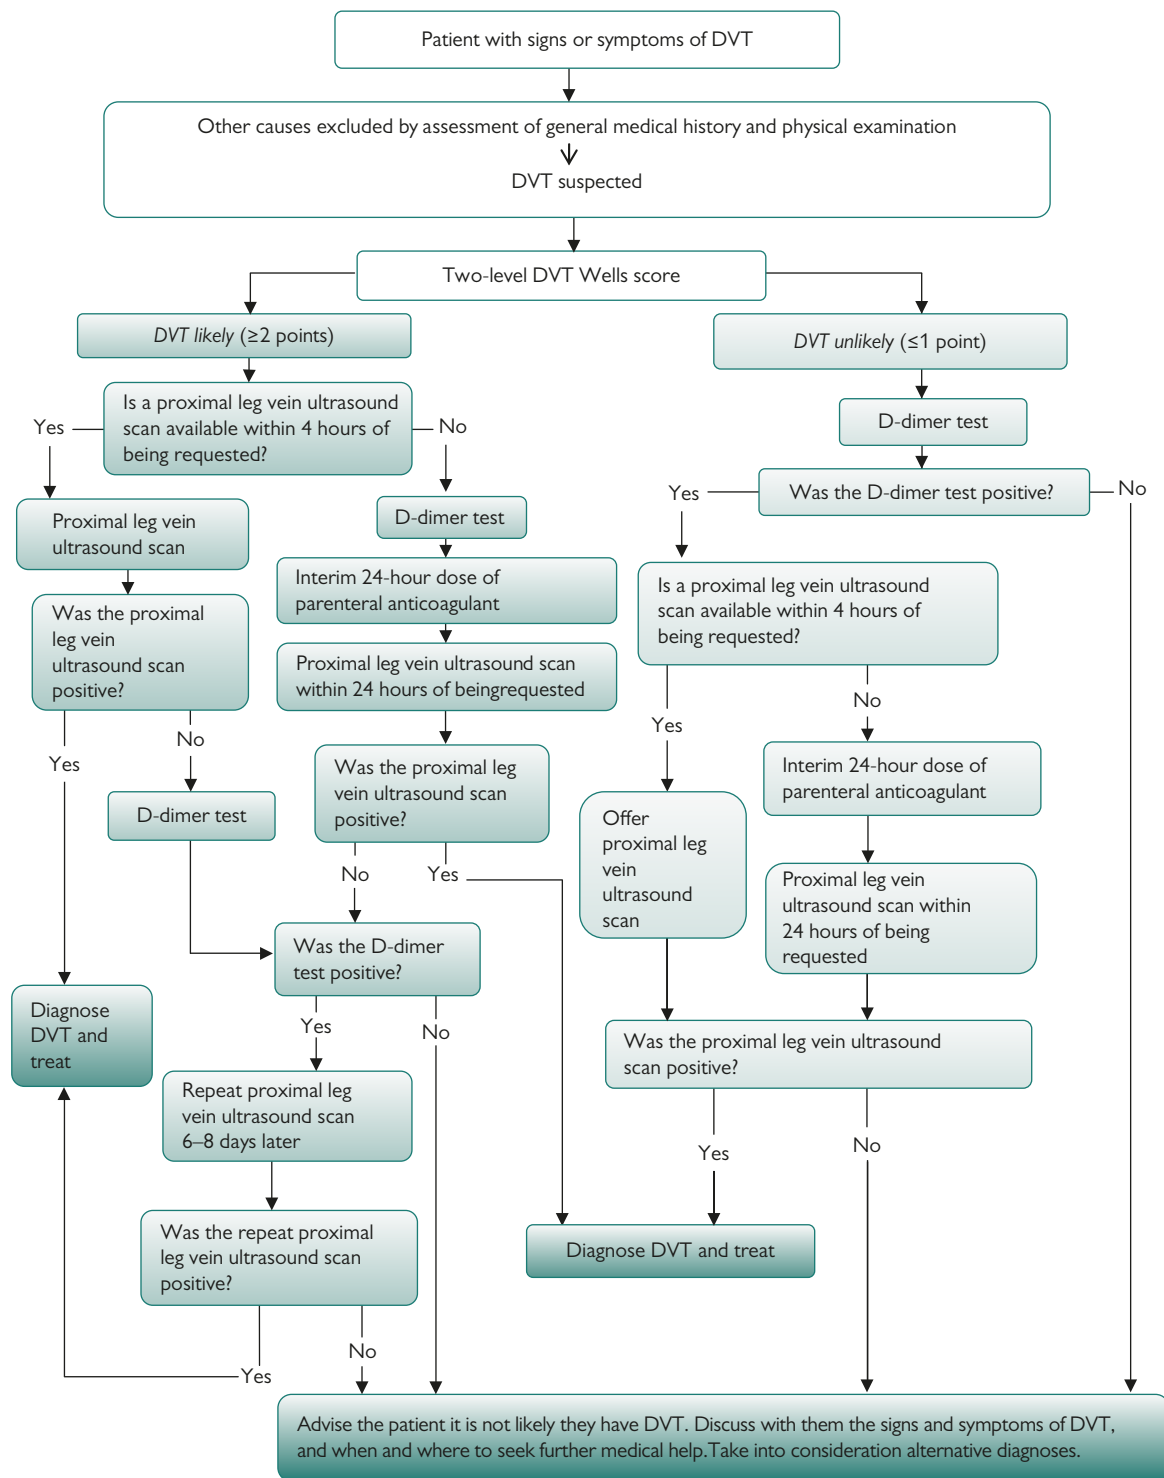

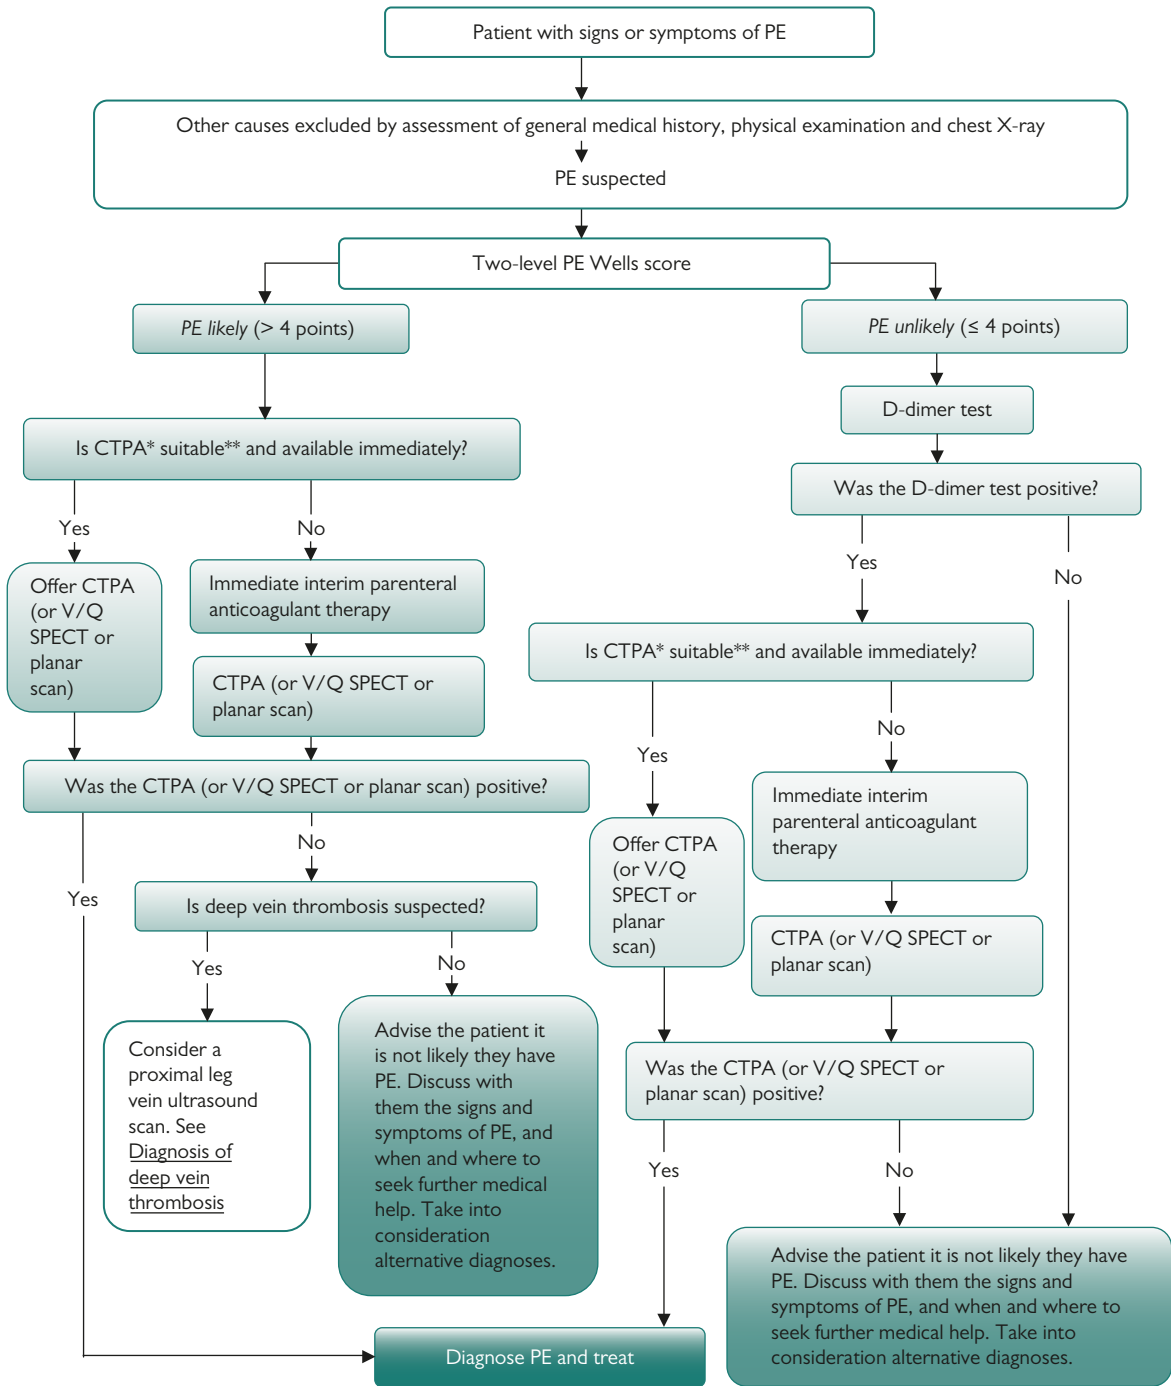

Figure 101.3 Diagnosis of deep vein thrombosis (DVT).

PE may be associated with hypoxaemia due to ventilation–perfusion mismatch, shunting through areas of collapse and infarction and/or through a patent foramen ovale, and low mixed venous oxygen saturation due to the reduced cardiac output. Up to 20% of patients with PE may have a normal arterial oxygen pressure and a normal alveolar–arterial oxygen gradient.

Routine full blood count and biochemistry might be normal. If pulmonary infarction has occurred, there may be polymorphonuclear leucocytosis, an elevated level of C-reactive protein, and an elevated erythrocyte sedimentation rate.

BNP and its precursor, NT-pro-BNP, are released during myocardial stretch and are markers of ventricular dysfunction.

*Computed tomography pulmonary angiogram

**For patients who have an allergy to contrast media, or who have renal impairment, or whose risk from irradiation is high, assess the suitability of V/Q SPECT† or, if not available, V/Q planar scan, as an alternative to CTPA.

†Ventilation/perfusion single photon emission computed tomography

Cardiac troponins may be elevated during right ventricular infarction and are associated with increased mortality, even in the subgroup of haemodynamically stable patients with PE.

There is an association between cancer and VTE. Careful history and examination may highlight patients who require further investigations for occult cancer.

Prognosis and how to estimate it

The European Society of Cardiology has suggested that patients with PE can be stratified into three levels of risk of early death, as measured by in-hospital or 30-day mortality. This classification system also helps in management. High-risk PE, previously known as massive PE, is characterized by cardiogenic shock or systemic hypotension (systolic blood pressure less than 90 mm Hg or a fall in systolic blood pressure by 40 mm Hg or more, for at least 15 minutes and which is not due to a new-onset arrhythmia, hypovolaemia, or sepsis. This life-threatening situation carries an early mortality of more than 15%. If a patient with suspected high-risk PE is too unstable or CTPA is not immediately available, echocardiography will show indirect signs of acute pulmonary hypertension and right ventricular overload; otherwise, an alternative diagnosis must be sought.

Intermediate-risk (submassive) PE is diagnosed in normotensive patients by evidence of right ventricular dysfunction and /or myocardial injury. Right ventricular dysfunction may be seen on echocardiography, CTPA, ECG, or by an elevation of BNP or NT-proBNP. Myocardial injury can be detected by elevated cardiac troponin levels.

Low-risk (non-massive) PE is diagnosed in haemodynamically stable patients with no evidence of right ventricular dysfunction or myocardial injury, and the risk of early mortality is less than 1%. This has important implications, as these patients may be considered for early discharge if they do not have additional comorbidities.

Treatment and its effectiveness

The aim of anticoagulation in VTE is to prevent death and VTE recurrences while minimizing the risk of bleeding. Patients with DVT or PE are treated with a rapidly acting anticoagulant (unfractionated heparin, low-molecular-weight heparin (LMWH), or fondaparinux) followed by oral vitamin K antagonists (commonly, warfarin). Parental anticoagulants should be stopped when the international normalized ratio is 2.0 or above for at least 24 hours. For patients at a high risk of bleeding and those with severe renal impairment, intravenous unfractionated heparin should be considered for initial treatment. Direct inhibitors of factor Xa or direct thrombin inhibitors are increasingly being used for treatment of VTE.

The duration of anticoagulation is dependent on whether the VTE event was provoked, the presence of temporary or permanent risk factors, previous history of VTE, and bleeding risks. A table giving the possible duration of anticoagulation is shown in Chapter 285. The use of elastic compression stockings reduces the incidence of post-thrombotic leg syndrome.

Patients with high-risk life-threatening PE should be treated with intravenous unfractionated heparin and be considered for early thrombolysis. This has been shown to improve survival, but there is a risk of major bleeding. High-risk patients with PE who have failed thrombolysis or in whom thrombolysis is contraindicated may

be considered for surgical embolectomy or percutaneous catheter embolectomy.

Studies with inferior vena cava (IVC) filters have not shown short-term or long-term survival benefits, and there are late complications, in particular, recurrent DVT and the post-thrombotic syndrome. Currently, temporary IVC filters may be used when there are absolute contraindications to anticoagulation and a high risk of VTE recurrence. The IVC filter should be removed as soon as the patient becomes eligible for anticoagulation treatment.

VTE prophylaxis is crucial in reducing the morbidity and mortality of VTE. All medical and surgical patients should be assessed for the risks for VTE and bleeding. Patients should be encouraged to mobilize as soon as possible, avoid dehydration unless clinically indicated, and be considered for mechanical (for example anti-embolism stockings, foot impulse or intermittent pneumatic compression devices) and/or pharmacological prophylaxis (such as LMWH, fondaparinux, or unfractionated heparin).

Pregnancy

PE is a leading cause of maternal death in the UK. Although the relative risk of VTE in pregnancy is elevated four- to sixfold, and this is increased further postpartum, the absolute risk is low, with an overall incidence of VTE in pregnancy and the puerperium of 1–2 in 1000. The clinical features of VTE are similar to those in the non-pregnant state and it is essential to confirm the diagnosis while minimizing radiation exposure to the mother and fetus.

Compression duplex ultrasonography should be undertaken where there is clinical suspicion of DVT. A positive result warrants anticoagulation and makes thoracic imaging unnecessary. If an acute PE is suspected and ultrasonography is negative, CTPA or perfusion scintigraphy may be considered, depending on local availability and discussion with the obstetrician, radiologist and patient. The radiation dose delivered to the fetus during a CTPA is lower than that of perfusion scintigraphy in the first or second trimester, but a CTPA carries a higher radiation dose to maternal breast tissue.

The treatment of VTE in pregnancy is with LMWH or unfractionated heparin, as these do not cross the placenta or are found in breast milk. Warfarin crosses the placenta and is teratogenic.

102 Aortic aneurysm

John Chambers

Definition of the disease

The epidemiology and natural history of thoracic aortic aneurysm (TAA) and abdominal aortic aneurysm (AAA) are different:

- The thoracic aortic diameter is dependent on age and body habitus as well as the level at which it is measured. Average diameters are 2.1 cm/m² for the ascending thoracic aorta, and 1.6 cm/m² for the descending thoracic aorta, giving approximate thresholds for the diagnosis of a TAA of 40 mm and 35 mm, respectively.
- AAAs are defined by a diameter >30 mm and are mainly infrarenal, with only 2%–5% in a suprarenal position.

Aetiology of the disease

Generic risk factors for all aortic disease are age, weakness of the aortic wall, and the arteriosclerotic risk factors: hypertension, dyslipidaemia, smoking, and diabetes. However, for AAA, the main risk factors are age >65, male gender, smoking (>100 cigarettes in a lifetime), and family history, with the other arteriosclerotic factors being less important.

Weakness of the aortic wall as a result of medial necrosis occurs in Marfan syndrome, Ehlers–Danlos syndrome type IV, and Loeys–Dietz syndrome. A bicuspid aortic valve should be regarded as a general thoracic aortopathy and is associated with coarctation, but also dilatation of the ascending aorta as a result of medial necrosis. Pregnancy also causes or exacerbates medial weakness. Vasculitides, especially giant cell arteritis and Takayasu's arteritis, trauma, cocaine, and amphetamines can also weaken the arterial wall. In contradistinction to the usual symmetrical 'fusiform' dilatation of a segment of aorta, a less common 'saccular' aneurysm consisting of an outpouching of the aorta can result from inflammation as a result of syphilis.

Typical symptoms of the disease, and less common symptoms

An aortic aneurysm is usually asymptomatic and an incidental finding on ultrasound scanning or chest X-ray. An enlarging aneurysm causes symptoms depending on its site. A TAA can cause hoarseness from stretching of the recurrent laryngeal nerve, occasionally tracheal or bronchial compression or phrenic nerve paresis leading to breathlessness or cough, or oesophageal compression causing dysphagia. Superior vena cava compression may also occur. Breathlessness and heart failure may also result from aortic regurgitation as a result of aortic root dilatation. An enlarging AAA can cause abdominal, groin, or back pain. Rupture or bleeding of an AAA causes the triad of acute back or abdominal pain (72%), hypotension (45%), and a pulsatile abdominal mass (83%).

Demographics of the disease

TAA is uncommon, with an incidence of six new aneurysms per 100 000 person-years, with median age 65 in men, and 77 in women. Of all degenerative aneurysms, about 5% are TAA, and most of the rest are AAA. The prevalence of AAA in the general population aged 65–79 is 5%–10%. AAA is rare in women or non-smokers, while TAA occurs approximately equally in both sexes, with median age 65 for men, and 77 for women. About 25% with TAA also have infrarenal AAA, while, of those presenting with AAA, only 3.5%–12.0% have TAA.

Natural history, and complications of the disease

TAA can be complicated by rupture or dissection. The mean rate of growth is 1 mm/year and is higher for the descending aorta than for the ascending aorta. The risk of rupture rises rapidly above a threshold of 60 mm for the ascending aorta, and 70 mm for the descending thoracic aorta (Elefteriades, 2002). The total risk of rupture or dissection above these thresholds is 30% for the ascending thoracic aorta, and 40% for the descending thoracic aorta. The risk is 7% per annum when the diameter of the ascending aorta exceeds 60 mm. Other complications of TAA involving the root are aortic regurgitation, and sinus of valsalva rupture. TAA involving the ascending or descending aorta can be complicated by perforation causing mediastinal haematoma.

The mean rate of growth for AAA is 2–5 mm/year, which is faster than for TAA. The annual risk of rupture for AAA is 9% for a diameter of 55–59 mm, 10% for a diameter of 60–69 mm, and 33% for a diameter ≥70 mm. Complications are dissection within the wall of the aneurysm, or rupture, causing retroperitoneal or free peritoneal blood. Intraluminal thrombus formation with distal embolization may cause cold and painful toes, livedo reticularis, and renal failure. Less commonly, embolization of the muscular branches of the lower extremities can cause intermittent claudication. Rare complications are bleeding as a result of erosion into the gastrointestinal tract, and renal dysfunction as a result of ureteric compression.

Approach to diagnosing the disease

TAA is usually detected incidentally on echocardiography, often as a result of investigating aortic regurgitation. It may also be detected on a routine chest X-ray. It must be sought by annual echocardiography in patients with collagen abnormalities (e.g. Marfan syndrome). Similarly, AAA is usually found by screening, which is recommended for AAA in men aged 65–75 who have smoked (US Preventative Services Task Force, 2014). Serial scans are not usually recommended if the aorta is normal, since the risk of a new aneurysm developing by 10 years is low. However, serial studies are recommended, either annually for an aneurysm 30–40 mm in diameter, or 6-monthly for an aneurysm 40–45 mm in diameter.

Other diagnoses that should be considered

TAA may be difficult to differentiate from a mediastinal mass on chest X-ray. The differential diagnosis of a pulsatile abdominal mass on examination includes a tortuous aorta, transmitted pulsation from an abdominal mass, and horseshoe kidney. The differential is easily resolved on imaging. Ruptured AAA must be part of the differential diagnosis of acute abdominal pain or shock; the differential diagnosis also includes pancreatitis and intestinal perforation.

'Gold-standard' diagnostic test

Screening for aortic aneurysm is with echocardiography for TAA, and abdominal ultrasound for AAA. Definitive imaging either to check dimensions or, more usually, as a prelude to intervention should be performed with CT or MRI.

Acceptable diagnostic alternatives to the gold standard

There are no acceptable diagnostic alternatives to the gold standard.

Other relevant investigations

The full range of tests for cardiovascular risk factors should be performed, particularly cholesterol and renal function. Syphilis serology, where relevant, should also be performed. Prior to any surgical intervention, it is usual to assess left ventricular function, and perform some form of non-invasive test to determine the presence and extent of coronary artery disease.

Prognosis and how to estimate it

See 'Natural history, and complications of the disease' for prognosis and how to estimate it.

Treatment and its effectiveness

Small asymptomatic aneurysms are managed medically with routine surveillance. Smoking cessation is essential. Beta blockers lower wall stress as well as absolute blood pressure and reduce the risk of rupture and the rate of dilatation (Judge and Dietz, 2005). There is also preliminary evidence that angiotensin-receptor blockers reduce the rate of progression of aortic dilatation in Marfan syndrome. Statins may reduce the risk of aortic rupture or dissection, particularly in descending thoracic and thoracoabdominal aneurysms (Stein et al., 2013).

Surgery should be considered at a diameter below the threshold beyond which the risk of events climbs. This is 55 mm for the ascending aorta if the aetiology is arteriosclerosis or low-risk bicuspid valve disease, and 50 mm for low-risk Marfan syndrome. High-risk features are family history of aortic dissection, aortic diameter increase >3 mm in a year, systemic hypertension, and, for bicuspid valves, the presence of aortic coarctation (Erbel et al., 2014). If high-risk features are present, the threshold for surgery should be lower: 50 mm with a bicuspid aortic valve, or 45 mm for Marfan syndrome (Vahanian et al., 2012). The threshold will also be lower if there is severe aortic regurgitation or if the patient is planning pregnancy. Conversely, higher thresholds may be accepted in patients with significant comorbidity.

For aneurysms of the descending thoracic aorta, including those involving the abdominal aorta (thoracoabdominal aneurysms), the threshold for surgery depends on the aetiology of the aneurysm and whether endovascular stenting is feasible. A diameter of 60 mm is the standard cut-point for surgery (Ziganshin and Elefteriades, 2014) if endovascular stenting is not feasible, and surgical risk is high, for example, because of comorbidities. However, the threshold is

55 mm if there is a collagen abnormality, the aetiology is chronic dissection, or if endovascular stenting is feasible (Hiratzka et al., 2010). The mortality for surgery of TAA is 3%–15%, depending on the case mix, the risk of paraplegia or paraparesis is 3%–10%, and the risk of renal failure is 2%–20% (Ziganshin and Elefteriades 2014). Results are improving with better methods of spinal cord and renal protection, including left heart bypass, CSF drainage, hypothermia, and neuromonitoring.

For AAA, surgery can be considered if the diameter is >55 mm or has increased by >5 mm in a year. Conventional surgery consists of replacement of the diseased aorta with a fabric graft. The mortality is 5% if elective, 25% if symptomatic, and 50% if rupture has occurred.

Endovascular repair using a stent is possible for aneurysms of the descending thoracic aorta and AAA, with a mortality of only 5% in elective cases, an incidence of paraplegia of 2%–3%, and an incidence of renal failure of 1% (Ziganshin and Elefteriades, 2014). However, complications may occur, including endoleaks at either anastomosis; stent migration; perforation of the aorta; or aneurysmal rupture (Ellozy et al., 2003). A repeat procedure is needed in 6%–7% cases, including conversion to open repair in about 1%–2%. The long-term durability of endovascular stents is not known.

103 Aortic dissection

John Chambers

Definition of the disease

Aortic dissection is the separation of an endothelial flap from the underlying media. The natural history and management depend on the classification of dissection as either Type A, which involves the ascending thoracic aorta, or Type B, which involves only the descending thoracic aorta.

Aetiology of the disease

Risk factors for dissection are age, hypertension, and medial necrosis of the aortic wall. Medial necrosis is a feature of Marfan syndrome and Ehlers–Danlos syndrome type IV, but also occurs with a bicuspid aortic valve and with pregnancy.

Aortic dissection is usually preceded by aortic dilatation leading to an increase in transmural shear stresses, but the aorta may be minimally dilated in pregnancy or in Marfan syndrome. Dissection occurs as a result of either endothelial damage or rupture of the vasa vasorum, causing an intramural haematoma. Both these events lead to the separation of an endothelial flap from the underlying vessel wall. Approximately 15% of clinically diagnosed acute dissections are caused by intramural haematoma. Dissection can also complicate aortic surgery or instrumentation. Aortic transection is a separate entity associated with trauma—most commonly, deceleration injuries. Approximately 85% of transections occur just distal to the origin of the descending thoracic aorta.

Typical symptoms of the disease, and less common symptoms

Dissection is characterized by pain which (a) is instantaneous in onset, (b) tracks along the line of the dissection, and (c) is associated with neurological symptoms. It may also present with unexplained syncope (15%) because of a small acute pericardial bleed. A larger bleed leads to acute tamponade and death.

Demographics of the disease

Dissection is rare and occurs in between 30 and 50 per million population per year, with a peak in the age range 50–65.

Natural history, and complications of the disease

The immediate mortality after acute type A dissection is 40% and, thereafter, the untreated mortality is about 1% each hour for the first 24 hours. Death occurs because of dissection into the pleural cavity or the pericardial space to cause acute tamponade. Early complications are aortic regurgitation and the results of involvement of branch arteries: of the cerebral vessels to cause stroke; of the right coronary artery to cause inferior myocardial infarction; of the iliac vessels to cause lower limb ischaemia; or of the mesenteric or renal arteries. For the few survivors, late complications are aneurysmal dilatation and redissection and heart failure as a result of severe aortic regurgitation. Early complications of type B dissection are rupture and organ or limb ischaemia. Late complications are aneurysmal dilatation leading to rupture.

Approach to diagnosing the disease

Acute dissection is strongly suggested by the symptoms in the presence of either a high-risk predisposing condition (e.g. Marfan

syndrome) or high-risk features on the examination (asymmetry of pulses or blood pressure, the immediate diastolic murmur of aortic regurgitation). The chest X-ray may be helpful showing widening of the mediastinum, a double aortic shadow, or left-sided pleural fluid. However, the posteroanterior and lateral films are normal in 50% cases, and the definitive diagnosis is with imaging (see ‘‘Gold-standard’’ diagnostic test’).

Other diagnoses that should be considered

Acute myocardial infarction can be differentiated from dissection because the pain rises to a peak within a minute or so, rather than instantaneously. In infarction there are associated evolutionary changes on the ECG, although, rarely, involvement of acute dissection with the right coronary artery can cause an inferior infarction. This can be suspected by the clinical presentation and widening of the mediastinum on the chest X-ray. Pulmonary embolism is initially differentiated by the clinical setting, hypoxia, and evidence of acute pulmonary hypertension and right ventricular strain on the echocardiogram. Oesophageal rupture also causes severe chest pain, but usually after instrumentation or prolonged vomiting. Other causes of an acute aortic syndrome are intramural haematoma, penetrating ulcer, pseudoaneurysm, and contained or free aortic rupture (usually after trauma).

‘Gold-standard’ diagnostic test

In suspected acute dissection with a characteristic history, it is possible to make the diagnosis in the emergency room using transthoracic echocardiography in 80% of cases of type A dissection, and 50%–70% of cases of type B dissection. This allows the patient to be referred immediately to a cardiothoracic centre. In cases that are clinically uncertain or where the transthoracic echocardiogram is non-diagnostic, the next step is either transoesophageal echocardiography or CT scanning. A transoesophageal study can be performed in the high-dependency unit or even in the operating theatre.

Acceptable diagnostic alternatives to the gold standard

MRI produces excellent three-dimensional reconstruction of the aorta in chronic disease, and is therefore an alternative to CT scanning, but is rarely suitable for patients presenting acutely.

Other relevant investigations

In patients with acute chest pain, a 12-lead ECG excludes an acute ST-segment elevation, although, in about 2% of all type A dissections, there is involvement of the right coronary artery. ST-segment depression and electrical evidence of left ventricular hypertrophy are commonly seen. Fibrinogen degradation products (FDP) are elevated in dissection as a result of sequestration of blood in the aortic wall. Although it is possible that very high levels (>1600 mg/ml) favour dissection above other causes of chest pain and raised FDP, notably pulmonary embolism, this is not used clinically as a ‘rule-in’ test. However, a normal FDP concentration is a clinically useful rule-out test, with a negative predictive value of 95% when the clinical likelihood is low (it may occasionally be normal in high-risk patients with intramural haematoma or localized dissections). Coronary angiography not usually necessary and should be avoided because of the risk of damage to the aorta.

Prognosis and how to estimate it

See 'Natural history, and complications of the disease' for prognosis and how to estimate it.

Treatment and its effectiveness

Dissection is treated initially with pain relief and blood pressure lowering, usually with labetalol. Patients should be transferred to a cardiothoracic centre unless surgery is contraindicated by comorbidity. Type A dissections require immediate surgery which carries a risk of about 20% and gives a 3-year survival of 70%. Uncomplicated type B dissections are treated medically since conventional surgical treatment carries an approximately 30% mortality and 20% risk of spinal cord damage. Complicated dissections are treated by endovascular stenting since the results (30-day mortality, 8%; stroke, 8%; and spinal cord ischaemia, 2%) are better than for conventional surgery. Complications include:

- severe pain that continues or recurs
- signs of rupture (large pleural effusion, increasing para-aortic or mediastinal haematoma)
- a fall in urine output; if not due to excessive hypotensive therapy or hypovolaemia, this suggests involvement of the renal arteries and is an ominous sign
- evidence of other branch artery involvement (e.g. abdominal pain with bloody diarrhoea due to ischaemic colitis)

- refractory hypertension
- early aortic expansion

Endovascular stenting is also used in the subacute (2–6 weeks) and chronic (>6 week) phases, indicated by aortic dilatation (diameter ≥ 55 mm, an increase by ≥ 10 mm acutely, or an annual increase ≥ 5 mm), refractory hypertension, recurrent symptoms, or failure of the false lumen to thrombose. Stenting is also beginning to be used in patients with acute type B dissections, although this is not established practice. There has been preliminary use of stenting for acute type A dissections in patients who are at unacceptably high risk for conventional surgery (Senay et al., 2007).

104 Peripheral arterial disease

Jeremy Perkins

Definition

Peripheral arterial disease is defined as an alteration to the blood supply to a limb, caused by an occlusion or stenosis in the arteries supplying that limb. The acuteness of the arterial compromise, and its severity and extent, will determine the symptoms experienced by the patient.

Aneurysmal disease is defined as a localized dilatation of an artery and is most commonly seen in the infrarenal abdominal aorta. An infrarenal abdominal aorta is defined as being aneurysmal if its maximum anteroposterior diameter is 3 cm or greater.

Aetiology

The majority of chronic peripheral arterial disease is caused by atherosclerosis. Atherosclerotic plaques cause luminal narrowing of the artery, which becomes progressively narrower with time, and the narrowing may progress to occlusion. Plaque rupture and ulceration in atherosclerotic stenoses of the extra-cranial internal carotid arteries results in embolization to the cerebral circulation, and stroke.

Risk factors for atherosclerosis include age, race, hyperlipidaemia, smoking, hypertension, and diabetes. Rarely, previous radiotherapy, popliteal entrapment, vasculitis, or elevated levels of homocysteine may be implicated.

Acute peripheral arterial disease may be caused by acute or chronic thrombosis, where there are preexisting atherosclerotic stenoses in the arteries, or when embolization from a proximal source causes acute occlusion of the normal arterial supply to a limb. In patients with atrial dysrhythmias, such as atrial fibrillation, the most likely source of embolization is the heart. Trauma—blunt, penetrating, or iatrogenic—for example, transection of the popliteal artery in knee dislocation caused by a road traffic accident—can cause acute limb ischaemia.

Aneurysm formation is an unspecified disorder of connective tissue.

Symptoms

Limb symptoms are commonest in the lower limb (symptoms occur in the arm in only one out of five cases). The symptoms of acute limb ischaemia are the six P's: pain, pallor, pulseless, paraesthesia, paralysis, and perishing coldness. These may vary, but the greater the degree of paralysis and sensory loss, the more severe the degree of ischaemia. The leg may be deathly white, but is often rather more mottled. Acute on chronic limb ischaemia is often characterized by less severe symptoms, with more minor sensory loss, some pain and coldness with preserved motor function (patients are able to move their foot/toes), but very limited mobility.

Chronic limb ischaemia produces two different sets of symptoms, depending on severity:

Intermittent claudication: Cramping pain is felt in the limb, predominantly the calf, on walking. It occurs after walking a reproducible distance and eases after stopping walking. There is no pain at rest or at night.

Critical limb ischaemia: Rest pain and night pain occur. This pain is felt in the toes and forefoot and not in the calf. It is often relieved by dependency. Tissue loss (ulceration or gangrene) may be present as well.

Carotid artery disease produces symptoms of stroke, transient ischaemic attack (TIA), or amaurosis fugax (transient loss of vision).

These neurological symptoms are focal, allowing localization to one cerebral hemisphere and carotid circulation.

Abdominal aortic aneurysms are usually asymptomatic, and frequently detected as an incidental finding in patients being scanned for other conditions. The major risk is of aneurysm rupture. This may be a cause of sudden death, or present with back, loin, groin, or suprapubic pain, and collapse with the associated signs of hypovolaemic shock. Rarely, aortic aneurysms may embolize, either with a solid embolus causing acute limb ischaemia, or with a shower of fine cholesterol emboli, resulting in fine punctuate areas of tissue loss on the feet or purpuric areas on the legs/feet.

Demographics

Peripheral arterial disease is a common problem. Twenty per cent of people aged 65 or over have some evidence of peripheral arterial disease on clinical examination, and 5% will have symptomatic intermittent claudication. Acute limb ischaemia affects approximately 14/100 000 population per year.

Abdominal aortic aneurysm (AAA) occurs predominantly in men aged 60–65 years. The prevalence of AAA in men aged 56 or over is ~5%, with around 2.5%–3.0% having an aneurysm of 4 cm or larger. Rupture of an AAA accounts for 1%–2% of all deaths for men aged 60 or over in the UK. The National Screening Committee has recommended a national screening programme in England and Wales to be rolled out over the next 3–4 years. This will comprise a single ultrasound scan, offered to all men when they are 65 years old. Patients with aneurysms in the 3.0–5.5 cm range will be entered into a surveillance programme with interval scans, depending on AAA size at initial detection. Patients with an AAA of 5.5 cm or greater will be offered treatment.

Natural history and complications

Acute limb ischaemia carries a high rate of death and limb loss: 25%–40% of patients will die in hospital after an episode of acute limb ischaemia, and amputation rates run as high as 50%. Late presentation (over 24 hours) or delay in treatment beyond 12 hours leads to a poor outcome.

Intermittent claudication is a benign condition that rarely progresses to limb loss. The risk of amputation for a claudicant is ~1% per year. The risk of cardiovascular death is 3–4 times higher than for an age- and sex-matched non-claudicant population. Risk factor management—stopping smoking; control of blood pressure and hypercholesterolaemia; diagnosis and control of diabetes; antiplatelet agents and statin—is important to reduce this excess mortality. In terms of walking performance, one-third of claudicants will remain stable, one-third will improve spontaneously, especially if encouraged to exercise, and one-third will deteriorate so that ~20% will come to some form of intervention.

Critical limb ischaemia is a limb-threatening condition and requires intervention to prevent limb loss. Mortality rates within 1 year of the onset of critical limb ischaemia may approach 30%–50%.

Carotid artery disease may be symptomatic or asymptomatic. Symptomatic carotid artery disease (TIA, amaurosis fugax, or completed stroke) carries a high risk of recurrent events. Patients with a severe symptomatic internal carotid artery stenosis (>60%) have a 20%–30% risk of a further stroke over the subsequent 2–3 years. If the stenosis is asymptomatic, then the risk of stroke is much less, being around 11%–12% over 5 years.

AAAs grow slowly in size, with growth rates related to size. AAAs between 4.0 and 5.5 cm grow ~0.3 cm per year. As the aneurysm increases in size, the growth rate increases also. Treatment is considered when the aneurysm diameter reaches or exceeds 5.5 cm. The

Table 104.1 Risk of rupture of an abdominal aortic aneurysm, according to aneurysm diameter

Size (cm)	Annual rupture risk (%)
<4.0	<0.5
4.0–4.9	0.5–1.0
5.0–5.9	1.0–5.0
6.0–6.9	5.0–15.0
7.0–7.9	15.0–30.0
>8.0	30.0–50.0

major complication of AAA is rupture. The risk of rupture is also size related. The rupture rates are at best a guesstimate, but typically quoted values are shown in Table 104.1.

Overall mortality for ruptured AAA is 80%–90%.

Approach to diagnosing the disease

Diagnosis of acute and chronic limb ischaemia is made on clinical grounds. Acute limb ischaemia is characterized by the absence of pulses, and a varying degree of sensory and motor impairment. The leg may be pale or mottled. The other limb should be examined for comparison. The presence of normal pulses on the other limb suggests embolization as the cause. Absent pulses (including femorals) on both legs, combined with loss of power bilaterally and mottling to the waist, indicate a saddle embolus or acute aortic occlusion.

Areas of fixed mottling distally, extensive skin blistering, and swelling of the foot with muscle rigidity raise doubts about the viability of the limb.

Intervention for acute limb ischaemia should not be delayed for angiography or other investigations, especially where there is significant motor or sensory loss, or calf muscle tenderness.

The diagnosis of intermittent claudication can be made largely on history alone. It is most frequently unilateral and characterized by cramping, gripping pain in the posterior calf or, less commonly, the thigh or buttock. The pain comes on after walking a set distance, which is less when walking uphill or carrying a load. There may be some variability in walking performance, but generally the distance the patient can walk is the same from day to day. It eases rapidly when the patient stops walking, and does not occur at rest or at night. Examination of pulses will confirm the presence of peripheral arterial disease.

Where patients have significant proximal disease, such as a chronic distal aortic occlusion or bilateral iliac occlusion, the leg symptoms may be more general and patients complain of a heaviness or tiredness in the whole leg that prevents them walking.

The presence of pedal pulses excludes the diagnosis of peripheral arterial disease, and the loss of one pedal pulse is not sufficient to cause claudication or critical limb ischaemia.

Handheld Doppler machines can be used as adjunct to clinical diagnosis in peripheral arterial disease to assess arterial signals from pedal arteries and to measure the ankle–brachial pressure index (ABPI). An ABPI >0.8 is normal, values for claudicants typically range from 0.5 to 0.8, and critical ischaemia is commonly associated with an ABPI <0.5. These cut-offs are not absolute and are taken in conjunction with clinical findings.

The neurological symptoms and signs of TIA, stroke, or amaurosis fugax are self-evident. Carotid endarterectomy is considered for patients with severe internal carotid artery stenoses of 60% or greater.

Abdominal aortic aneurysms are mostly asymptomatic and are diagnosed frequently on abdominal ultrasound or CT scans to investigate other pathology. Routine abdominal examination may reveal an enlarged aorta, although sizing of an AAA on clinical examination is unreliable and should be confirmed by additional investigation.

Other diagnoses that should be considered

Nerve trauma, spinal disease, and cerebrovascular accident can all simulate acute limb ischaemia, but the finding of absent pulses is the absolute criterion for acute ischaemia.

Leg pain on walking, the characteristic of intermittent claudication, may occur with other pathology. The major differential diagnosis comes from musculoskeletal disorder. Spinal claudication (from spinal stenosis) produces a more variable restriction on walking, often with back pain and associated numbness or paraesthesia distally. Hip and knee osteoarthritis and peripheral neuropathies can cause pain on exercise.

Tissue loss in the toes may result from embolization rather than true critical ischaemia. Severe cardiac disease can cause toe discoloration and ulceration from simple 'pump failure', even with normal arteries in the leg.

'Gold-standard' diagnostic tests and acceptable alternatives

Angiography is infrequently used for diagnostic purposes, and is used when treatment (angioplasty and/or stenting) is required.

Duplex ultrasound scanning is the initial investigation of choice for peripheral arterial disease. Duplex ultrasound may be non-diagnostic in obese patients when looking at the aorta and iliac arteries, or where arteries are very calcified. Magnetic resonance angiography or CT angiography are useful alternatives in this scenario. These are all non-invasive diagnostic methods. Intra-arterial angiography may be necessary to investigate disease in the crural (below knee) arteries.

Carotid artery stenosis is diagnosed using duplex ultrasound or magnetic resonance angiography.

Abdominal aortic aneurysms are diagnosed using ultrasound or CT. CT is the investigation of choice to demonstrate the relationship to the renal arteries and aneurysm morphology if treatment with an endovascular stent graft is being considered.

Other relevant investigations

Patients with carotid artery disease presenting with TIA or stroke require structural brain imaging with CT or MRI to exclude any space-occupying lesion as the cause of their symptoms.

Patients being considered for aortic aneurysm surgery require cardiac investigation, depending on local protocols. Stress investigation with dobutamine stress echocardiography, exercise multigated acquisition scan, exercise myocardial perfusion scanning, or cardiopulmonary exercise testing is often used.

Prognosis and how to estimate it

Acute limb ischaemia carries a high rate of limb loss and mortality. Any delay in presentation and treatment, and the presence of significant comorbidities, will significantly increase limb loss and mortality.

Claudication carries a very low rate of limb loss, but a high mortality from cardiovascular disease (50% at 10 years).

Patients with critical limb ischaemia are a heterogeneous group, usually with significant comorbidities. Mortality approaches 30% at 1 year, and the rate of limb loss without intervention is high. Limb salvage is preferable to amputation where feasible.

The prognosis for AAA is related to rupture risk (see 'Natural history and complications').

Treatment and its effectiveness

Acute limb ischaemia due to arterial embolization requires urgent surgical embolectomy when there is significant motor and sensory loss. Acute on chronic ischaemia, when thrombosis occurs on pre-existing atheromatous disease, may present less severely and allow time for treatment with intrarterial thrombolysis. In all cases of acute ischaemia, mortality is high. Revascularization later than 8–12 hours carries a high rate of limb loss.

Intermittent claudication can be safely managed conservatively where impairment of walking performance is mild to moderate. Pharmacological treatment is generally ineffective. Minimally invasive intervention with angioplasty and/or stenting is the preferred treatment, with results being more durable in the iliac arteries than in the femoral or popliteal arteries. Femoropopliteal bypass grafting may be considered.

Critical limb ischaemia requires revascularization for limb salvage either by percutaneous angioplasty/stenting or by bypass grafting. Bypass grafts are more long lasting and effective the more proximal the recipient artery (i.e. above-knee popliteal versus posterior tibial at the ankle).

Carotid endarterectomy is the treatment of choice for symptomatic carotid artery stenosis with an absolute risk reduction at 2 years of 17% for ipsilateral ischaemic stroke. Carotid stenting has shown worse results, but remains under trial.

AAAs can be repaired by open surgery or endovascular stent grafting. Perioperative mortality and morbidity are reduced from 5% to 2% with endovascular stent grafting, but patients require continuing surveillance to detect potential stent migration or failure.

105 Raynaud's phenomenon

Kenny Sunmboye and Rachel Jeffery

Definition

Raynaud's phenomenon is characterized by episodic digital ischaemia due to vasospasm causing closure of the small arteries and arterioles of the distal extremities, in response to cold exposure or emotional stimuli. This is manifested clinically by the sequential development of intense pallor of the fingers or toes, cyanosis, and rubor, following cold exposure and subsequent rewarming. These colour changes may be accompanied by paraesthesiae and other sensations, but pain is not usually a prominent feature.

Raynaud's phenomenon is separated into two categories:

- primary (idiopathic): Raynaud's disease
- secondary Raynaud's phenomenon, which may be due to underlying disease or environmental associations (Box 105.1)

Diagnosis

A history of cold, painful hands since childhood or adolescence, especially in females, is suggestive of Raynaud's phenomenon. There

Box 105.1 Causes of secondary Raynaud's phenomenon

- rheumatic diseases:
 - systemic sclerosis (occurs in 90% of patients)
 - mixed connective tissue disease (85%)
 - SLE (40%)
 - dermatomyositis or polymyositis (25%)
 - rheumatoid arthritis (10%)
 - Sjögren's syndrome
 - vasculitis
- haematologic diseases:
 - polycythaemia rubra vera
 - leukaemia
 - thrombocytosis
 - cold agglutinin disease (mycoplasma infections)
 - paraproteinaemias
 - protein C deficiency, protein S deficiency, antithrombin III deficiency
 - presence of the factor V Leiden mutation
 - hepatitis B and C (associated with cryoglobulinaemia)
- occlusive arterial diseases:
 - external neurovascular compression, carpal tunnel syndrome, and thoracic outlet syndrome
 - thrombosis
 - thromboangiitis obliterans
 - embolization
 - arteriosclerosis
 - Buerger's disease
- environmental associations:
 - vibration injury
 - vinyl chloride exposure
 - lead exposure
 - organic solvent exposure (e.g. xylene, toluene, acetone, chlorinated solvents)
- neoplastic disease

Box 105.2 Clinical features pointing to secondary Raynaud's phenomenon

- males presenting at any age
- females presenting at age >40
- swollen fingers
- vasculitic changes, ulcers, or loss of finger pulp
- presence of dilated capillaries in the finger nail bed and fold (use of an ophthalmoscope set at +20 and with aqueous clear gel for contact can often pick these up without need for capillaroscopy)
- presence of antinuclear antibodies in titres >1:160, particularly if an anticentromere pattern is present on immunofluorescence

is often a family history. Patients with Raynaud's disease may have hands and feet that are of normal appearance in a warm atmosphere. Hypersensitivity to cold is common. A typical attack may be precipitated by immersion of the hands in cold water, when the digits will first go white, then blue, and finally a dusky red.

There is no specific objective test for Raynaud's phenomenon, but secondary causes need to be excluded. Raynaud's phenomenon that begins in childhood, during the teen years, or in the patient's 20s, is most likely to be primary Raynaud's phenomenon in the absence of overt connective tissue disease symptomatology. Leading clinical features of secondary Raynaud's phenomenon are given in Box 105.2.

Investigations

Investigations of the patient with Raynaud's phenomenon are given in Table 105.1.

Table 105.1 Investigations of the patient with Raynaud's phenomenon

Investigation	Comment
Full blood count	To check for polycythaemia rubra vera, leukaemia, or thrombocytosis
Blood film	To check for leukaemia
Thrombophilia screen (including antiphospholipid screen)	To check for antiphospholipid syndrome, protein C and S deficiency, and factor V Leiden mutation
Hepatitis screen	To rule out hepatitis B and C
Cryoglobulins	To check for cryoglobulinaemia
Serum and urine electrophoresis	To evaluate for paraproteinaemias
ANA and extra-nuclear antibodies	ANA titres >1:160 should raise suspicion, and ENAs may contain connective tissue disease-related antibodies
Rheumatoid factor	May be positive in rheumatoid arthritis or cryoglobulinaemia
Creatinine kinase	To check for poly- and dermatomyositis
Nail fold capillaroscopy	Abnormal in secondary causes of Raynaud's phenomenon related to connective tissue disease

Abbreviations: ANA, antinuclear antibody; ENA, extractable nuclear antigen antibody.

Treatment

The treatment for primary Raynaud's phenomenon (Raynaud's disease) is as follows:

- reassurance, and advice to dress warmly and avoid cold exposure
- ancillary aids: hand and feet warmers, heated gloves and garments
- avoidance of tobacco and aggravating medications such as nonselective beta blockers
- calcium-channel antagonists (nifedipine, diltiazem) may be tried, but can cause more side effects (ankle oedema, facial flushing, headache) than clinical benefit

The treatment for secondary Raynaud's phenomenon is as follows:

- general treatments as listed for primary Raynaud's phenomenon

- treatment of the underlying disorder
- drug treatments tailored to the severity of Raynaud's phenomenon, including calcium-channel blockers, losartan, fluoxetine, prostacyclin analogues, administered intravenously in severe cases with critical digital ischaemia, and newer oral agents such as bosentan and sildenafil for severe Raynaud's phenomenon associated with recurrent digital ulceration

106 Heart muscle disease (cardiomyopathy)

Kazem Rahimi

Introduction

Cardiomyopathy is defined as disease of heart muscle, and typically refers to diseases of ventricular myocardium. A consensus statement of the European Society of Cardiology (ESC) working group on myocardial and pericardial diseases, first published online in 2007, abandoned the inconsistent and rather arbitrary classification into primary and secondary causes and based its classification on ventricular morphology and function only (Elliot et al., 2008). This classification distinguishes five types of cardiomyopathy: dilated cardiomyopathy, hypertrophic cardiomyopathy, restrictive cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy, and unclassified cardiomyopathies (such as takotsubo cardiomyopathy and left ventricular non-compaction). Each category is further subdivided into familial and non-familial causes.

In a departure from the 1995 WHO classification (Richardson et al., 1996), the ESC consensus statement excludes myocardial dysfunction caused by coronary artery disease, hypertension, valvular disease, and congenital heart disease from the definition of cardiomyopathy. The rationale for this was to highlight the differences in diagnostic and therapeutic approaches of these common diseases, and to make the new classification system more acceptable for the routine clinical use. In addition, in contrast to the American Heart Association scientific statement (Maron et al., 2006), the ESC definition does not consider channelopathies as cardiomyopathies. The sections on cardiomyopathy in this chapter are based on the ESC definition, with a brief reference to channelopathies.

Dilated cardiomyopathy

Definition of dilated cardiomyopathy

Dilated cardiomyopathy (DCM) is defined by left ventricular dilatation and left ventricular systolic dysfunction in the absence of abnormal loading conditions (hypertension, valve disease) or coronary artery disease sufficient to cause global systolic impairment. Right ventricular dilation and dysfunction may be present but are not necessary for the diagnosis. DCM does not require severe left ventricular dilation. Mild dilatation is sufficient to confirm diagnosis if systolic function is severely impaired.

Aetiology of DCM

The list of causes of DCM is extensive, with about 20%–48% of all cases being familial.

Familial causes include:

- genetic mutation (sarcolemma–sarcomere genes)
- mitochondrial dysfunction
- metabolic with storage disturbance
- unknown hereditary causes

Non-familial causes include:

- viral myocarditis (e.g. parvovirus B19) and viral persistence
- non-viral myocarditis (e.g. Chagas disease)
- toxicity (alcohol; drugs such as adriamycin)
- antibodies and autoimmune disease
- non-hereditary infiltrative diseases (e.g. haemochromatosis)
- peripartum
- endocrine causes (e.g. thyrotoxicosis)

- nutritional and electrolyte disturbances: thiamine, carnitine, selenium, hypophosphataemia, hypocalcaemia
- chronic incessant tachycardia (e.g. persistent atrial fibrillation with a rapid ventricular response)

Typical symptoms of DCM, and less common symptoms

Patients with DCM may be asymptomatic. Some may present with features of heart failure, such as exertional dyspnoea, orthopnoea, reduced exercise tolerance, and peripheral oedema. DCM may also manifest with palpitations due to conduction disorders and arrhythmia, thromboembolic complications, or sudden cardiac death.

Demographics of DCM

DCM is the most common cardiomyopathy worldwide. It develops at any age, but is more common in adults. In children, the yearly incidence is 0.57 cases per 100 000 per year overall, but is higher in boys than in girls, in black people than in white people, and in babies younger than 1 year than in children. In adults, DCM is more common in men than in women. The prevalence is estimated at 1 in 2500 individuals, with an incidence of 7 per 100 000 per year. However, these may be an underestimate of true figures, due to underdiagnosis of a disease which can remain asymptomatic.

Natural history, and complications of DCM

The clinical course is largely unpredictable in the individual patient and may depend on the underlying cause. In the absence of more reliable evidence, information gained from studies in the general systolic heart failure population is often extrapolated to the DCM population to predict outcome. Thus, factors such as degree of systolic function and presence of symptoms are thought to correlate with patient's risk of future adverse events. Long-term complications include pump failure, sudden death, arrhythmic events, and systemic embolism.

Approach to diagnosing DCM

The approach to the diagnosis of DCM depends on patient history, and clinical, echocardiographic, or cardiac MRI features of DCM or heart failure, or both. The diagnostic strategy is usually the same as for chronic heart failure (see Chapter 92). In addition, some specific diagnostic tests may be required to elicit the underlying cause of DCM and to tailor treatment accordingly.

Endomyocardial biopsy is recommended to further define the cause of the disease in those presenting with acute or fulminant heart failure of unknown aetiology and who deteriorate rapidly with ventricular arrhythmia and/or heart block, or in patients who are unresponsive to conventional heart failure therapy. In such cases, the histology of heart muscle can be clinically useful to distinguish between disease processes that need alternative treatment strategies, such as storage diseases, malignancies, sarcoidosis, and haemochromatosis. Confirmation of viral myocarditis is sometimes possible with endomyocardial biopsy (but not routinely recommended), as is the identification of virus-negative, immune-mediated myocarditis, which could result in additional treatment such as immunomodulation or immunosuppression therapies. The role of cardiac MRI as a non-invasive technique for the diagnosis of the cause of DCM is evolving rapidly. In particular, a midwall pattern of late gadolinium enhancement suggests DCM.

If the cause of DCM is not apparent, the following studies may be warranted, depending on the potential findings identified in the history and physical examination:

- thyroid function tests, particularly in patients over the age of 65 or in patients with atrial fibrillation
- uron studies (ferritin and total iron-binding capacity) to screen for hereditary haemochromatosis (the absence of other characteristic findings of haemochromatosis does not preclude the diagnosis)
- antinuclear antibody and other serologic tests for lupus
- viral serologies and antimyosin antibody if myocarditis is suspected
- evaluation for phaeochromocytoma
- thiamine, carnitine, and selenium levels

In confirmed familial DCM, screening of first-degree relatives should be considered (yield depending on the cause less than 60%).

Other diagnoses that should be considered in addition to DCM

Diagnosis of DCM requires exclusion of coronary artery disease, hypertension, valvular disease, and congenital heart diseases which are sufficient to explain the degree of left ventricular dilatation and systolic dysfunction. This is, however, often clinically challenging because of the high prevalence of such conditions in the general population.

'Gold-standard' diagnostic test for DCM

Diagnosis requires imaging (e.g. echocardiography, cardiac MRI) to show a dilated left ventricle with or without impaired systolic function.

Acceptable diagnostic alternatives to the gold-standard test for DCM

Any imaging modality that allows assessment of the size of the heart and its function can be considered as an alternative to the 'gold standard'.

Other relevant investigations for DCM

Diagnosis of DCM requires exclusion of other causes of heart failure, such as coronary artery disease, hypertension, valve disease, and congenital heart disease. Exclusion of coronary artery disease in particular may require a coronary angiography.

Prognosis for DCM, and how to estimate it

DCM is a heterogeneous condition, and the prognosis of those affected largely depends on the underlying cause of DCM. Prognostic tools developed for patients with acute or chronic heart failure may be useful in people with DCM.

Treatment of DCM, and its effectiveness

Since DCM accounts for only 10% of all heart failure population, patients with DCM have been naturally underrepresented in many heart failure trials. Current guidelines for treatment of people with systolic heart failure assume that evidence gained from trials conducted in the general heart failure population is similarly applicable to those with DCM. Based on current guidelines, treatment of symptomatic patients should follow the recommendations for patients presenting with acute or chronic heart failure. In brief, diuretics and vasodilators should be used to relieve symptoms in the acute phase. Inotropes and haemodynamic support with medical devices may be necessary in more severe cases presenting with severe hypotension and signs of organ hypoperfusion.

Medical therapy is the mainstay for the long-term therapy of DCM. Angiotensin-converting enzyme (ACE) inhibitors and beta blockers are routinely initiated and complemented with other drugs such as aldosterone antagonists, aldosterone-receptor antagonists, and digoxin. Medical devices, such as cardioverter defibrillators, and cardiac resynchronization therapy are recommended in subgroups of people with systolic heart failure. In people with the most severe symptomatic heart failure despite optimal medical and device therapy, cardiac transplantation (with or without bridging with ventricular assist devices) should be considered. In addition to these general heart failure therapies, treatment of the underlying causes of

non-familial DCM can have some disease-modifying effect for certain conditions.

Hypertrophic cardiomyopathy

Definition of hypertrophic cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is defined by increased ventricular wall thickness or mass in the absence of loading conditions (hypertension, valve disease) sufficient to cause the observed abnormality. This definition contrasts with previous definitions which required the absence of intramyocardial storage material as the cause of myocardial hypertrophy, and has the advantage of avoiding the conundrum of not being able to reliably exclude storage disorders in many patients, even with endomyocardial biopsy.

The distribution and severity of left ventricular hypertrophy can vary greatly. The major patterns include:

- asymmetrical septal hypertrophy (80%), with or without left ventricular outflow obstruction
- concentric hypertrophy, with maximal thickening at the level of papillary muscles (8%)
- apical hypertrophy

Aetiology of HCM

Many individuals have familial disease with an autosomal dominant pattern of inheritance (with incomplete penetrance) caused by mutations in genes that encode different proteins serving contractile, structural, and regulatory functions in the cardiac sarcomere. More than 400 mutations in 11 genes have been identified that are associated with HCM. The most common mutations are in the genes that encode beta-myosin heavy chain and cardiac myosin-binding protein C.

Typical symptoms of HCM, and less common symptoms

Most patients have no or only minor symptoms and are often diagnosed during family screening. Common symptoms include palpitations, dyspnoea, angina, and syncope or presyncope.

Demographics of HCM

Left ventricular hypertrophy in the absence of hypertension and valve disease occurs in approximately 1 in 500 in the general population. It affects men and women equally and occurs in many races and countries.

Natural history, and complications of HCM

The clinical course of HCM is variable. It can manifest clinically at any age, with many asymptomatic or mildly symptomatic patients having a normal life expectancy. Others develop progressive symptoms of heart failure despite medical therapy. The degree of hypertrophy can increase in adolescents and young adults but remains usually stable in older adults. Atrial fibrillation occurs in 10%–15% of patients. A small proportion of patients can develop left ventricular dilatation with reduced systolic function. The annual mortality rate is about 1% in adults, and 2% in children.

Approach to diagnosing HCM

Diagnosis is based on family history, physical examination, ECG, and echocardiography. Cardiac MRI is becoming a valuable tool to complement echocardiography. Alternative causes of left ventricular hypertrophy need be excluded. Genetic testing can be useful for confirming the diagnosis and guiding family screening.

Physical examination may be normal. The classic murmur of obstructive HCM is a harsh systolic murmur that increases in intensity with physical or pharmacologic manoeuvres that reduce afterload or preload, or increase ventricular contractility (e.g. the Valsalva manoeuvre, or nitrate application).

ECG shows voltage criteria for left ventricular hypertrophy; prominent Q waves in inferior or precordial leads; left axis deviation; and left atrial enlargement. In apical HCM, deep T-wave inversions in precordial leads are often present.

Echocardiography shows left ventricular hypertrophy with a diastolic wall thickness of 15 mm or greater. Other findings include a septal-to-posterior wall ratio of 1.3 or more; a small left ventricular cavity; reduced septal motion and thickening; normal or increased motion of the posterior wall; systolic anterior motion of the mitral leaflets; mitral regurgitation; and partial midsystolic closure of the aortic valve, with coarse fluttering of the leaflets in late systole. In the setting of obstructive HCM, a resting gradient of more than 30 mm Hg and a provokable gradient of more than 50 mm Hg are present, with a late-peaking (dagger-shaped) Doppler signal. Tissue Doppler imaging can detect reduced early diastolic (E') and systolic (S') velocities of the myocardium.

Cardiac MRI allows a more accurate assessment of myocardial mass, regional hypertrophy, or wall motion abnormalities. Late gadolinium enhancement may be seen in a patchy intramyocardial distribution or, typically, at the junctions of the interventricular septum and right ventricular free wall.

Cardiac catheterization is usually reserved for assessment of coronary artery disease and assessment prior to surgical or interventional procedures. In the setting of obstructive HCM, there is typically a subaortic outflow gradient on catheter pullback, spike-and-dome pattern of aortic pressure tracing, elevated left atrial and left ventricular end-diastolic pressures and elevated pulmonary capillary wedge pressure. A post-extrasystolic pulse pressure typically increases as a result of increased dynamic obstruction (Brockenbrough sign).

Other diagnoses that should be considered in addition to HCM

Main alternative causes of left ventricular hypertrophy that need to be considered are hypertension, aortic stenosis, athlete's heart, and Fabry's disease.

Athlete's heart is a benign physiological condition caused by long-term athletic training. In athlete's heart, the hypertrophy is usually symmetric and rarely greater than 16 mm. In HCM the left ventricular end-diastolic dimension is usually less than 45 mm and shows signs of impaired relaxation and an enlarged left atrium. In addition, left ventricular hypertrophy does not regress with deconditioning.

Fabry's disease is a rare, multisystem, X-linked recessive glycolipid storage disease. Echocardiography and cardiac MRI can be used to differentiate between Fabry's and HCM, even without any other systemic involvement of the storage disease.

'Gold-standard' diagnostic test for HCM

The gold-standard diagnostic test for HCM is echocardiography.

Acceptable diagnostic alternatives to the gold-standard test for HCM

Cardiac MRI is often used to confirm diagnosis and rule out other causes.

Other relevant investigations for HCM

Screening of first-degree relatives of patients with HCM should be performed. This should include history, physical examination, ECG, and echocardiography. Genetic testing may also be useful in those from families with a known genetic mutation.

Prognosis for HCM, and how to estimate it

The prognosis of the majority of HCM patients is good. The major concern with the disease is sudden cardiac death. Risk factors for sudden cardiac death include:

- prior cardiac arrest or sustained ventricular tachycardia
- family history of sudden cardiac death
- unexplained syncope
- hypotensive blood pressure response to exercise
- nonsustained ventricular tachycardia on ambulatory monitoring
- identification of a high-risk mutant gene
- massive hypertrophy, with a wall thickness of 30 mm or greater

Outflow tract obstruction per se is not a strong predictor of sudden cardiac death.

Treatment of HCM, and its effectiveness

Asymptomatic patients usually do not require pharmacological therapy. Beta blockers, verapamil, and disopyramide are used to reduce left ventricular contractility, relieve outflow tract obstruction, and improve symptoms. Patients with refractory symptoms due to left ventricular outflow obstruction should be considered for septal myectomy (Morrow procedure) or alcohol septal ablation. An implantable cardioverter defibrillator (ICD) is recommended for survivors of cardiac arrest or sustained ventricular tachycardia and for high-risk patients, who are defined as having two or more of the major risk factors for sudden cardiac death. Dual-chamber pacing has not been shown to be effective in improving symptoms.

Restrictive cardiomyopathy

Definition of restrictive cardiomyopathy

Restrictive cardiomyopathy (RCM) is defined as non-dilated ventricles (one or both) showing a restrictive physiology, that is, a pattern of ventricular filling in which increased stiffness of the myocardium causes ventricular pressure to rise precipitously with only small increases in volume. Hypertrophy is typically absent, although infiltrative and storage diseases such as amyloidosis may cause an increase in left ventricular wall thickness. Systolic function was historically defined as being normal, but many patients have some degree of systolic dysfunction.

Aetiology of RCM

Approximately half of RCM cases are idiopathic without specific histological findings. Identifiable causes are usually due to systemic disorders, but familial causes have been described. Most common causes include:

- amyloidosis
- sarcoidosis
- endomyocardial fibrosis without eosinophilia
- radiation
- chemotherapy such as anthracycline

Less common causes include:

- haemochromatosis
- Fabry's disease
- carcinoid
- scleroderma
- pseudoxanthoma elasticum
- endomyocardial fibrosis with eosinophilia (Löffler's syndrome)
- metastatic cancer
- advanced stages of HCM, DCM
- familial, mostly autosomal dominant (e.g. mutations in the troponin I gene)

By definition, restrictive pathologies caused by ischaemic heart disease, valvular disease, or hypertension do not classify as RCM.

Typical symptoms of RCM, and less common symptoms

Most patients present with signs of heart failure (e.g. dyspnoea, peripheral oedema, palpitations, fatigue, weakness, reduced exercise tolerance, hepatosplenomegaly, and ascites). Syncope or presyncope due to orthostatic hypotension or bradycardic events due to conduction disorders are less common. Thromboembolic complications may be the initial presentation.

Demographics of RCM

The exact prevalence of RCM is unknown, but it is probably the least common type of cardiomyopathy in Europe and North America. RCM due to endomyocardial fibrosis, however, is a common cause of heart failure and death in tropical regions, including parts of Africa, Central and South America, India, and other parts of Asia. Idiopathic

RCM is commonly diagnosed in elderly adults and is more common in older women than men.

Natural history, and complications of RCM

The natural history of the RCM is variable and depends on the underlying cause. Most types of RCM are associated with chronic heart failure symptoms and thromboembolic events which determine patient's prognosis.

Approach to diagnosing RCM

Diagnosis is based on clinical findings of heart failure, with supporting evidence from ECG and chest X-ray. Echocardiography is crucial to identify the restrictive physiology. Cardiac catheterization, cardiac MRI, and endomyocardial biopsy can help in confirming the diagnosis and identifying the underlying cause.

ECG

An ECG will show large P waves indicating biatrial enlargement, with nonspecific STsegment and T-wave abnormalities. Atrial fibrillation is common. Even in the presence of myocardial thickening (e.g. in amyloidosis), QRS voltage is normal or even low. Infiltration of the conductive system may lead to a prolonged PR interval (or high-degree heart blocks).

Chest X-ray

A chest X-ray usually shows a normal-sized heart with enlarged atria and variable degrees of pulmonary congestion.

Echocardiography

On echocardiography, there is typically biatrial enlargement, with normal-sized ventricles and normal or slightly impaired systolic function. Thickening of the myocardium and valves may be present. The myocardium may show a 'granular' appearance. The endocardium may be involved, showing extensive thrombi in the ventricular apices (common in endomyocardial fibrosis without eosinophilia). Mild pericardial effusion may be present (e.g. in amyloidosis).

Restrictive physiology is assessed by mitral inflow Doppler velocities, tissue Doppler, and speckle tracking. Severe diastolic dysfunction is suggested by a high early diastolic left ventricular filling wave (E wave) with a short deceleration time, and a low late-diastolic filling wave (A wave, if the patient is in sinus rhythm), and decreased isovolumic

relaxation time. Tissue Doppler velocities of the mitral annulus (E' wave) are reduced (in both systole and diastole), resulting in a high E/E' ratio. Speckle tracking is less prone to errors and allows a more reliable assessment of filling pattern.

Cardiac catheterization

Cardiac catheterization will show a square-root (or dip-plateau) sign, which is characterized by an early diastolic dip quickly followed by a plateau. Usually, the diastolic pressure of both ventricles is elevated, with the highest plateau being in the left ventricle.

Patients may show a spectrum of ventricular filling abnormalities, from a more advanced typical restrictive pattern to a milder form of abnormal relaxation with long isovolumic relaxation time. Measurement of restriction during catheterization and Doppler measures will vary according to the volume status, heart rate, and rhythm.

Other diagnoses that should be considered in addition to RCM

The main differential diagnosis of RCM is constrictive pericarditis (see Table 106.1).

Endomyocardial biopsy or response to pericardiectomy may reveal the definite pathology in some patients.

'Gold-standard' diagnostic test for RCM

Endomyocardial biopsy may show distinctive features of the underlying condition. However, this is often not necessary and can only be considered complementary once restrictive physiology is confirmed.

Acceptable diagnostic alternatives to the gold-standard test for RCM

Acceptable diagnostic alternatives to the gold-standard test for RCM are echocardiography and MRI.

Other relevant investigations for RCM

ECG, cardiac catheterization, CT, and blood investigations (e.g. BNP) can contribute to the diagnostic strategy.

Prognosis for RCM, and how to estimate it

The epidemiology of RCM, as it is a heterogeneous condition, is not well described. In idiopathic RCM, mortality without cardiac

Table 106.1 Features differentiating restrictive cardiomyopathy from constrictive pericarditis

Feature	Favours restrictive cardiomyopathy	Favours constrictive pericarditis
History	Amyloidosis Sarcoidosis	Previous pericarditis Cardiac surgery Uraemia TB Malignancy
Clinical examination	Kussmaul's sign and pulsus paradoxus absent	Kussmaul's sign and pulsus paradoxus present
ECG	Normal or low voltage Conduction abnormalities Pathological Q-waves	Low voltage
Echocardiography	Granular appearance of the myocardium Normal or low normal systolic function No significant respiratory variation of the mitral Doppler velocities Reduced tissue Doppler of mitral annulus (E' velocity <8 cm/s).	Pericardial thickening (>5 mm) Normal or supranormal systolic function Increased myocardial contractility on tissue Doppler (E' velocity >12 cm/s) and speckle tracking Paradoxical septal movement, with a D-shaped left ventricle during inspiration
CT	Normal pericardium Ventricular thrombus	Pericardial thickening (>5 mm) or calcification
MRI	Normal pericardium Ventricular thrombus Myocardial tissue characterization consistent with underlying disease (e.g. late gadolinium enhancement)	Pericardial thickening Paradoxical septal movement, with a D-shaped left ventricle during inspiration
Cardiac catheterization	Left ventricular filling pressures are >5–7 mm Hg higher than right ventricular ones, with no significant respiratory variation	Equilibration of filling pressures (mainly during inspiration)
Plasma BNP level	Significantly elevated	Usually normal

transplantation is >50% after manifestation of symptoms. Embolic stroke is a common complication as a consequence of large atria and atrial fibrillation.

Treatment of RCM, and its effectiveness

There is no established treatment for RCM. Treatment of the underlying causes is described elsewhere. Symptomatic treatment is achieved with careful dosing of diuretics to avoid hypovolaemia, and rate control with beta blockers, calcium-channel antagonists, or digoxin. Prophylactic anticoagulant therapy is recommended in RCM patients with enlarged atria even before supraventricular tachycardia has developed. Cardiac transplantation in children with idiopathic RCM should be considered.

Arrhythmogenic right ventricular cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy, also called arrhythmogenic right ventricular dysplasia, is characterized by a scarred appearance with fibrous or fibrofatty replacement of the right ventricular myocardium and which can also involve the left ventricle. It should be considered in patients who present with ventricular tachycardia with a left branch bundle block configuration in the absence of apparent heart disease. However, ECG can be normal in early years of manifestation. Detailed diagnostic criteria based on ECG, echocardiography, cardiac MRI, family history, and endomyocardial biopsy have been proposed (Marcus et al., 2010) and should be used for diagnosis.

Unclassified cardiomyopathies

Takotsubo cardiomyopathy

Takotsubo, or stress-induced, cardiomyopathy is an increasingly reported diagnosis which is characterized by transient, regional, left ventricular dysfunction in the absence of significant coronary artery disease. It presents usually with an acute coronary syndrome. Pheochromocytoma and myocarditis need to be ruled out. In addition, the absence of left ventricular function recovery after 4 weeks makes the diagnosis unlikely.

Left ventricular non-compaction

Left ventricular non-compaction (LVNC) is a rare type of cardiomyopathy which manifests with heart failure, atrial and ventricular arrhythmias, and thromboembolic events. It is usually characterized by an altered myocardial wall with prominent trabeculae and deep intertrabecular recesses, resulting in thickened myocardium with two layers consisting of compacted and

noncompacted myocardium, respectively. The diagnosis of LVNC is usually established by echocardiography. Cardiac MRI, CT, and left ventriculography are other imaging modalities that may be diagnostic or raise the initial clinical suspicion. The differential diagnosis of LVNC includes dilated cardiomyopathy, hypertensive heart disease, apical hypertrophic cardiomyopathy, infiltrative cardiomyopathy, and eosinophilic endomyocardial disease.

Channelopathies

Channelopathies are a group of genetic disorders that are caused by defects in the movement of ions (e.g. sodium, potassium, and calcium) across the cardiac cell membrane. The main types of channelopathies are long-QT syndrome (ECG: prolonged QT interval, and T-wave abnormalities), Brugada syndrome (ECG: ST-segment elevation in Leads V1–V3, and a right bundle branch block pattern in the right precordial leads), and catecholaminergic polymorphic ventricular tachycardia (ECG: premature ventricular contractions, and non-sustained polymorphic VT). Channelopathies usually present with syncope, arrhythmia, and sudden death.

107 Tumours and the heart

Kazem Rahimi

Myxoma

Definition of myxoma

Myxoma is the most common primary tumour of the heart in adults and constitutes about 40% of all cardiac tumours. About 75%–85% of myxomas occur in the left atrium, with another 15%–20% being located in the right atrium. Less than 10% arise in the left ventricle and right ventricle together. Myxomas are usually pedunculated and typically arise from the interatrial septum (and often in the fossa ovalis) via a stalk. Tumours vary widely in size, ranging from 1 to 15 cm in diameter.

Aetiology of myxoma

Myxoma is a tumour of primitive connective tissue, with a gelatinous consistency on histopathological examination. Most cases are sporadic, but about 10% are familial, with autosomal dominant inheritance. Although they are typically benign, local recurrence due to inadequate resection or malignant transformation has been reported.

Typical symptoms of myxoma, and less common symptoms

Symptoms depend on tumour location and are related to intermittent mechanical obstruction of the mitral (or tricuspid) valve, systemic emboli, or paraneoplastic effects. Hence, symptoms can include paroxysmal shortness of breath, cough, haemoptysis, fatigue, and stroke. About a third of patients report fever and weight loss.

Demographics of myxoma

Actual incidence is unknown, but in one study surgical incidence was 1 in 500 000 population per year. Myxomas usually occur between the third and sixth decades of life and are more common in women.

Natural history, and complications of myxoma

The natural history of the disease is not well understood, as most patients undergo surgical removal of the tumour after the initial diagnosis. Complications include stroke, sudden cardiac death, valvular complications, and infection.

Death is typically caused by coronary or systemic embolization, or by obstruction of blood flow at the mitral or tricuspid valve.

Approach to diagnosing myxoma

The approach to diagnosing myxoma includes the following investigations:

History: A positive family history may be present.

Physical examination: A characteristic diastolic 'tumour plop' may be audible.

Chest X-ray: This may reveal atrial calcification.

ECG: This will show left (or right) atrial enlargement.

Echocardiography: This will show a solitary, mostly atrial, tumour, which commonly has an irregular contour. Often a stalk is visible, arising from the interatrial septum.

MRI: Tissue characterization can help to differentiate myxomas from thrombus and lipomas.

Other diagnoses that should be considered aside from myxoma

Other diagnoses that should be considered aside from myxoma are other cardiac tumours, and thrombus. Associated valvular damage needs to be ruled out.

'Gold-standard' diagnostic test for myxoma

The gold-standard diagnostic test for myxoma is histopathology.

Acceptable diagnostic alternatives to the gold-standard test for myxoma

Acceptable diagnostic alternatives to the gold-standard test for myxoma are imaging with echocardiography, and tissue characterization with MRI.

Other relevant investigations for myxoma

Another relevant investigation for myxoma is the erythrocyte sedimentation rate, which may be elevated.

Prognosis of myxoma, and how to estimate it

Tools for the prediction of the risk of complications for myxoma are currently not available, but risk is likely to be related to tumour location, size, and shape. The major risks of left-sided myxomas are stroke and embolic events. Embolism occurs in about 30%–40% of patients, but this may be more common in polypoid than in round tumours (58% vs 0%).

Treatment of myxoma, and its effectiveness

Myxomas are usually removed surgically along with at least 5 mm of surrounding atrial septum. The septum is then repaired, using material from the pericardium. Conduction disorders and atrial arrhythmias may occur after the operation. Recurrences rate is about 5%, but can be about 30% in familial cases. Recurrence after 4 years is uncommon.

Pericardial malignancy

Definition of pericardial malignancy

Pericardial malignancy is defined as malignant involvement of the pericardium, as a primary tumour (less common) or as a secondary tumour which has spread from either a nearby or a distant focus of malignancy.

Aetiology of pericardial malignancy

Secondary tumours

Secondary tumours can involve the pericardium by contiguous extension from a mediastinal mass, nodular tumour deposits from haematogenous or lymphatic spread, or diffuse pericardial thickening from tumour infiltration (with or without effusion). Common causes include lung, breast, or oesophageal cancer, lymphoma, leukaemia, and Kaposi sarcoma. Melanomas have a very high propensity of metastasis to the myocardium (up to 65%).

Primary tumours (extremely rare)

In pericardial malignancy, the primary tumours, which are extremely rare, are mesotheliomas, teratomas, and paragangliomas.

Typical symptoms of pericardial malignancy, and less common symptoms

Pericardial malignancy may be asymptomatic and incidentally diagnosed, or present with shortness of breath, chest pain, reduced exercise tolerance, and/or oedema as the manifestation of pericarditis; pericardial effusion; cardiac tamponade; and/or pericardial constriction.

Demographics of pericardial malignancy

Malignant involvement of the pericardium is detected in 1%–20% of cases in autopsy studies, with similar rates in men and women. It can occur at any age.

Natural history, and complications of pericardial malignancy

The natural history of pericardial malignancy is usually determined by the underlying malignancy, but people with pericardial involvement have a more extensive disease and, hence, a worse prognosis, compared to those without pericardial involvement. Pericardial tamponade may add to the mortality unless promptly detected and appropriately treated.

Approach to diagnosing pericardial malignancy

The diagnostic approach for pericardial malignancy is the same as for the diagnosis of pericardial diseases and includes ECG, echocardiography and other imaging studies, and diagnostic pericardiocentesis with cytology testing. In addition, pericardial biopsy may be necessary. Pericardial effusion as the initial presenting sign of a previously undiagnosed cancer is uncommon. Screening for occult malignancy is recommended for patients who have persistent pericarditis that is unresponsive to anti-inflammatory therapy, and those who present with a new large pericardial effusion or cardiac tamponade.

Other diagnoses that should be considered aside from pericardial malignancy

In addition to pericardial malignancy, alternative causes of pericardial disease should be considered.

'Gold-standard' diagnostic test for pericardial malignancy

The gold-standard diagnostic tests for pericardial malignancy are cytology and histology.

Acceptable diagnostic alternatives to the gold-standard test for pericardial malignancy

For pericardial malignancy, an acceptable diagnostic alternative to cytology and histology is non-invasive imaging, which may guide diagnostic strategy.

Other relevant investigations for pericardial malignancy

Other relevant investigations for pericardial malignancy include CT thorax and PET scan.

Prognosis of pericardial malignancy, and how to estimate it

The life expectancy of patients with symptomatic malignant pericardial effusion is, on average, only 2–4 months. However, the prognosis may be better in certain subsets of patients, such as those with an absence of malignant cells in the pericardium, those with haematologic rather than solid tumours, and those whose primary malignancy is otherwise well controlled.

Treatment of pericardial malignancy, and its effectiveness

In pericardial malignancy, individualized treatment, requiring a detailed consideration of patient's condition and the prognosis of the underlying malignancy, is mandatory. Components of management may include:

- pericardiocentesis, for symptom relief
- prevention of effusion reaccumulation, via pericardial ballooning, pericardial sclerosis, or surgical window pericardiectomy
- pericardiectomy, for management of pericardial constriction
- treatment of the underlying malignancy

Myocardial malignancy

Definition of myocardial malignancy

Myocardial malignancy is defined as the malignant involvement of the myocardium as the result of a primary cardiac tumour (less common) or secondary to spread from a nearby or distant focus of malignancy. Secondary malignancies are not discussed further here (see 'Pericardial malignancy').

Aetiology of myocardial malignancy

Primary malignancies in myocardial malignancy (very rare) are mainly caused by sarcomas (angiosarcoma, rhabdomyosarcoma, leiomyosarcoma, and fibrosarcoma).

Typical symptoms of myocardial malignancy, and less common symptoms

In addition to pericardial involvement (see 'Pericardial malignancy'), the symptoms of myocardial malignancy are related to local obstruction, embolic complications, and rhythm abnormalities. About 75% of primary myocardial tumours have already metastasized at the time of initial diagnosis. Hence, symptoms related to distal metastases may lead to the initial diagnosis.

Demographics of myocardial malignancy

Cardiac sarcomas are extremely rare and, for most types, only isolated case reports have been described.

Natural history, and complications of myocardial malignancy

Sarcomas proliferate rapidly, and cause death through widespread infiltration of the myocardium, obstruction of blood flow through the heart, and/or distant metastases.

Approach to diagnosing myocardial malignancy

The diagnostic approach is based on echocardiography, MRI, and CT, with or without biopsy.

Other diagnoses that should be considered aside from myocardial malignancy

Other diagnoses that should be considered aside from myocardial malignancy are benign tumours, and thrombus

'Gold-standard' diagnostic test for myocardial malignancy

The gold-standard diagnostic test for myocardial malignancy is histopathology.

Acceptable diagnostic alternatives to the gold-standard test for myocardial malignancy

Non-invasive imaging tests are acceptable diagnostic alternatives to histopathology for diagnosing myocardial malignancy.

Other relevant investigations for myocardial malignancy

Other relevant investigations for myocardial malignancy are CT and PET scan.

Prognosis of myocardial malignancy, and how to estimate it

The prognosis of sarcomas is very poor and is not much affected by currently available treatment.

Treatment of myocardial malignancy, and its effectiveness

In the treatment of myocardial malignancy, surgery with or without chemotherapy is often attempted, but the mean survival of treated

patients only ranges from 6 to 12 months. Cardiac transplantation and autotransplantation (transplantation after tumour resection *ex vivo* and reconstruction of the heart) are alternative measures with little evidence for their efficacy.

Cancer treatment and the heart

Radiation therapy is a vital component of modern cancer management. During the course of their treatment, approximately two-thirds of cancer patients receive radiotherapy with either curative or palliative intent. However, radiotherapy may be associated with some unintended harms to the cardiovascular system. This section focuses on cardiac complications of radiotherapy. The effect of chemotherapy on the heart is discussed in Chapter 122.

A few decades ago, the cardiovascular system was considered to be relatively resistant to radiation-induced injury, and little consideration was given to avoidance of the heart during thoracic radiotherapy. During the 1960s, the first reports of patients treated with radiotherapy for Hodgkin's lymphoma, including doses of >30 Gy to the heart, established radiation-induced cardiovascular disease as a distinct entity. However, it was still thought that cardiovascular disease was not induced by cardiac radiation doses of <30 Gy. Over the last 10 years, new evidence from several independent sources has revealed that cardiovascular risks are also increased by much lower doses of radiation. Although modern radiotherapy techniques undoubtedly deliver lower doses to normal tissues, such as the heart, than in previous decades, some degree of cardiovascular radiation exposure remains inevitable.

The pathology of radiation-induced injury to the human cardiovascular system is non-specific to radiation. Irradiation of a substantial volume of the heart to a sufficiently high dose can damage virtually any component of the heart, including the pericardium, myocardium, heart valves, coronary arteries, capillaries, and conducting system. Therefore, radiotherapy can increase the risk of a variety of heart conditions, such as coronary artery disease, pericarditis, restrictive

or dilative cardiomyopathy, valvular conditions, and conduction disorders. In modern practice, the majority of these diseases are rarely seen in the first few years following exposure, and usually occur after a latency of many years. Subclinical effects may be detected earlier, but the proportion of cases which progress to clinical disease, and the rate of disease progression, are largely unknown. The incidence that may occur in the future as a result of modern radiation therapy is therefore difficult to predict, particularly as the doses and techniques of radiotherapy have altered substantially over the last half century, and due to a lack of validated dose-response relationships on which to base such predictions. Reduction of cardiac doses of radiotherapy to a minimum is therefore recommended by many experts. Whether treatment with established therapies such as blood pressure lowering or LDL lowering can reduce the risk of radiation-induced heart disease is unknown.

108 Cardiac infection

Cheerag Shirodaria and Jim Newton

Endocarditis

Definition of the disease

Endocarditis is inflammation of the endocardium, and is typically infection of valve tissue, most commonly the aortic or mitral valves. Infective endocarditis (IE) is caused by bacterial infection but there are other rare varieties such as fungal and non-IE (in connective tissue disease and malignancy).

Typical symptoms of endocarditis, and less common symptoms

A classical patient with endocarditis will present with chronic fever, malaise, anorexia, and symptoms of heart failure due to progressive valve destruction and regurgitation, often with chronic vasculitic phenomena due to peripheral emboli and immune activation. Alternatively, patients can present with a very brief history of fever and rapid onset of fulminant heart failure due to acute aortic or mitral regurgitation, usually due to staphylococcal infection.

While fever is almost universal in endocarditis, the associated symptoms are varied, and patients can present in numerous ways to a wide range of specialities, such as:

- Neurology (for stroke due to embolic infarction, or intracranial haemorrhage)
- Orthopaedics (for back pain due to discitis)
- Haematology (for chronic anaemia, splenomegaly, lymphadenopathy)
- Nephrology (for renal dysfunction, glomerulonephritis)
- Rheumatology (for vasculitis, arthropathy)
- Elderly care (for confusion, weight loss)
- Ophthalmology (for visual field loss, retinitis, ophthalmitis)

Demographics and aetiology of endocarditis

IE is more common in men, and over half of all cases occur in patients over the age of 60. Most patients who develop IE have underlying acquired or congenital structural heart disease, although endocarditis can occur in completely normal hearts. Risk factors for IE include prosthetic valves, prior endocarditis, renal failure, intravenous catheter, or drug use.

In any patient with a prosthetic heart valve, there is an annual 1% risk of developing endocarditis, the risk being higher in the first year post surgery. High-risk congenital lesions include ventricular septal defects and aortic stenosis, with pulmonary stenosis being at low risk. Rheumatic heart disease has largely been eradicated from the developed world, but should always be considered, particularly in patients from areas where the disease remains endemic. Tricuspid or pulmonary valve endocarditis is usually related to intravenous drug use or the presence of a permanent pacemaker. Patients with chronic renal disease have an increased risk for developing endocarditis due to a higher incidence of calcific valvular heart disease, long-term venous access catheters and, in the case of transplant recipients, long-term immunosuppression.

In the developed world, staphylococcal endocarditis is more common than streptococcal disease, particularly in patients undergoing haemodialysis or with long-term venous catheters. Table 108.1 outlines the microbiological diagnosis of endocarditis.

Cases of endocarditis should be described according to the underlying aetiology, culture results, and treatment status:

- native valve or prosthetic valve
- left-sided or right-sided valve involvement
- device-related infection (e.g. pacemaker)
- community acquired or nosocomial

- active or treated
- relapse or reinfection
- culture positive or negative

Describing a case as 'culture-negative prosthetic aortic valve endocarditis' conveys important information and assists in multidisciplinary management.

Natural history of endocarditis

IE is often described as a subacute illness with a chronic presentation due to streptococcal infection; often, an acute presentation in an elderly patient with staphylococcal infection of a prosthetic valve or degenerative valve lesion is more common.

Presentation is vague with fever and weight loss, and endocarditis is often initially misdiagnosed as a viral illness. With a careful history and clinical examination, paying particular attention to the cardiovascular examination and the ECG, the diagnosis can be made earlier.

Complications of endocarditis

Three-quarters of patients with endocarditis will develop at least one complication during the course of the disease. The most common are heart failure, embolism, infection, renal complications, and iatrogenic complications.

Heart failure

One-third of patients develop heart failure, usually due to leaflet destruction and perforation leading to severe regurgitation. Rarely, physical obstruction of the valve orifice by a large vegetation can occur. Left ventricular damage following coronary obstruction by a large vegetation or a more diffuse septic myocarditis can further contribute to haemodynamic decline.

Embolism

Emboli are common and can be widespread, leading to a wide variety of clinical syndromes, including stroke, myocardial infarction, abscess formation, spinal cord involvement, and solid organ infarction. Right-sided endocarditis is associated with pulmonary embolism and, rarely, with systemic embolism in the presence of a right-left communication (e.g. patent foramen ovale).

Infection

Fever usually settles within a week of starting antibiotics. Persisting fever may suggest a resistant organism or an uncontrolled local infection (e.g. abscess formation), or may be a side effect of the antibiotics themselves. A thorough search for other sources of infection (e.g. infected venous catheters) should be carried out, and further blood cultures obtained. Uncontrolled local infection is most common with aortic valve involvement, and in prosthetic valve endocarditis (>50%). Rarely, mycotic aneurysms may form within the vascular tree and should be suspected in patients with any focal neurological deficit.

Renal complications

Acute renal failure is common and may be caused by acute glomerulonephritis due to immune complex deposition, renal infarction secondary to septic emboli, or the nephrotoxic effect of antibiotics such as aminoglycosides or high-dose penicillin.

Iatrogenic complications

The duration of antimicrobial therapy puts the patient at risk of a number of complications: antibiotic toxicity (e.g. ototoxicity with

Table 108.1 Microbiological diagnosis of endocarditis

Organism	Estimated incidence	Relevant clinical history	Blood cultures	Serology
<i>Staphylococcus aureus</i>	30% of community-acquired 46% of hospital-acquired	IVDU/IV access devices	Usually positive	Under development (lipid S)
Coagulase-negative staphylococci	5% of native valve endocarditis	Vasectomy/angiography/haemodialysis IVDU	Usually positive	In progress
<i>Viridans streptococci</i>	Up to 58%	Dental abscess/poor oral hygiene	Positive, if no previous antibiotics	In progress
<i>Streptococcus bovis</i>	Up to 12%	Gastrointestinal malignancy/presumed normal heart valves/older patient population	Positive, if no previous antibiotics	None
HACEK	3%	Dental treatment/URTI/IVDU	Most positive in 6 days with high CO ₂ concentrations	None
Fungal	Up to 10%	Prosthetic valves/IVDU/immunosuppression/long-term IV lines. Should be performed if multiple risk factors for fungal endocarditis	Filamentous fungi rarely positive, candida commonly positive	Fungal serology not validated for endocarditis
<i>Enterococcus</i> spp.	Up to 10%	Urinary catheter insertion/gastrointestinal malignancy	Positive, if no previous antibiotics	In progress
<i>Brucella</i> spp.	1–4%	Endemic area/contaminated milk consumption	Positive in 80%. May need prolonged incubation	Reference assay = tube agglutination
<i>Coxiella burnetii</i> (Q fever)	3–5%	Farming background/exposure to domestic ruminants/raw milk consumption/previous valvulopathy/endemic area	Rarely positive. gentamicin), infection of central venous catheters, and interactions with any oral anticoagulant drug therapy.

Approach to diagnosing endocarditis

Endocarditis is challenging to diagnose and easy to miss. It should be considered in any patient with a fever and no other obvious cause, and blood cultures (taken carefully to avoid contamination) are absolutely key to achieving a diagnosis. Even in acutely ill patients with sepsis and haemodynamic upset, it should be possible to take at least one peripheral blood culture before antibiotic therapy is administered.

One practical strategy is to define the likelihood of endocarditis by utilizing the Duke criteria. IE is probable if there are two major criteria present, or one major plus three minor criteria, or five minor criteria.

The major criteria are:

- positive blood culture with an organism typical for endocarditis
- echocardiographic abnormalities consistent with endocarditis

The minor criteria are:

- predisposing heart condition, or intravenous drug use
- temperature >38.0°C (100.4°F)
- vasculitic injury, such as arterial emboli, mycotic aneurysms
- conjunctival haemorrhage
- atypical positive blood cultures or positive antigens to organisms causing endocarditis
- abnormal echocardiographic findings but no definite endocardial involvement

Other diagnoses that should be considered aside from endocarditis

The list of potential differential diagnoses is large and, given the common finding of a murmur in elderly patients, many patients present with murmur and fever but do not have IE. It is important, however, to always consider the possibility and ensure blood cultures are taken. If fever persists despite antibiotic treatment, consider other sources of infection, either as an alternative diagnosis, or reflecting malignant spread from a cardiac lesion.

'Gold-standard' diagnostic test for endocarditis

The gold-standard diagnostic test for endocarditis is demonstration of vegetations or microorganisms histologically, but this is only practical if the patient is undergoing surgery.

Acceptable diagnostic alternatives to the gold-standard test for endocarditis

In clinical practice, the gold standard is a combination of positive blood cultures and echocardiographic evidence of vegetations. Transoesophageal echocardiography (TOE) is the preferred investigation, as it will identify vegetations in the majority of positive cases, or evidence of valve involvement. Given the invasive nature of TOE, transthoracic echocardiography (TTE) is usually performed first. TTE has reasonable sensitivity for IE, but it can underestimate the size of vegetations, or miss small vegetations (<3 mm). A normal TTE with no vegetations or valve regurgitation makes endocarditis unlikely, but

frequently a TOE is required to fully exclude the diagnosis if there is high clinical suspicion.

Echocardiographic abnormalities typical for endocarditis include:

- vegetations: an oscillating intra-cardiac mass on valvular apparatus, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation
- abscess cavity or fistula formation
- new partial dehiscence of prosthetic valve
- new valvular regurgitation

All patients with suspected prosthetic valve endocarditis should undergo TOE examination, as the sensitivity of TTE is poor. A negative TOE is reassuring (sensitivity >90%) but a low threshold should be applied to rescanning if the clinical situation changes. For right-sided endocarditis (e.g. pacemaker, intravenous drug use), TTE and TOE are of comparable sensitivity and specificity, but both may be required for a full assessment.

Routine serial echocardiography is not recommended but, if there is treatment failure or there are new clinical findings, then repeat imaging is warranted. An increase in vegetation size, or development of an abscess, suggests failure of antimicrobial therapy and warrants consideration of surgical intervention.

Other relevant investigations for endocarditis

Three blood cultures from different sites should be taken, ideally 30 minutes apart, with further samples on subsequent days until a microbe is identified. Draw at least 5 ml for each blood culture bottle with a scrupulous sterile technique as this increases the likelihood of identifying a pathological microbe. Blood cultures can be taken at any time; taking them during a fever does not increase their sensitivity, as the bacteraemia in IE is continuous. Seek assistance from the local microbiologist for further advice on other specialist tests that may be appropriate.

Routine haematology and biochemistry may reveal elevated inflammatory markers (C-reactive protein, erythrocyte sedimentation rate, or white-cell count) and a normocytic anaemia. Baseline assessment of renal and liver function should be performed, to screen for complications of IE and for monitoring during antibiotic therapy.

Patients should have regular ECGs to monitor rhythm and any evidence of atrioventricular block (especially in aortic valve endocarditis), as this may indicate abscess formation and should prompt repeat echocardiography.

Prognosis of endocarditis, and how to estimate it

Estimating the prognosis of endocarditis is difficult, as patients with endocarditis make up a heterogeneous group and often have other comorbidities. Broadly speaking, in-hospital mortality with IE is around 15%–20%, with 1-year mortality approaching 40%.

Predictors of higher mortality include increasing age, staphylococcal infection, prosthetic valve endocarditis, and the presence of heart failure. Staphylococcal and fungal infections are also associated with an increased embolic risk. Early surgical intervention is associated with lower mortality.

Treatment of endocarditis, and its effectiveness

Multidisciplinary management, with a team including a cardiologist, a cardiac surgeon, and a microbiologist, is the key to effective management of endocarditis (see Box 108.1).

Antibiotic therapy in endocarditis

Empirical antibiotic therapy (see Table 108.2) should be started early, after blood cultures have been taken. The choice of antibiotic depends on local policy, recent antibiotic exposure, and whether it is native endocarditis or prosthetic valve endocarditis. Once a microbe has been identified, narrow-spectrum antibiotics can be selected and these should continue for at least 6 weeks in prosthetic valve endocarditis, and for between 2 and 6 weeks in native valve endocarditis. Outpatient (or home) antibiotic therapy can be considered in stable patients after the first 2 weeks, if local facilities exist.

Box 108.1 Characteristics of the 'Endocarditis Team'

When to refer a patient with IE to an 'Endocarditis Team' in a reference centre

1. Patients with complicated IE (i.e. endocarditis with HF, abscess, or embolic or neurological complication or CHD), should be referred early and managed in a reference centre with immediate surgical facilities.
2. Patients with non-complicated IE can be initially managed in a non-reference centre, but with regular communication with the reference centre, consultations with the multidisciplinary 'Endocarditis Team', and, when needed, with external visit to the reference centre.

Characteristics of the reference centre

1. Immediate access to diagnostic procedures should be possible, including TTE, TOE, multislice CT, MRI, and nuclear imaging.
2. Immediate access to cardiac surgery should be possible during the early stage of the disease, particularly in case of complicated IE (HF, abscess, large vegetation, neurological, and embolic complications).
3. Several specialists should be present on site (the 'Endocarditis Team'), including at least cardiac surgeons, cardiologists, anaesthesiologists, ID specialists, microbiologists and, when available, specialists in valve diseases, CHD, pacemaker extraction, echocardiography and other cardiac imaging techniques, neurologists, and facilities for neurosurgery and interventional neuroradiology.

Role of the 'Endocarditis Team'

1. The 'Endocarditis Team' should have meetings on a regular basis in order to discuss cases, take surgical decisions, and define the type of follow-up.
2. The 'Endocarditis Team' chooses the type, duration, and mode of follow up of antibiotic therapy, according to a standardized protocol, following the current guidelines.
3. The 'Endocarditis Team' should participate in national or international registries, publicly report the mortality and morbidity of their centre, and be involved in a quality improvement programme, as well as in a patient education programme.
4. The follow-up should be organized on an outpatient visit basis at a frequency depending on the patient's clinical status (ideally at 1, 3, 6, and 12 months after hospital discharge, since the majority of events occur during this period).

Abbreviations: CHD, coronary heart disease; CT, computed tomography; HF, heart failure; ID, infectious disease; IE, infective endocarditis; MRI, magnetic resonance imaging; TOE, transthoracic echocardiography; TTE, transthoracic echocardiography.

Reproduced with permission from Gilbert Habib, Patrizio Lancellotti, Manuel J. Antunes. Et al., 2015 ESC Guidelines for the management of infective endocarditis, *European Heart Journal*, Volume 36, Issue 44, pp.3075-3123, Copyright © 2015 Oxford University Press

Surgery in endocarditis

The timing of surgery in endocarditis can be difficult; the patients who are the most unwell, and are therefore at highest risk for surgery, may be the most likely to benefit. There are three principal indications for surgery in IE: heart failure, uncontrolled infection, and prevention of embolism.

Heart failure

Heart failure is the most common reason for surgical intervention in IE, whether it is due to acute valve incompetence, fistulae, or valve obstruction by vegetation. Intractable pulmonary oedema or cardiogenic shock is an indication for emergency surgery. If heart failure is less severe, a period of stabilization and intravenous antibiotics prior to surgery may be possible.

Uncontrolled infection

The indications for surgery in endocarditis with uncontrolled infection are as follows:

Ongoing systemic sepsis: If fever persists for more than 7 days despite appropriate antibiotic therapy, urgent surgery is indicated once

Table 108.2 Proposed antibiotic regimens for initial empirical treatment of infective endocarditis in acute severely ill patients (before pathogen identification)^a

Antibiotic	Dosage and route	Class ^b	Level ^c	Comments
Community-acquired native valves or late prosthetic valves (≥12 months post surgery) endocarditis				
Ampicillin with (Flu)cloxacillin or oxacillin	12 g/day IV in 4–6 doses	IIa	C	Patients with BCNIE should be treated in consultation with an ID specialist.
Gentamicin	12 g/day IV in 4–6 doses			
Gentamicin	3 mg/kg/day IV or IM in 1 dose			
Vancomycin with Gentamicin	30–60 mg/kg/day IV in 2–3 doses	IIb	C	For penicillin-allergic patients
Gentamicin	3 mg/kg/day IV or IM in 1 dose			
Early PVE (<12 months post surgery) or nosocomial and non-nosocomial healthcare associated endocarditis				
Vancomycin with Gentamicin	30 mg/kg/day IV in 2 doses	IIb	C	Rifampicinis only recommended for PVE and it should be started 3–5 days later than vancomycin and gentamicin has been suggested by some experts. In healthcare associated native valve endocarditis, some experts recommend in settings with a prevalence of MRSA infections >5% the combination of cloxacillin plus vancomycin until they have the final <i>S. aureus</i> identification
Gentamicin with Rifampicin	3 mg/kg/day IV or IM in 1 dose			
Rifampicin	900–1200 mg IV or orally in 2 or 3 divided doses			

Abbreviations: BCNIE, blood culture-negative infective endocarditis; ID, infectious disease; IM, intramuscular; IV, intravenous; PVE, prosthetic valve endocarditis.

^aIf initial blood cultures are negative and there is no clinical response, consider BCNIE aetiology and maybe surgery for molecular diagnosis and treatment, and extension of the antibiotic spectrum to blood culture-negative pathogens (doxycycline, quinolones) must be considered.

^bClass of recommendation.

^cLevel of evidence.

Reproduced with permission from Gilbert Habib, Patrizio Lancellotti, Manuel J. Antunes. Et al., 2015 ESC Guidelines for the management of infective endocarditis, *European Heart Journal*, Volume 36, Issue 44, pp.3075–3123, Copyright © 2015 Oxford University Press

other potential sources of infection have been excluded (e.g. cerebral/renal/spinal abscess).

Uncontrolled local infection: An increase in the size of vegetations, or local abscess/fistula formation, is an indication for urgent surgery.

Resistant organisms: If the infection is likely to be difficult to treat (e.g. a fungal infection; infection from MRSA or Gram-negative organisms), early surgical intervention should be considered.

Prevention of embolism

The risk of embolism during endocarditis is highest earlier in the disease and during the first two weeks of antibiotic therapy. Large vegetations (>10 mm) are associated with a higher risk of embolism and early surgery may be appropriate.

Prevention of endocarditis

Antibiotic prophylaxis for patients at risk of IE, such as those with structural heart disease or prosthetic valves or grafts, has been a controversial area over the last few years. European and North American guidelines broadly agree that high-risk patients (e.g. patients with prosthetic heart valves or previous endocarditis) should have antibiotic prophylaxis for invasive respiratory, gastrointestinal, dental, and genitourinary procedures. However, current UK NICE guidelines do not recommend antibiotic prophylaxis at all, except in gastrointestinal or genitourinary procedures where there is suspected infection. An increasing number of patients with endocarditis have no previous cardiac disease, so identifying those at risk, and targeting antibiotic prophylaxis, can be very challenging. Emphasis on meticulous oral hygiene and regular dental review is important to reduce the incidence of endocarditis.

Acute rheumatic fever

Definition of acute rheumatic fever

Acute rheumatic fever is a disease that follows Group A streptococcal infection (usually presenting as pharyngitis) and develops into a syndrome affecting the joints, heart, skin, and brain.

Aetiology of acute rheumatic fever

The clinical manifestations of acute rheumatic fever are thought to be due to a phenomenon known as molecular mimicry. Following a streptococcal infection, antibodies generated against Group

A streptococcus cross-react with the myosin and membrane proteins in cardiac tissue, causing inflammation which can lead to pancarditis. A similar process is seen in joints, skin, and the brain.

Typical symptoms of acute rheumatic fever, and less common symptoms

For lists of the typical and the less common symptoms of acute rheumatic fever, see 'Approach to diagnosing rheumatic fever'.

Demographics of acute rheumatic fever

Although Group A streptococcal infection is common, acute rheumatic fever is rare in the developed world, partly due to improved living conditions and partly to the routine treatment of pharyngitis with antibiotics. Infection with Group A streptococcus remains a considerable problem in the developing world, resulting in half a million deaths from the infection itself and its sequelae (rheumatic heart disease, glomerulonephritis).

Natural history, and complications of acute rheumatic fever

Acute rheumatic fever presents with fever, myalgia, and arthralgia, which is usually preceded by streptococcal pharyngitis occurring approximately 2 weeks before any other symptoms.

Most patients will develop a carditis, which is often subclinical. Carditis is inflammation affecting all layers of the heart; the most common findings are pericarditis (causing chest pain and a pericardial rub), systolic dysfunction (caused by myocarditis), and mitral or aortic regurgitation. A large-joint polyarthritis is another common finding. Other, rare, findings are subcutaneous nodules (firm, painless nodules, <2 cm in diameter, found over tendons), and erythema marginatum.

Sydenham's chorea is a late neurological manifestation which is seen in around a third of cases. It occurs around 3 months after initial infection, and is a movement disorder characterized by rapid, jerking movements of the limbs and face, associated with emotional instability.

A third of patients will develop chronic rheumatic heart disease. The mitral valve is most commonly affected; initial inflammation becomes a fibrotic process, resulting in the gradual fusion of the mitral valve commissures and shortening of the chordae tendineae. This leads to mitral stenosis.

Approach to diagnosing acute rheumatic fever

Rheumatic fever is defined by the Jones criteria: a diagnosis is made when a patient has evidence of preceding Group A streptococcal infection, as well as two major, or one major and two minor, criteria:

The major criteria are:

- carditis
- migratory polyarthritides
- subcutaneous nodules
- erythema marginatum
- Sydenham's chorea

The minor criteria are:

- fever
- arthralgia
- elevated inflammatory markers (e.g. erythrocyte sedimentation rate (ESR), or C-reactive protein (CRP))
- leucocytosis
- evidence of heart block on ECG
- evidence of streptococcal infection (e.g. a positive anti-streptolysin O test)
- previous episode of rheumatic fever

Other diagnoses that should be considered aside from acute rheumatic fever

A post-streptococcal reactive arthritis (Reiter's syndrome) is the other main differential diagnosis for acute rheumatic fever, the main difference between the two diagnoses being that the former does not result in a carditis.

'Gold-standard' diagnostic test for acute rheumatic fever

There is no single diagnostic test for acute rheumatic fever, but evidence of Group A streptococcal infection can help to secure a diagnosis. Throat-swab culture may identify the pathogen but, as patients with acute rheumatic fever may present weeks after any pharyngitis has resolved, the culture may be negative. A test for antibodies to Group A streptococcus (e.g. anti-streptolysin O) is more reliable.

Acceptable diagnostic alternatives to the gold-standard test for acute rheumatic fever

Not all patients with acute rheumatic fever will demonstrate an elevated anti-streptolysin O level and, in patients where the clinical suspicion of acute rheumatic fever is high, testing for other streptococcal antibodies (such as anti-DNAse B) should be performed.

Other relevant investigations for acute rheumatic fever

Initial blood tests will demonstrate a leucocytosis with elevated CRP and ESR. The chest X-ray may be normal but, in fulminant disease, it may show cardiomegaly and evidence of pulmonary oedema. ECG may demonstrate A–V block or features consistent with pericarditis. Echocardiography will show evidence of systolic dysfunction and/or valve abnormalities (regurgitation in the acute phase, stenosis, or regurgitation chronically).

Treatment for acute rheumatic fever, and its effectiveness

The risk of developing acute rheumatic fever can be reduced by the prompt antibiotic treatment of Group A streptococcal pharyngitis. The treatment of acute rheumatic fever includes antibiotic therapy to eliminate Group A streptococcal carriage, high-dose aspirin for symptomatic management of arthritis, and, if heart failure is present, conventional medical heart failure therapy.

Patients who develop chronic rheumatic heart disease affecting the mitral valve are at high risk of developing atrial fibrillation and subsequent systemic thromboembolism and should therefore be followed up regularly.

109 Pericardial disease

David Adlam

Definition of the disease

The pericardium forms a continuous sac around the heart, analogous to the pleura surrounding the lungs, and the peritoneum surrounding the abdominal viscera. Between the parietal and visceral layers of the serous pericardium is the pericardial space, which normally contains a small volume of pericardial fluid.

The clinical spectrum of pericardial diseases can be divided into:

- pericarditis, caused by acute inflammation
- pericardial effusion, or fluid accumulation in the pericardial space, which may lead to cardiac tamponade
- constrictive pericarditis, caused by chronic infiltration or inflammation leading to pericardial constriction

Aetiology of the disease

Pericardial inflammation has multiple causes. It can be caused by:

- infection (viral, bacterial, mycobacterial, or, rarely, fungal)
- inflammatory disease (connective tissue disorders, vasculitis)
- metabolic causes (uraemia, hypothyroidism)
- neoplasia (usually infiltrative)
- injury (due to trauma, cardiomyotomy, myocardial infarction, or acute dissection)
- other causes, including unknown causes (in the case of idiopathic pericardial inflammation), rare genetic syndromes, and, more commonly, drugs such as minocycline, which have side effects which can lead to serositis

An autoimmune process may be central to the pathophysiology of 'idiopathic' and, indeed, several other types of pericarditis (including post cardiomyotomy pericarditis, rheumatic pericarditis, and Dressler's syndrome). The nature of the ensuing clinical presentation depends on the cause and duration of the inflammatory process.

Typical symptoms of the disease, and less common symptoms

Symptoms of acute pericarditis

Acute pericarditis is common, accounting for 5%–10% of emergency admissions with chest pain syndromes. The predominant aetiology is viral or idiopathic. Presentation varies, but classically the pain is worse on inspiration and lying flat and is eased by sitting forwards. There may be associated coryzal symptoms and myalgia.

Symptoms of pericardial effusion

Pericardial effusions are often asymptomatic until the rate of fluid accumulation in the pericardial space exceeds the rate at which the pericardium can dilate and remodel. When this occurs, the pressure in the pericardial space rises. When pericardial pressure exceeds that within the cardiac chambers in diastole, cardiac chambers collapse, atrial and ventricular filling are impaired, and pericardial tamponade ensues. Presentation acutely is usually with dyspnoea and/or haemodynamic collapse. When fluid accumulates more gradually, a less acute presentation may occur with worsening effort dyspnoea and signs of right-sided heart failure.

Symptoms of constrictive pericarditis

Chronic constrictive pericarditis often presents insidiously with dyspnoea, oedema, abdominal distension, and ascites, or, rarely, a protein-losing enteropathy.

Natural history, and complications of the disease

Natural history, and complications, of acute pericarditis

Acute pericarditis is usually self-limiting. Reported recurrence rates depend on the population studied and disease definition. In the COPE study (Imazio et al., 2005), reported recurrence of symptoms was 22.5%. Serious sequelae such as multiple severe clinical relapses, pericardial tamponade, or constrictive pericarditis are rare.

Natural history, and complications, of pericardial effusion

Pericardial effusions causing tamponade are a medical emergency, requiring immediate drainage. Those not causing tamponade require careful serial imaging to exclude progression and risk of tamponade.

Natural history, and complications, of constrictive pericarditis

Constrictive pericarditis is progressive if untreated. Pericardectomy is the definitive treatment and, if successful, is associated with good long-term survival.

Approach to diagnosing the disease

Approach to diagnosing acute pericarditis

Acute pericarditis is a clinical diagnosis. Typical symptoms may be accompanied by fever, tachycardia, and, occasionally, a pericardial friction rub.

Approach to diagnosing pericardial effusion

Pericardial effusions causing tamponade may be suspected from the clinical findings. These are classically hypotension, a raised jugular venous pressure (JVP), and quiet heart sounds. The most sensitive reported clinical signs are raised JVP (76%), pulsus paradoxus (82%), tachycardia (77%), and tachypnoea (80%). Pulsus paradoxus, a condition in which the systolic blood pressure falls more than 10 mm Hg during inspiration, is reportedly the most specific clinical sign (80%).

Approach to diagnosing constrictive pericarditis

Constrictive pericarditis causes clinical findings of right-sided heart failure. There is a high venous pressure with rapid x and y descent (Kussmaul's sign of a rise in venous pressure with inspiration may be present), relative hypotension, pleural effusions, peripheral oedema, hepatic congestion, and even ascites. A pericardial knock in early diastole, reflecting abrupt cessation of ventricular filling, is a characteristic but rare finding.

Other diagnoses that should be considered

Other diagnoses that should be considered aside from acute pericarditis

Acute pericarditis has a broad differential diagnosis covering the causes of acute chest pain syndromes. Most importantly, acute coronary syndromes and acute pulmonary embolus must be excluded.

Other diagnoses that should be considered aside from pericardial effusion

Pericardial effusion should be considered in all new presentations of symptoms and signs of right-sided heart failure, especially where there is a history of malignancy. Echocardiographic diagnosis is usually straightforward, once the investigation has been requested.

Other diagnoses that should be considered aside from constrictive pericarditis

Constrictive pericarditis is usually a gradual process and frequently presents insidiously. The diagnosis should particularly be considered in patients presenting with features of right-sided heart failure or ascites, especially where there is a past history of cardiac surgery, tuberculosis, or pericardial effusion requiring drainage.

'Gold-standard' diagnostic test

'Gold-standard' diagnostic test for acute pericarditis

Acute pericarditis is a clinical diagnosis usually made via a combination of typical symptoms, ECG findings, and the exclusion of alternative differential diagnoses.

'Gold-standard' diagnostic test for pericardial effusion

Pericardial effusion and tamponade are usually diagnosed echocardiographically. Pericardial fluid is demonstrated as an echolucent pool (although an acute haemopericardium may be less lucent) surrounding the heart and must be carefully distinguished from a pleural effusion. The principle echocardiographic features of tamponade are chamber collapse (because of their differential diastolic pressures, in a global effusion, the right atrium and then the right ventricle collapse first, with the left ventricle most rarely affected).

'Gold-standard' diagnostic test for constrictive pericarditis

Constrictive pericarditis requires careful echocardiographic assessment, and often cardiac catheterization is needed for definitive diagnosis. Echocardiographic features are of biatrial dilation with normal systolic function. There may be a paradoxical septal movement or a wobble, and the inferior vena cava is dilated without dynamic change in dimensions with respiration. Doppler velocities across the mitral or the tricuspid valve show increased respiratory variation (>25%) with rapid deceleration of the E wave and an absent A wave. At cardiac catheterization, elevation and equalization of chamber end-diastolic pressures are seen, with typical 'dip-and-plateau' patterns.

Other relevant investigations

Other relevant investigations for acute pericarditis

Acute pericarditis is classically associated with ECG findings of wide-spread scalloped ST-segment elevation with PR depression, although less typical ST and T wave changes may occur. Inflammatory markers and the white-cell count are often elevated. A small increase in troponin is common, with larger elevations occurring when the inflammatory process extends into the myocardium (myopericarditis). There are currently no published data on the relative sensitivity and specificity of particular clinical or laboratory findings.

Other relevant investigations for pericardial effusion

Pericardial effusions may show small complexes on the ECG or rarely electrical alternans where QRS voltage varies on a beat-to-beat basis,

although neither finding has sufficient sensitivity and specificity to aid diagnosis. A globular appearance of the heart on chest X-ray carries a reported 89% sensitivity. Assessment of a fluid sample may provide useful diagnostic material to identify the cause of the effusion (for example in malignancy or tuberculous effusions).

Other relevant investigations for pericardial effusion

Constrictive pericarditis may have abnormal chest X-ray and CT imaging, with thickening and/or calcification of the pericardium.

Treatment and its effectiveness

Specific treatments of pericardial inflammation and its sequelae depend on the underlying cause.

Treatment of acute pericarditis

Acute pericarditis can usually be safely treated in an outpatient setting, providing there is no significant pericardial effusion at presentation. Treatment is with NSAIDs such as ibuprofen (300–800 mg, 6–8 hourly) or aspirin (600–650mg, 6 hourly). There are no randomized data demonstrating either the effect or the optimal duration of therapy with NSAIDs. Treatment is usually continued until resolution of symptoms and markers of inflammation. The COPE study (Imazio et al., 2005) demonstrated that the addition of colchicines to NSAIDs leads to more rapid symptom resolution and reduced symptom recurrence. COPE also showed increased recurrence in patients treated with steroids, although this was from a secondary multivariate analysis. Steroids are therefore usually reserved for patients with autoimmune or connective tissue disorders and pericarditis. The data on steroids in tuberculous pericarditis have not demonstrated clear benefit.

Treatment of pericardial effusion

Pericardial effusions causing tamponade require immediate drainage. This is usually performed percutaneously via an apical or sub-costal route. Complications are rare (4.7% in a large series), but recurrence is common (up to 27% reported), so follow-up with serial echocardiography is recommended. Outcome relates to the underlying condition, with malignant effusions having a universally poor survival (reported median, 134 days). Recurrent effusions may require a surgical pericardial window or balloon fenestration.

Treatment of constrictive pericarditis

Constrictive pericarditis requires operative pericardectomy. Operative mortality is reported at 6%–12% but, if successful, a good long-term outcome can be expected.

110 Extrasystoles

Moutaz El-Kadri and George Hart

Definition

An extrasystole is a cardiac electrical impulse (often premature) that is not part of the normal heart rhythm. Extrasystoles most frequently arise from the ventricles and are then called ventricular extrasystoles, or premature ventricular complexes. Less often they originate from the atria, the atrioventricular junction, or rarely from the sinus node—these are termed supraventricular extrasystoles. The term 'bigeminy' refers to an extrasystole every second beat, and 'trigeminy', every third beat. Two successive extrasystoles are called a 'couplet'; three are called a 'triplet'. Extrasystoles with varying morphology are described as 'polymorphic' or 'multifocal', whereas those maintaining the same morphology are termed 'unifocal'.

Aetiology and demographics

Extrasystoles are common in all age groups, including in people with normal hearts, but may also be a marker of cardiac disease. The quoted prevalence of extrasystoles varies greatly, being sometimes as high as 80%, depending on study design. In general, the frequency of ectopy increases with age and is commoner in males. Many factors can provoke extrasystoles, such as:

- cardiovascular factors:
 - acute ischaemia
 - heart failure
 - hypertension (particularly with left ventricular hypertrophy)
 - cardiomyopathies (dilated, hypertrophic, or arrhythmogenic right ventricular)
 - myocarditis
 - cardiac contusion
 - congenital heart disease
 - cardiac channelopathies
 - mitral valve prolapse
- respiratory factors:
 - hypoxia
 - hypercapnoea
 - COPD (mainly supraventricular extrasystoles)
- drugs:
 - digoxin
 - aminophylline
 - β -2 agonists
 - alcohol
 - caffeine
 - tobacco
 - cocaine
- biochemical factors:
 - hypokalaemia
 - hypomagnesaemia
 - hypercalcaemia
- other factors:
 - anxiety
 - exhaustion
 - sleep deprivation

Three mechanisms underlie extrasystoles. Re-entry is responsible for ectopy in many patients with structural heart disease, such as post-infarction scarring; enhanced automaticity is probably the underlying mechanism in acute ischaemia and electrolyte imbalance; and triggered activity is prominent in drug toxicity (digitalis), ischaemia (reperfusion arrhythmias), and right ventricular outflow tract (RVOT) ectopy.

Typical symptoms of the disease

Most extrasystoles are asymptomatic, and are found incidentally during ECG monitoring. When symptomatic, they typically produce palpitations, often characterized as extra or skipped beats (due to the compensatory pause which occurs after an ectopic beat). Less commonly, patients can experience light-headedness, presyncope, and chest or neck discomfort. When associated with severe left ventricular dysfunction or profound sinus bradycardia, frequent extrasystoles can give rise to symptoms of fatigue or hypotension.

Natural history of the disease

Extrasystoles generally become more prevalent with advancing age. In most cases, they produce few or no symptoms and, in these settings, reassurance is probably the best treatment. There is no evidence that suppressing ectopic beats can reduce the risk of more serious arrhythmias or improve overall prognosis, even in patients with heart disease. The Cardiac Arrhythmia Suppression Trial showed that treatment with Class Ic antiarrhythmic agents to suppress ventricular extrasystoles in patients who had sustained myocardial infarction actually increased overall mortality (Echt et al., 1991).

Symptoms may develop if extrasystoles become frequent, sometimes due to provoking factors such as stress, drugs, or electrolyte imbalance. In these circumstances, treatment of the offending cause may be all that is needed to achieve a substantial improvement in symptoms.

Complications

Sustained ventricular arrhythmias such as ventricular tachycardia or ventricular fibrillation can sometimes be triggered by ventricular extrasystoles. This is more likely to occur in the presence of underlying heart disease (e.g. acute myocardial infarction), particularly if ventricular extrasystoles are frequent (e.g. >10/hour) or complex (e.g. polymorphic). Similarly, supraventricular extrasystoles can sometimes precipitate supraventricular (e.g. atrial fibrillation) and, rarely, ventricular tachyarrhythmias.

Patients with ventricular extrasystoles may have an increased risk of sudden cardiac death (SCD), depending on the nature and severity of their intrinsic heart disease.

There is evidence to suggest that reversible left ventricular dysfunction may develop in patients with very frequent ventricular extrasystoles (e.g. >10 000 per 24 hours). The mechanism is not fully understood, but may be due to dyssynchronous contraction of the ventricles. Left ventricular function may be improved in such cases by pharmacological suppression or catheter ablation.

Frequent extrasystoles can sometimes provoke considerable anxiety.

Approach to diagnosing the disease

Diagnosis is normally based on history, examination, and ECG. The history should document the description of the palpitations (frequency, timing, and any triggering factors such as exercise), the presence of syncope or presyncope, coexisting heart disease, and a family history of SCD.

Physical signs are subtle and rarely helpful. Cannon a waves may occasionally be noted in the jugular venous pulse. Peripheral pulse palpation may demonstrate the premature beat (often as a weaker beat) or the compensatory pause (followed by an augmented beat). Extrasystoles are often associated with a reduction in the intensity of

the heart sounds and coexisting cardiac murmurs due to reduction in diastolic filling times and volumes.

An ECG recording is usually required to confirm the presence of extrasystoles and to establish their origin. It is important not to attribute palpitations to extrasystoles unless there is a clear correlation between symptoms and extrasystoles on ECG. This may require prolonged periods of monitoring, as well as a detailed symptom diary.

Other diagnoses that should be considered

Frequent extrasystoles may be confused with atrial fibrillation on palpation of peripheral pulses. Furthermore, pulse rate may appear slow during sustained episodes of bigeminy, suggesting a bradyarrhythmia. An ECG should easily establish the correct diagnosis.

'Gold-standard' diagnostic test

An ECG recording demonstrates the presence of extrasystoles. A 12-lead ECG will identify their potential origin and possible underlying cause (e.g. Q waves or long QT). Ambulatory ECG monitoring

devices are useful, and a Holter monitor can be used if symptoms occur daily. Patient-activated loop recorders can provide monitoring periods of up to 2 weeks. Implantable loop recorders may also be used (battery life ~2 years).

Typically, ventricular extrasystoles have wide QRS complexes (>120 ms), large T waves in the opposite direction to the QRS complex, and a full compensatory pause. Supraventricular extrasystoles have normal QRS complexes (unless conducted aberrantly), and less than a full compensatory pause. They may completely fail to conduct if the ventricles are still in the refractory period. Atrial extrasystoles are usually associated with abnormally shaped P waves (the PR interval may vary, but is rarely <120 ms). Junctional extrasystoles may have a very short PR interval (<90 ms), no P wave (hidden within the QRS), or a P wave within the ST segment.

Acceptable diagnostic alternatives to the gold standard

Extrasystoles are often seen during electrophysiological studies, during which their exact nature may be identified. However, such an invasive test is rarely warranted to establish the diagnosis.

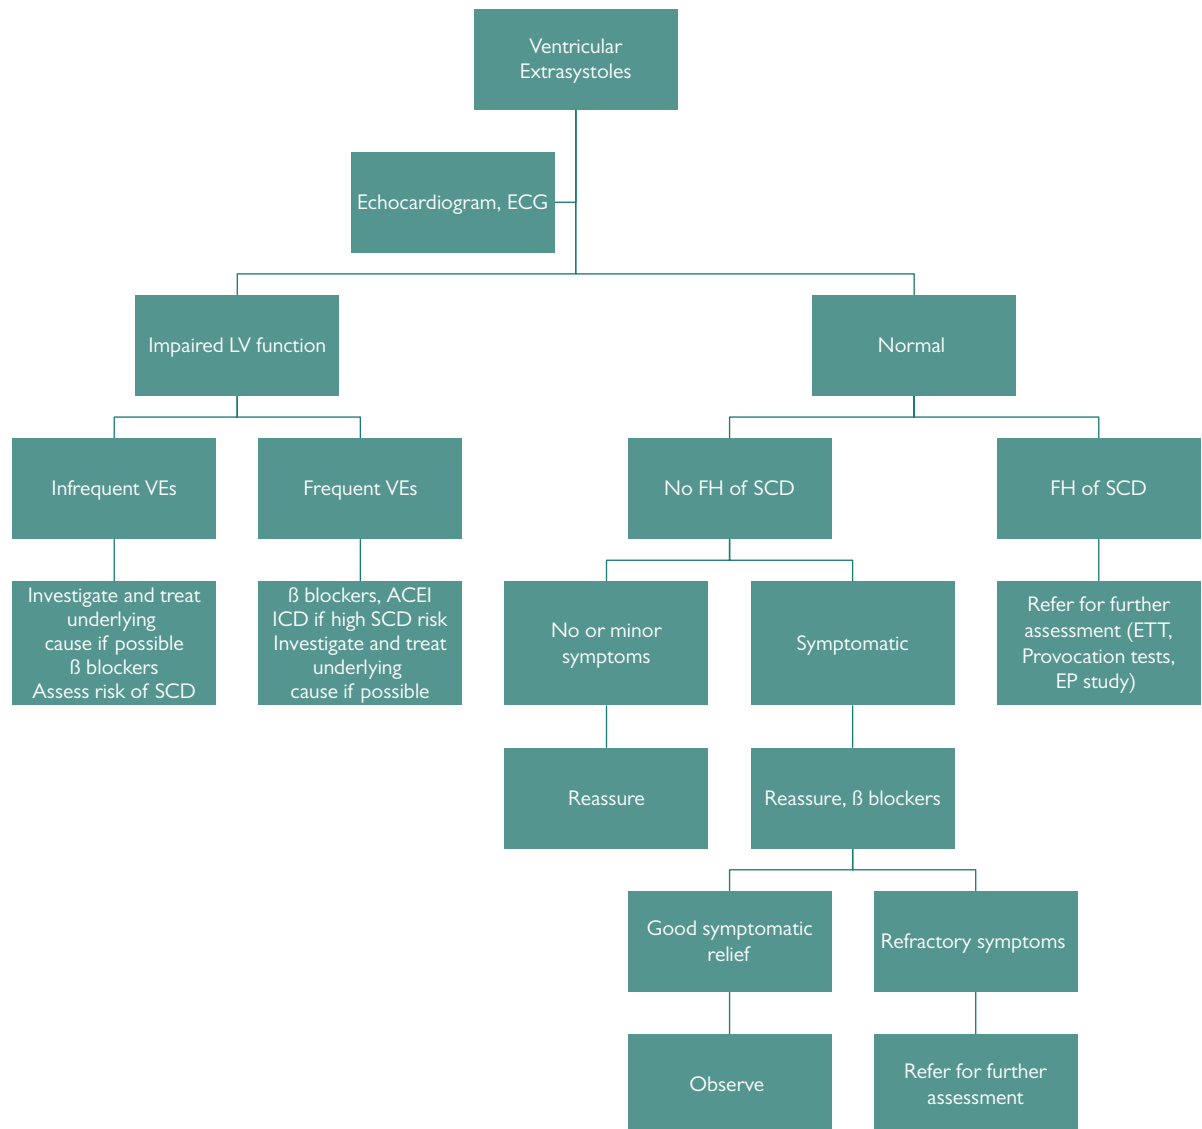

Figure 110.1 Management of ventricular extrasystoles; ACEI, angiotensin-converting enzyme inhibitor; EP, electrophysiology; ETT, exercise treadmill testing; FH, family history; ICD, implantable cardioverter defibrillator; LV, left ventricular; RF, radiofrequency; VEs, ventricular extrasystoles.

Other relevant investigations

Other relevant investigations include:

- 12-lead ECG
- biochemistry: electrolytes (K⁺, Mg²⁺), thyroid function tests, drug levels
- echocardiogram: to assess for structural heart disease and left ventricular function
- exercise stress test: useful in the assessment of complex ectopy and exercise-induced palpitations (catecholamine mediated), and to screen for coronary artery disease. If coronary disease is considered to be anything other than low probability, CT coronary angiography or a functional test such as dobutamine stress echocardiography, or myocardial perfusion imaging should be undertaken.

Prognosis

Supraventricular extrasystoles are generally benign and have an excellent prognosis. Similarly, in subjects with no structural heart disease, ventricular extrasystoles appear to carry no adverse prognostic implications. In contrast, ventricular extrasystoles predict an increased risk of mortality in the presence of structural heart disease. The risk of SCD appears to be directly related to the extent of structural damage, although ventricular extrasystoles may simply be just a marker of the severity of the underlying disease rather than an independent risk factor for SCD (since pharmacological suppression of premature ventricular contractions does not improve overall survival). Ventricular extrasystoles elicited during exercise testing, even in apparently normal subjects, appear to imply increased risk over time. RVOT ectopy generally has a good prognosis, whereas right ventricular ectopy in

the presence of structural abnormality (such as arrhythmogenic right ventricular cardiomyopathy) has a more sinister prognosis.

Treatment and its effectiveness

No therapy is required for asymptomatic patients. When present, symptoms may be alleviated by reassurance, and treating precipitating causes. If these measures fail, then β blockers may be effective in suppressing extrasystoles, and should normally be first choice (particularly post myocardial infarction or in heart failure). Alternatives include calcium-channel blockers, amiodarone, sotalol, and flecainide (the latter should be avoided post myocardial infarction). Radiofrequency ablation may be considered in refractory cases with symptomatic, frequent, monomorphic ventricular extrasystoles (especially if causing left ventricular impairment), and in cases where ventricular tachycardia is consistently provoked by ventricular extrasystoles of a similar morphology. Patients at high risk of SCD should be considered for implantation of an implantable cardioverter defibrillator (Figure 110.1).

111 Sinus tachycardia

Michael Jones, Norman Qureshi, and Kim Rajappan

Definition of the disease

Sinus tachycardia is a condition of multiple different potential etiologies, characterized by an elevated rate of automaticity of the sinoatrial node, such that the heart rate is elevated. The exact point at which sinus tachycardia meets sinus rhythm is debatable; however, by convention, an upper rate of 100 min^{-1} is accepted for sinus rhythm; $>100 \text{ min}^{-1}$ denotes sinus tachycardia.

Aetiology of the disease

The commonest cause of sinus tachycardia is enhanced sympathetic drive (catecholamine mediated), which has the secondary effect of increasing the frequency of the automaticity of the sinoatrial node, thus increasing the atrial and ventricular rates. Possible causes include the following:

- fever/septicaemia
- anaemia
- hypovolemia
- hyperthyroidism
- hypotension
- catecholamine overproduction (phaeochromocytoma)
- heart failure
- anxiety states
- pulmonary embolus
- myocardial ischaemia/infarction
- hypoxia/chronic pulmonary disease
- stimulant-drug use (caffeine, nicotine, cocaine, etc.)
- beta-agonist drug use (isoprenaline, salbutamol, etc.)
- anticholinergic drug poisoning (atropine, tricyclic antidepressants, antihistamines, etc.)
- acute beta-blocker withdrawal (rebound sinus tachycardia)

There are two other categories of sinus tachycardia: one comprises inappropriate sinus tachycardia (IST; also termed 'chronic non-paroxysmal sinus tachycardia') and postural tachycardia syndrome (POTS); the other comprises sinus node re-entrant tachycardia (SNRT).

Typical symptoms of the disease and less common symptoms

Sinus tachycardia may be associated with symptoms of palpitations and an elevated heart rate, but it can also be completely asymptomatic. The underlying disease leading to the sinus tachycardia may also cause symptoms in its own right (e.g. acute myocardial infarction, pulmonary embolus, thyrotoxicosis); in addition, sinus tachycardia may worsen the symptoms of underlying conditions (such as heart failure, angina, etc.) through its elevation of the heart rate.

Demographics of sinus tachycardia

Sinus tachycardia is usually present in infants (normal physiology), where the heart rate is between 110 and 150 min^{-1} . The sinus rate then falls progressively with advancing age to the normal range for an adult ($<100 \text{ min}^{-1}$).

Natural history, and complications

Generally, correction of the underlying physiological basis of the sinus tachycardia results in a lowering of the sinus rate to 'normal' levels

(i.e. correction of hypovolaemia, treatment of sepsis, etc.). In the case of acute beta-blocker withdrawal (the so-called 'rebound' sinus tachycardia), normalization of the sinus rate may take days to weeks, and significant symptoms may require a more gradual down-titration of the beta-blocker dose. In the long term, untreated persistent sinus tachycardia may lead to a tachycardia-related cardiomyopathy, like the other persistent supraventricular tachycardias. This cardiomyopathy is generally reversible with correction of the tachycardia, in the absence of another cause for cardiomyopathy.

Approach to diagnosing the arrhythmia, including clinical clues, through concentrating on the ECG diagnosis

Sinus tachycardia is diagnosed from the 12-lead ECG, and requires that the P-wave morphology match the baseline sinus-rhythm P-wave morphology exactly (see Figure 111.1). This may be difficult to discern if there is no premorbid ECG; nevertheless, a P wave that demonstrates a positive morphology in the inferior limb leads (II, III, and aVF), a negative (or positive) morphology in aVR, and a positive morphology across the precordial leads (V1–V6) is likely to have its origin in the vicinity of the sinus node.

Sinus tachycardia may slow in response to enhanced vagal tone (carotid sinus massage (CSM)), but this is less likely to occur in SNRT than in the other forms of sinus tachycardia. Occasionally, slowing of the sinus rate may be necessary to clearly see the P waves and exclude atrial flutter or atrial tachycardia, when alternate P waves may be superimposed (hidden) in the QRS complexes.

The effect of IV adenosine administration may be to (1) increase AV nodal block and so result in 2:1 or other degrees of AV conduction block, (2) slow the sinus rate slightly, or (3) terminate the tachycardia. As with carotid massage, adenosine administration may assist in identifying any intervening P waves which had been hidden (superimposed) in QRS complexes.

The QRS morphology is usually the same as that seen during sinus rhythm, although aberrant conduction may occur with higher ventricular rates.

Other diagnoses that should be considered

Atrial flutter with 2:1 atrioventricular (AV) conduction may be mistaken for sinus tachycardia, especially if the P waves are hidden (superimposed) inside the QRS complexes. The diagnosis can be clarified by increasing AV nodal blockade (via CSM and/or IV adenosine administration) so that the P wave morphology and atrial rate can be clearly seen. The importance of differentiating sinus tachycardia from atrial flutter lies in the fact that, like multifocal atrial tachycardia, sinus tachycardia is not an indication for consideration of anticoagulation per se, whereas atrial flutter may be, depending on the patient's intrinsic risk (as determined by e.g. the CHADS-Vasc score).

'Gold-standard' diagnostic test

The diagnosis of sinus tachycardia should be able to be made from the surface 12-lead ECG. Very rarely, an invasive electrophysiology (EP) study may be helpful in differentiating sinus tachycardia from other forms of supraventricular tachycardia, where the 12-lead ECG is insufficient to make the diagnosis. At an invasive EP study, the site of origin of the tachycardia can be mapped to the sinus node region, and subsequent radial atrial activation can be demonstrated by activation mapping techniques.

Figure 111.1 Sinus tachycardia ECG; note that the P waves are positive in the inferior and precordial leads and aVL, and negative in aVR. Also, the QRS is normal in width.

Acceptable diagnostic alternatives to the gold standard

Aside from the 12-lead ECG, or invasive EP study, there are currently no other diagnostic tests that can definitively diagnose sinus tachycardia.

Other relevant investigations

As there are a large number of potential etiologies for sinus tachycardia, there are a number of investigations that might need to be considered, in selected cases:

- full blood count, renal function, inflammatory markers (if anaemia, sepsis, hypovolaemia, or electrolyte disturbance is suspected)
- arterial blood gas analysis, D-dimer levels, and possibly lung perfusion scanning (if pulmonary embolus is suspected)
- chest X-ray (if infective or obstructive airways disease, pleural effusion/empyema, or heart failure is suspected)
- thyroid-stimulating hormone level (if hyperthyroidism is suspected)
- cardiac troponin assay (if acute coronary ischaemia is suspected)
- serum toxicology screen (if drug abuse is suspected)
- 24-hour urinary excretion of catecholamines (if phaeochromocytoma is suspected)

Echocardiography should be performed in all cases where sinus tachycardia cannot be readily explained by an obvious underlying pathology, and in cases where structural heart disease or heart failure is suspected.

Other investigations may subsequently be indicated, depending on the results of the initial testing—for example, myocardial perfusion studies or coronary angiography in cases where underlying coronary ischaemia is suspected.

Prognosis

The prognosis of sinus tachycardia is dependent upon the underlying pathology that is present, rather than the tachycardia itself. The exception to this is the possibility of developing a rate-related cardiomyopathy, if the tachycardia goes unnoticed and uncontrolled for a prolonged period of time.

Treatment and its effectiveness

The treatment of sinus tachycardia is essentially the treatment of the underlying condition predisposing to the tachycardia. The tachycardia should rarely ever require treatment per se in the case of an appropriate (reactive or physiological) sinus tachycardia. The syndromes

of IST/POTS and SNRT are the exceptions to this rule, and are discussed separately in the following paragraphs.

Treatment of IST and POTS

The uncommon condition IST remains poorly defined, but essentially consists of elevated sinus rates with no apparent cause or physiologic explanation, in the context of normal cardiac structure and function. The mechanism of IST is still debated, but may be a primary 'dysautonomia' (excess sympathetic tone—depressed vagal efferent activity and/or enhanced beta-adrenoceptor sensitivity) that leads to the chronically elevated sinus rates. Alternatively, the sinus node itself may be abnormally sensitive to circulating catecholamines. The diagnosis is one of exclusion, when the potential causes for sinus tachycardia have been excluded, and cardiac structure and function have been assessed and shown to be normal. The prognosis is generally benign, although the symptoms can be very intrusive.

Treatment of IST is difficult and often unsuccessful in alleviating symptoms entirely. Beta blockers and non-dihydropyridine calcium-channel blockers (diltiazem, verapamil) may help in some cases, but both classes of drugs can result in side effects that are more troublesome than the tachycardia. Ivabradine is a newer agent that acts directly upon the sinus node itself (selectively inhibits the I_f current in a dose-dependent manner, which reduces cardiac pacemaker activity, slowing the sinus rate), and has been shown to be beneficial in some cases. Occasionally, catheter ablation (modification) of the sinus node is helpful if other treatments have been unsuccessful or poorly tolerated, but results are mixed, and chronotropic incompetence of the sinus node is a possible complication of this procedure (potentially requiring the implantation of a cardiac pacemaker). Catheter ablation should therefore be considered only as a last option for the management of IST.

POTS is a condition characterized by orthostatic intolerance symptoms, with a rapid increase in heart rate of ≥ 30 bpm, usually up to ≥ 120 bpm, but without orthostatic hypotension. Symptoms can be classic orthostatic in nature (light-headedness, dizziness, presyncope, palpitations) and non-orthostatic (bloating, nausea, vomiting, abdominal pain, constipation, diarrhoea, fatigue, migraine, sleep disturbance). Symptoms may be exacerbated by heat and exercise, are worse postprandially, and can intensify during the menstrual period. Females are predominantly affected (female to male ratio, 4:1), between 15 and 50 years of age. The prevalence of POTS is unknown, and the pathophysiology remains unclear, with some studies suggesting the presence of dysautonomia, a hyperadrenergic state, hypovolaemia, and an abnormal rennin-aldosterone response to hypovolaemia in POTS patients. There is considerable overlap between POTS, IST, vasovagal syncope, and chronic fatigue syndrome.

The diagnosis of POTS is made on the basis of a sustained rise in the heart rate of ≥ 30 bpm, or to ≥ 120 bpm with orthostatic stress (upright tilting), and this is conventionally performed on an automated tilt table.

The evidence base for treating POTS is poor, but treatments that may be of benefit include salt and water supplementation, lower-limb resistance training exercises, and the use of pressure stockings (non-pharmacological approach). Pharmacological therapies which may improve symptoms include fludrocortisone, midodrine, beta blockers, clonidine, pyridostigmine, ivabradine, octreotide, and possibly desmopressin. Decisions regarding therapy are best referred to a specialist service with experience in the management of dysautonomia, as the response to treatments is variable and requires tailoring to each individual patient.

Generally, the long-term prognosis of POTS is benign, with the majority of patients being able to return to normal activities after assessment, and treatment has been instituted.

Treatment of SNRT

SNRT is an uncommon arrhythmia, and is rarely symptomatic. The sinus rate is generally between 100 and 150, with P waves that are identical to normal P waves during sinus rhythm. The QRS is similarly unchanged compared to sinus rhythm, save that rate-related aberrancy may occur at faster sinus rates. The mechanism is thought to be a re-entrant circuit involving the sinus node, and possibly the perinodal tissues. The arrhythmia may be paroxysmal (brief and infrequent or frequent and sustained), or even incessant—in which case, it can be associated with a tachycardia-mediated cardiomyopathy, which is generally reversible with elimination of the tachycardia. The diagnosis can be difficult to make, but essentially relies upon the demonstration of spontaneous paroxysms of rapid sinus rates (which differentiates this condition from other atrial tachyarrhythmias). At electrophysiological studies, SNRT can be induced by programmed atrial extra-stimuli, and terminated in similar fashion; the atrial activation sequence will be shown to be similar to that seen during normal sinus rhythm.

Given the high degree of autonomic innervation of the sinoatrial node, CSM will generally terminate an episode of SNRT, whereas it will result in a gradual slowing and then acceleration of sinus tachycardia (on cessation of the CSM); AV nodal conduction block may also be seen during CSM. This manoeuvre can be helpful in differentiating the two conditions. Adenosine, similarly, will usually terminate an episode of SNRT.

Therapy is rarely required for SNRT, but beta blockers, non-dihydropyridine calcium-channel blockers (diltiazem, verapamil), and digoxin may be beneficial. In refractory cases, catheter ablation of the re-entrant circuit may be an appropriate treatment.

Key points

- Sinus tachycardia is an atrial tachyarrhythmia of multiple potential etiologies, characterized by an elevation in the rate of automaticity of the sinus node.
- The P-wave morphology is identical to that of normal sinus rhythm, and QRS complexes are generally identical to those associated with sinus rhythm; however, rate-related aberrancy may occur.
- AV conduction during sinus tachycardia may be 1:1; alternatively, Wenckebach or higher degrees of AV conduction block may be seen. This depends on the intrinsic AV nodal conduction of the patient, and the concomitant use of AV nodal blocking drugs.
- There are three broad categories of sinus tachycardia: (1) sinus tachycardia due to enhanced sympathetic tone (hyperadrenergic state), (2) IST/POTS, and (3) sinus node re-entrant tachycardia.
- Careful assessment of sinus tachycardia is essential, and a thorough search for an aetiology is required in all cases, so that secondary sinus tachycardia can be differentiated from the other causes of sinus tachycardia (namely IST, POTS, and SNRT); there must also be consideration of potential predisposing conditions.
- The effects of **adenosine** and **CSM or other vagal manoeuvres** are as follows: (1) in secondary sinus tachycardia, IST, or POTS, a transient slowing of the ventricular rate is likely to be seen (the mechanism is increased AV nodal conduction block), but termination of the arrhythmia is unlikely; (2) in SNRT, termination of the tachycardia is more likely.
- The differential diagnosis includes ectopic atrial tachycardia and atypical AV nodal re-entrant tachycardia; however, the P-wave morphology on the 12-lead ECG changes in these latter arrhythmias, thus clearly differentiating the conditions.
- The management of secondary sinus tachycardia is focused on treatment of the underlying cause of the elevated sinus rate.
- The management of IST is more difficult and challenging than that of secondary sinus tachycardia but, in the first instance, non-dihydropyridine calcium-channel blockers or beta blockers are helpful in some cases. Ivabradine is a newer agent that also can control symptoms in many cases.
- The management of POTS is complex, but the initial approach involves salt and fluid repletion, leg exercises, the use of pressure stockings, and fludrocortisone. Midodrine may also be helpful. Referral to a specialist clinic is recommended.
- SNRT rarely produces symptoms and so rarely requires treatment, but non-dihydropyridine calcium-channel blockers, beta blockers, and digoxin are reasonable first choices. Catheter ablation may be appropriate in selected cases.

112 Focal (ectopic) atrial tachycardia

Michael Jones, Norman Qureshi, and Kim Rajappan

Definition of the disease

Focal atrial tachycardia is an atrial arrhythmia arising in either the left or the right atrium, usually faster than 100 min^{-1} and regular, with a P-wave morphology that is different from the normal P-wave morphology associated with sinus rhythm—the difference in morphology being more pronounced the further away the focus lies from the sinus node.

The ventricular rate is generally fast also, dependent on the nature of the atrioventricular (AV) conduction; 1:1 conduction may be seen, especially in younger patients or patients with accessory pathways capable of very rapid antegrade conduction; alternatively, 2:1, Wenckebach-type, or higher-grade AV block may be seen.

Aetiology of the disease

Focal atrial tachycardia may be the result of three different atrial mechanisms: (1) enhanced automaticity, (2) triggered activity (early after-depolarizations, occurring during the plateau phase of the action potential, or delayed after-depolarizations, occurring during the fourth phase of the action potential), or (3) micro-re-entry (via small, protected area of tissue with conduction slowed to such an extent that tissue recovery occurs in sufficient time for the same wavefront, on re-encountering that tissue, to re-depolarize the tissue repeatedly).

Focal atrial tachycardia may occur in normal hearts, or may be associated with conditions leading to atrial stretch, elevated atrial pressure, inflammation, and fibrosis (scarring), such as chronic hypertension (systemic or pulmonary), cardiomyopathy, ischaemia, infection, and alcohol ingestion. Metabolic conditions such as hypokalaemia and hypoxia may predispose to atrial tachycardia. Stimulant drug abuse (cocaine, amphetamine), and the medications theophylline and digoxin can predispose to focal atrial tachycardia, especially at supratherapeutic levels.

Focal atrial tachycardias arise in specific locations in the atria, due to the particular tissue characteristics of those locations (alterations in myocyte orientation, and the presence of tissue with automaticity properties): in the right atrium (75%), commonest locations include the tricuspid valve annulus, the crista terminalis, the coronary sinus ostium, tissue directly adjacent to the sinoatrial and the atrioventricular nodes, and the right atrial appendage; in the left atrium (25%), the commonest sites of origin include the pulmonary vein antra, the mitral valve annulus, the coronary sinus body, septum, and the left atrial appendage.

Typical symptoms of the disease, and less common symptoms

Most patients experience paroxysmal palpitations as the cardinal symptom of focal atrial tachycardia. Attacks can last for seconds or up to as long as hours. Other patients may present with a cardiomyopathy from incessant atrial tachycardia (i.e. atrial tachycardia present for 90% or more of the time) rather than with palpitations. This cardiomyopathy is often reversible, with successful elimination of the tachycardia. Other symptoms of cardiac disease may manifest more prominently during episodes of atrial tachycardia, including angina and heart failure, owing to the rapid ventricular rates during the atrial tachycardia.

Demographics of focal atrial tachycardia

The overall prevalence of atrial tachycardia is low, and accounts for only 10% of the arrhythmias in patients undergoing electrophysiology studies for supraventricular tachycardias. Men and women are equally affected.

Natural history, and complications

Focal atrial tachycardia usually carries a benign prognosis, and may spontaneously remit over time. The exception to this is incessant atrial tachycardia, which can result in a tachycardia-mediated cardiomyopathy.

Approach to diagnosing the arrhythmia, including clinical clues, through concentrating on the ECG diagnosis

Focal atrial tachycardia is essentially an ECG diagnosis. The arrhythmia is generally of abrupt onset and offset, with an atrial rate of between 100 and 300 min^{-1} , and a P-wave morphology that is unlike that of sinus rhythm. This last point may be difficult to appreciate if the focus of the tachycardia is located adjacent to the SA node (e.g. high cristal atrial tachycardia, which may be indistinguishable from sinus tachycardia on P-wave morphology alone). The episodes may be brief (seconds) or prolonged (days), and changes to the atrial rate tend to be sudden, rather than gradual (as is the case for sinus rhythm). The PR relationship may give clues to the diagnosis of atrial tachycardia, as there is generally a long and variable RP interval during tachycardia, and AV dissociation may be seen. This last point helps differentiate atrial tachycardia from AV nodal re-entrant tachycardia and AV re-entrant tachycardia, where AV dissociation is not seen.

Performance of carotid sinus massage will typically increase AV nodal block (and so reduce ventricular rate), and reveal the P waves more clearly. IV adenosine may have the same effect, but it may also terminate the atrial tachycardia.

The QRS morphology is usually the same as that seen during sinus rhythm, although aberrant conduction may occur with higher ventricular rates. Autonomic tone and the use of concomitant AV nodal blocking medications will determine the ventricular response rate to the atrial tachycardia, which itself generally remains constant during an episode of tachycardia.

On preliminary inspection, the ECG shown in Figure 112.1 might be mistaken for sinus tachycardia, but the morphology and vector of the P waves (indicated by arrows) differ significantly from those of normal sinus P waves. The deeply negative P waves in Leads II, III, and aVF suggest that atrial electrical activation is proceeding caudocranially rather than craniocaudally, and the positive P waves in aVL and aVR suggest a more atrial-septal than free-wall location of the focal atrial tachycardia. This tachycardia may be located in the interatrial septum, coronary sinus os, or the right inferior pulmonary vein antrum. The exact location can be mapped during an electrophysiology study, and the focus ablated.

Other diagnoses that should be considered

Other causes of narrow complex tachycardia should be considered, such as atrial flutter, AV nodal re-entrant tachycardia, and AV re-entrant tachycardia. Sometimes, administration of carotid sinus massage, IV adenosine, or invasive electrophysiology studies are required to make the diagnosis.

'Gold-standard' diagnostic test

While the 12-lead ECG may make and confirm the diagnosis of focal atrial tachycardia, the gold-standard investigation is the electrophysiology study. Pacing manoeuvres that demonstrate VA dissociation,

Figure 112.1 Atrial tachycardia on a 12-lead ECG; P waves are indicated by arrows.

and that demonstrate the tachycardia is driven by atrial activity, confirm the diagnosis. Catheter mapping techniques can demonstrate a radial atrial activation pattern from the atrial focus of the tachycardia.

Acceptable diagnostic alternatives to the gold standard

Aside from the 12-lead ECG or invasive electrophysiology study, there are currently no other diagnostic tests that can definitively diagnose atrial tachycardia.

Other relevant investigations

Echocardiography should be performed in all cases, to exclude the presence of structural heart disease (cardiomyopathy, significant valvular lesions, intra-cardiac shunts (an agitated saline study may be required if clinical suspicion of a shunt is high)) and to assess left ventricular size and function, left atrial dimension, pulmonary pressures, right-heart function, and pericardial appearance.

Full blood count and renal function testing may be relevant in certain cases where a predisposing cause is suspected, percutaneous catheter intervention is planned, or antiarrhythmic drug therapy is being considered.

Other investigations may be indicated, depending on the clinical setting. A suspicion of coronary disease or the desire to use Class 1 antiarrhythmic drugs might prompt an exercise treadmill test, a myocardial perfusion scan, or a coronary angiogram. Ambulatory heart rate monitoring (Holter monitoring) may be useful in assessing heart rate variability over a 24-hour period, to help differentiate atrial tachycardia from sinus tachycardia in cases where the P-wave morphology is very similar to sinus rhythm.

Prognosis

The prognosis is generally benign, apart from cases of incessant tachycardia, where a tachycardia-mediated cardiomyopathy may ensue.

Treatment and its effectiveness

Acute treatment

Any underlying or predisposing factors for focal atrial tachycardia should be identified and corrected—for example, hypokalaemia;

hypoxia; or theophylline or digoxin toxicity (anti-digitalis antibodies may be considered). And, as is the case with other tachyarrhythmias, assessment of the patient's haemodynamic state is the first consideration. In cases where haemodynamic compromise is present, acute cardioversion should be attempted—focal atrial tachycardia may respond less well to electrical cardioversion than the other tachyarrhythmias, or may reinitiate soon after cardioversion. In such a situation, chemical cardioversion with a Class III (amiodarone) or Class I (flecainide) antiarrhythmic drug should be considered. If the haemodynamic state is not compromised, vagal manoeuvres or IV adenosine may be administered; these can terminate the tachycardia or, alternatively, slow the ventricular response rate (via increased AV nodal block). Additionally, beta blockers or non-dihydropyridine calcium-channel blockers can be administered, with similar effects of slowing the ventricular response, and occasionally terminating the arrhythmia.

Chronic treatment

The aim of chronic therapy of focal atrial tachycardia is to prevent recurrence of atrial tachycardias and to control the ventricular response rate during atrial tachycardia if it should recur. Generally, beta blockers or non-dihydropyridine calcium-channel blockers are prescribed first, as these are the safest agents available which have reasonable efficacy.

If these agents fail, then consideration of an interventional approach to the management should be given. In an electrophysiology study, focal atrial tachycardias can be mapped to their site of origin in the atria, and ablated successfully and curatively in the majority of cases. The added advantage of this interventional approach is the fact that ongoing suppressive pharmacotherapy is generally not required after the ablation.

If ablation is unsuccessful, or if a particular patient is not a suitable candidate or refuses intervention, then Class III (amiodarone, sotalol) or Class I (flecainide) antiarrhythmic drugs can be tried, but the long-term side effects of these agents (especially their proarrhythmia tendencies) need to be considered in such cases.

Finally, if none of these approaches provide relief from atrial tachycardia, an AV nodal ablation together with the implantation of a permanent pacemaker is a reasonable option. This strategy necessarily renders a patient dependent on their pacemaker; moreover, it dictates repeated (7–10 yearly) pacemaker generator replacements (due to battery depletion) for the life of the patient. Hence, this is a less attractive strategy for younger patients, who would be faced with a future of repeated surgical procedures.

Key points

- Focal atrial tachycardia is a regular atrial arrhythmia, with atrial rates of between 100 and 300 min⁻¹, usually paroxysmal but occasionally incessant in nature, with QRS complexes generally identical to sinus rhythm, but with a different P-wave morphology to sinus rhythm.
- The prognosis of focal atrial tachycardia is generally benign, save when the tachycardia is incessant, and a tachycardia-mediated cardiomyopathy results—this is generally reversible with successful treatment of the tachycardia.
- Ventricular activation during atrial tachycardia may be 1:1; alternatively, Wenckebach or higher degrees of AV conduction block may be seen. This depends on the intrinsic AV nodal conduction of the patient, and the concomitant use of AV nodal blocking drugs
- Atrial rates fluctuate less than sinus rhythm rates, and generally change in sudden steps, rather than gradually as seen with sinus rhythm.
- The effect of **adenosine** and **carotid sinus massage or other vagal manoeuvre** is transient slowing of ventricular rate (the mechanism is increased AV nodal conduction block) or, occasionally, slowing and termination of the atrial tachycardia itself.
- Differentials in the diagnosis include sinus tachycardia, atrial flutter, AV nodal re-entrant tachycardia, and AV re-entry tachycardia.
- ECG clues to the diagnosis of focal atrial tachycardia are (1) variable RP interval, (2) AV dissociation/evidence of AV nodal block, and (3) P-wave morphology different from that of sinus rhythm (it may be difficult to ascertain if the focal atrial tachycardia is arising in the high crista terminalis, close to the sinus node itself).
- Focal atrial tachycardia may arise in normal hearts, in patients with atriopathy or in patients with certain metabolic conditions; in addition, certain drug toxicities predispose to focal atrial tachycardia.
- Acutely, the intention of management is to terminate focal atrial tachycardia or control ventricular rate, with consideration of haemodynamic compromise being paramount.
- In the chronic setting, medical therapy or catheter ablation is appropriate, the decision being made on an individual patient basis.
- If all else fails, an AV nodal ablation and implantation of a permanent pacemaker is a reasonable option for treatment, but renders the patient pacemaker dependent for life.

113 Multifocal atrial tachycardia

Michael Jones, Norman Qureshi, and Kim Rajappan

Definition of the disease

Multifocal atrial tachycardia (MAT) is an atrial arrhythmia arising in the left or right atrium, or both, with multiple different P wave morphologies (at least three), with an atrial rate usually faster than 100 min^{-1} . The atrial rhythm may be irregular; however, the defining difference between MAT and atrial fibrillation is the presence of a P wave prior to each QRS complex in MAT (but the absence of P waves in atrial fibrillation). MAT may be compared to sinus rhythm with very frequent polymorphic atrial ectopic beats, and in fact similar pathophysiologic mechanisms underlie both conditions; thus, differentiating one from the other may be difficult—the principle difference is the lack of a single dominant sinus pacemaker in MAT.

Aetiology of the disease

MAT most probably arises as a consequence of abnormal automaticity, or triggered activity, rather than re-entry, given that, during electrophysiology study, programmed electrical stimulation is generally unable to induce or interrupt the arrhythmia.

MAT is associated with significant lung disease in over half of the cases, and is frequently seen on the ECGs of patients admitted with respiratory failure. COPD is the most commonly associated pulmonary condition, most probably through the mechanism of pulmonary hypertension causing right atrial pressure elevation and stretch. Other pulmonary conditions associated with MAT include pneumonia, pulmonary arterial embolus, hypoxia, hypercapnoea, acidosis, autonomic imbalance, and right atrial enlargement. Cardiac disease is also associated with developing MAT, especially conditions leading to elevation of right and left atrial pressures—valvular disease, hypertension, left ventricular systolic dysfunction, and ischemia.

Certain drugs are associated with MAT, including aminophylline, theophylline, and isoprenaline, and other conditions that may predispose to MAT include impaired glucose tolerance, hypokalaemia, hypomagnesaemia, and chronic renal failure.

Typical symptoms of the disease, and less common symptoms

Patients with MAT may experience palpitations; however, they are more likely to be symptomatic of significant pulmonary or cardiac comorbidity, as previously explained. As with focal atrial tachycardia, if MAT is incessant or very frequently present, it may be associated with a tachycardia-mediated cardiomyopathy.

Demographics of MAT

MAT is an uncommon arrhythmia, and is seen on roughly 15 out of 10 000 ECGs performed in hospital patients. Patients are generally elderly, with an average age of approximately 75 years. Respiratory disease is present in 50%–80% of patients with MAT (mainly COPD). MAT is less often seen in the younger age groups but, when it does occur, it is generally associated with a benign prognosis.

Natural history, and complications

Studies have demonstrated that MAT is associated with an in-hospital mortality rate of 45%, which is probably attributable more to the severe underlying respiratory and cardiac comorbidities than to the MAT itself. MAT is often preceded by, or progresses to, atrial

fibrillation or another atrial tachycardia. MAT occurs far less often than atrial fibrillation.

Occasionally, patients present with a heart rate less than 100 min^{-1} but otherwise fulfil all of the criteria for MAT. This condition should be termed slow MAT or multifocal atrial rhythm. It is not the same rhythm as wandering atrial pacemaker (WAP), as the latter is usually a benign rhythm of stable, healthy patients. Clinical criteria alone thus differentiate slow MAT from WAP: MAT and slow MAT occur almost exclusively in the setting of serious coexisting cardiopulmonary disease, while WAP occurs in healthy individuals.

Approach to diagnosing the arrhythmia, including clinical clues, through concentrating on the ECG diagnosis

MAT is diagnosed on the 12-lead ECG (Figure 113.1), based upon the presence of (1) at least three different P-wave morphologies, (2) evidence of an isoelectric segment between the P waves, and (3) an atrial rate of greater than 100 min^{-1} . The ECG may demonstrate changes consistent with significant pulmonary disease (pulmonary hypertension) in addition to the tachycardia. Performance of carotid sinus massage (should it be considered necessary) may increase atrioventricular (AV) nodal block (and so reduce ventricular rate), and reveal the P waves more clearly. Intravenous adenosine may have the same effect.

The QRS morphology is usually the same as that seen during sinus rhythm, although aberrant conduction may occur with higher ventricular rates. Autonomic tone and the use of concomitant AV nodal blocking medications will determine the ventricular response rate to the atrial tachycardia. Various degrees of AV nodal block are usually observed, given that these patients usually have significant cardiac comorbidity.

This ECG may be initially mistaken as showing atrial fibrillation; however, on close inspection, a definite P wave can be observed before each QRS complex. There are at least three different morphologies of P wave, each with subtly different PR intervals. This is most apparent on Lead V1 in this case. On this 12-lead ECG, AV conduction appears to be 1:1.

Other diagnoses that should be considered

Atrial fibrillation and atrial flutter are the two arrhythmias that should be considered in the differential diagnosis, but the presence of different P waves of different morphologies with isoelectric segments in-between should exclude these two diagnoses in the majority of cases. The importance of differentiating MAT from atrial fibrillation lies in the implications for thromboembolism and stroke risk—MAT is not considered an indication for anticoagulation per se, whereas atrial fibrillation and flutter may be, depending on the patient's intrinsic risk (as determined by the CHADS-Vasc score).

'Gold-standard' diagnostic test

The 'gold-standard' diagnostic test is the electrophysiology study, which may be required in a minority of cases to make the diagnosis. The placement of cardiac catheters inside the atria may demonstrate the multifocal nature of this arrhythmia and, moreover, pacing manoeuvres will enable other mechanisms for supraventricular tachycardia to be excluded.

Figure 113.1 Multifocal atrial tachycardia 12-lead ECG.

Acceptable diagnostic alternatives to the gold standard

An acceptable diagnostic alternative to the gold standard is interpretation of the 12-lead ECG in the clinical context.

Other relevant investigations

Given that MAT occurs so frequently in the setting of severe cardiopulmonary disease, investigation and management should focus on coexistent pulmonary and cardiac disease.

Echocardiography should be performed in all cases, to exclude the presence of structural heart disease (cardiomyopathy, significant valvular lesions, intra-cardiac shunts (an agitated saline study may be required if clinical suspicion of a shunt is high), left ventricular size and function, left atrial dimension, pulmonary pressures, right-heart function, and pericardial appearance).

Myocardial perfusion studies or coronary angiography may be indicated in cases where underlying coronary ischaemia is suspected.

Full blood count and renal function should be assessed, in all cases, once again on the basis of the likely underlying cardiopulmonary disease.

Prognosis

MAT is often benign in infants and children, but the prognosis is poor in adults; in-hospital mortality from underlying disease (generally respiratory) is between 40% and 60% and, in most cases, advanced age is compounded by severe cardiopulmonary comorbidity.

Treatment and its effectiveness

The main focus of treatment in patients with MAT is of the underlying disease; with improvement in pulmonary or respiratory status, MAT also improves.

Magnesium administration may be an effective treatment, with one study demonstrating a slowing of the heart rate and restoration of sinus rhythm in patients treated with magnesium. Potassium supplementation may have a similar effect.

Verapamil is effective in reducing the degree of atrial ectopy in MAT, and may restore sinus rhythm. Caution has to be exercised in its use, given the potential for hypotension (negative inotropy and

peripheral vasodilatation). Beta blockers (metoprolol) also suppress the atrial ectopy, and reduce AV nodal conduction, thus decreasing the ventricular rate by both mechanisms; however, bronchospasm and decompensated systolic function can complicate the use of beta blockers in these patients.

The limited studies of antiarrhythmic drugs in this condition have failed to demonstrate efficacy, and digoxin does not have a role in the management of MAT. Electrical cardioversion similarly has no role in the treatment of MAT.

In cases of refractory MAT with sustained elevated ventricular rates, in spite of optimal management of underlying cardiopulmonary disease, AV nodal ablation and permanent pacemaker implantation may be appropriate. Given the multifocal nature of MAT, this condition is not considered amenable to catheter ablation of the multiple foci per se, unlike focal atrial tachycardia, where a single atrial focal origin of the tachycardia may be found and successfully ablated.

Key points

The key points concerning MAT are as follows:

- MAT is an atrial arrhythmia, characterized by at least three different P wave morphologies with an isoelectric intervening segment, atrial rates greater than 100 min^{-1} , and QRS complexes generally identical to sinus rhythm.
- MAT generally arises in patients with significant underlying pulmonary or cardiac pathology, the commonest being COPD.
- MAT occurs either as a consequence of enhanced automaticity or triggered atrial activity; it is unlikely to be a re-entrant arrhythmia, given the inability of pacing manoeuvres to induce or terminate MAT.
- Ventricular activation during MAT may be 1:1 or, alternatively, Wenckebach or higher degrees of AV conduction block may be seen. This depends on the intrinsic AV nodal conduction of the patient, and the concomitant use of AV nodal blocking drugs
- The effect of **adenosine, carotid sinus massage, or other vagal manoeuvre** is transient slowing of the ventricular rate (via increased AV nodal conduction block); termination of the arrhythmia is unlikely.
- Differentials in the diagnosis include sinus rhythm with frequent multifocal atrial extrasystoles, and 'coarse' atrial fibrillation.
- ECG clues to the diagnosis of MAT are (1) irregular atrial rate, (2) P waves of at least three different morphologies, with no single

dominant sinus pacemaker apparent, and (3) a clear isoelectric segment between P waves.

- The management of MAT is essentially the management of the underlying significant respiratory or cardiac disease.
- Non-dihydropyridine calcium channel blockade (e.g. verapamil) and cardioselective beta blockade (e.g. metoprolol) both have efficacy in suppressing the atrial ectopy, and beta blockade reduces AV nodal transmission.
- Magnesium and potassium repletion therapy may be beneficial in suppressing MAT.
- Antiarrhythmic drugs and electrical cardioversion have not been shown to have efficacy in the treatment of MAT

- If heart rates remain elevated and symptoms uncontrolled despite adequate management of the underlying cardiopulmonary disease, AV nodal ablation and permanent pacing may be the appropriate treatment.

114 Atrioventricular nodal re-entrant tachycardia

Michael Jones, Norman Qureshi, and Kim Rajappan

Definition of the disease

Atrioventricular nodal re-entrant tachycardia (AVNRT; also known as atrioventricular junction reciprocating tachycardia) is one of the five subtypes of supraventricular tachycardia (SVT), manifesting most commonly as a regular, narrow QRS complex tachycardia, rate 150–250 min⁻¹ (usually 160–180 min⁻¹), occurring paroxysmally, with P waves either not apparent, or seen to follow the QRS complexes.

Aetiology of the disease

AVNRT arises in structurally normal hearts, or in the presence of heart disease. The requirement for AVNRT is the presence of two functionally discrete electrical pathways (Limb A and Limb B in Figure 114.1(A)) within or adjacent to the atrioventricular (AV) node in the low septal right atrium. These pathways are not macroscopically or microscopically visible in tissue section; rather, they comprise tracts of electrically conductive cells that display certain distinct electrophysiological properties. Limb A demonstrates rapid conduction velocity but a slow recovery time, whereas limb B conducts slowly, but recovers more quickly. In the normal situation, impulses travel down both A and B, but as A is faster, this is the route by which activation occurs (His–Purkinje activation, in this case). The impulse does enter the other limb (Limb B), at both ends, and collision occurs (impulse extinguishes in Limb B), owing to the slower conduction velocity in Limb B. Figure 114.1(B) shows what happens when a critically timed premature impulse encounters these pathways—Limb A has not yet recovered, but Limb B has done, so the impulse travels down B to the His–Purkinje system, but it travels slowly, as B can only conduct impulses slowly. The result is prolonged AV conduction (i.e. a long PR interval for that beat). The impulse can then enter Limb A at its distal end, and conduct backwards up Limb A to the atrium, as Limb A has by now recovered from the previous beat. The atrium is thus activated retrogradely via Limb A, and the impulse then re-enters B anterogradely, and thus AVNRT is initiated (Figure 114.1(C)).

The exact anatomical location of these pathways is not clear, but they are believed to lie in the region of the inferior inter-atrial septum, adjacent to the tricuspid valve and the coronary sinus os. This region is termed the ‘triangle of Koch’; the compact AV node and

the fast pathway fibres lie at the apex of this triangle, and the slow pathway fibres run along the right side of the triangle, adjacent to the coronary sinus os. These pathways meet distally in the distal compact AV node, just proximal to the His bundle, and their proximal ends are joined most probably by perinodal atrial tissue

The association between dual AV nodal pathways and clinical AVNRT is not perfect; the presence of two AV nodal pathways does not necessarily imply AVNRT will occur, and neither can dual AV nodal pathways be demonstrated in all cases of AVNRT.

Typical symptoms of the disease, and less common symptoms

The most common symptom is palpitations, affecting nearly all patients. Other symptoms include dizziness, dyspnoea, chest pain, fatigue, and syncope. The type and severity of symptoms depends in part on the rate of the tachycardia, and the presence of any associated heart disease. AVNRT involves near-simultaneous mechanical activation of the atria and the ventricles and, as a consequence, the contraction of the right ventricle against an open tricuspid valve may result in a pounding sensation in the neck in many patients.

Demographics of the disease

AVNRT represents 50%–60% of SVT cases. It is more common in women (2:1). AVNRT is more likely to occur in younger patients, but can present at any age. The mean age of symptom onset is the third decade.

Natural history, and complications of the disease

Although the natural history of AVNRT is quite variable, the electrophysiological properties of the AV node change over time and, generally speaking, symptoms decrease with advancing age. Given that SVT due to AVNRT is rarely ever incessant but, rather, is paroxysmal in nature, it is not associated with a tachycardia-mediated

Figure 114.1 (A) Fast and slow pathways, conducting both antero- and retrogradely. In this diagram, the electrical impulse passes quickly down the fast pathway, and back up the slow pathway, meeting the much slower anterograde impulse, so blocking ongoing conduction in the slow pathway. (B) The longer refractory period of the fast pathway means that when a supraventricular extrasystole arrives early, the fast pathway is blocked, as shown here, and the impulse passes down the slow pathway, which has a shorter refractory period. (C) A ventricular extrasystole passes up the fast pathway, but not up the slow pathway, which has depolarized more recently and so is still refractory. This allows the impulse to re-enter the slow pathway from above, triggering a re-entrant arrhythmia.

Reproduced with permission from Yaver Bashir, Timothy R. Betts, and Kim Rajappan, *Cardiac Electrophysiology and Catheter Ablation*, Oxford University Press, Oxford, UK, Copyright © 2010

cardiomyopathy. And, unlike atrial flutter and fibrillation, there is no need for anticoagulation associated with AVNRT, in the absence of another indication for anticoagulation.

Approach to diagnosing the disease (including diagnostic pitfalls)

The ECG during AVNRT demonstrates a regular tachycardia, usually with narrow QRS complexes (which implies that ventricular activation is occurring only over the normal His–Purkinje cardiac conduction system). P waves may not be visible (i.e. completely buried inside the QRS), may be seen in the ST segment, or, less commonly, may be seen after the T wave, usually with a negative vector in the inferior ECG leads. The finding of an ‘RsR’ pattern in Lead V1 during tachycardia is highly specific for AVNRT (see Figure 114.2). Comparing the tachycardia 12-lead ECG to the sinus rhythm ECG is the easiest way to identify if P waves are visible.

Clues to differentiating AVNRT from the other types of SVT are found in the mode of initiation of the tachycardia—often, AVNRT is seen to initiate after a premature P wave conducts to the ventricles via the slow AV nodal pathway, as the fast AV nodal pathway (the usual route for A–V conduction) has not yet recovered sufficiently from the previous beat to conduct an impulse. The result is a longer PR interval, followed by retrograde atrial activation via the fast AV nodal pathway (which has now recovered), and ongoing AVNRT. The QRS is usually narrow, but may be wide if rate-related left or right bundle branch aberration occurs or, alternatively (and more rarely), in the presence of a bystander accessory A–V connection (bundle of Kent) capable of A–V conduction during AVNRT (termed ‘pre-excited AVNRT’).

Roughly 10% of patients demonstrate 2:1 A:V block during AVNRT, and only a very small minority show 2:1 V:A (retrograde) block—but, as the P waves are often not apparent, this is usually not seen on the ECG. There can be variation in cycle length (tachycardia rate) during an episode of AVNRT, and this is generally due to variation in the antegrade AV nodal conduction time (slow pathway conduction). QRS alternans can also be seen during AVNRT, again, due to antegrade AV nodal conduction variability.

Another 12-lead ECG clue to diagnosing AVNRT is the finding of alternating long and short PR intervals on a sinus rhythm ECG. Some patients can demonstrate ongoing antegrade conduction down both fast and slow AV nodal pathways, resulting in two QRS complexes for each P wave. This ‘two-for-one’ phenomenon is rarely seen, and is essentially a non-re-entrant form of AV nodal tachycardia.

Another form of AVNRT, atypical AVNRT, occurs less frequently than the typical AVNRT just described. In atypical AVNRT, antegrade conduction is via a fast or ‘intermediate’ pathway, and retrograde conduction via the slow pathway (i.e. the same circuit, in reverse). The result is an SVT with a long RP interval (owing to the slow pathway conducting retrogradely in this case). A ‘slow–slow’ form of AVNRT also exists, but this is rare.

Often, an invasive electrophysiology study is required to make the diagnosis of AVNRT when the ECG diagnosis is not clear.

‘Gold-standard’ diagnostic test

The gold-standard diagnostic test is the invasive electrophysiology study.

Acceptable diagnostic alternatives to the gold standard

There are currently no other diagnostic tests that can definitively diagnose AVNRT, other than an invasive electrophysiological investigation.

Other relevant investigations

No other specific investigations are routinely indicated; however, some patients may warrant investigation for coronary ischaemia (if chest pain and ischaemic ECG changes are noted during episodes of AVNRT), and echocardiography to exclude structural heart disease (if hypotension, shock, and syncope are prominent features).

Prognosis and how to estimate it

As previously mentioned, the symptom burden tends to decrease with advancing age and, as this is almost never a persistent arrhythmia but rather a paroxysmal SVT, it is not associated with tachycardia-mediated cardiomyopathy. In the absence of heart disease, the prognosis is usually good.

Treatment and its effectiveness

Acute management

Acute management focuses on acutely changing the conduction properties of the slow or fast pathways, to rendering them less favourable to ongoing re-entry. Carotid sinus massage, Valsalva, or other ‘vagal’ manoeuvres can terminate an episode of AVNRT, by slowing antegrade slow-pathway conduction. They are more successful if performed early after tachycardia onset. The tachycardia may only slow briefly, rather than terminating with these manoeuvres.

If these fail to terminate tachycardia, adenosine is the next and best treatment. It is given by rapid intravenous push (12 mg and then, if necessary, 18 and 24 mg, preferably via a proximal vein), although the drug will still be effective if given at a larger dose (18–24 mg) peripherally. Vagal manoeuvres should be reattempted after adenosine administration, if the drug has been unsuccessful. As with vagal manoeuvres, the effect of adenosine may be to merely slow the tachycardia briefly (reflecting slowing of conduction velocity in the slow AV nodal pathway) rather than terminating it.

Figure 114.2 The PR interval duration will depend on whether a fast or slow pathway is used for conduction; AVN, atrioventricular nodal.

Alternatives to adenosine for acute termination of AVNRT include intravenous calcium-channel blockers (diltiazem, verapamil) or beta blockers (metoprolol, atenolol, esmolol), but these agents can cause significant negative inotropic side effects and, in the case of beta blockers, can precipitate acute bronchospasm in patients with reactive airways disease.

As is the case for all tachycardias in the setting of haemodynamic compromise, electrical cardioversion (synchronized) is the first treatment of choice.

Class IA, IC, and III antiarrhythmic drugs are rarely ever used for the acute termination of AVNRT, but are effective in slowing retrograde fast-pathway conduction, and thus terminating the tachycardia.

Prevention of recurrences

Digoxin, beta blockade, and calcium-channel blockade are all effective in prevention of recurrent episodes of AVNRT, but these agents need to be taken every day in order to be effective, and so the frequency of episodes would need to justify this approach. Also, the use of these agents is frequently complicated by side effects (fatigue, dizziness, effort intolerance, depression). Similarly, Class IA (procainamide, disopyramide, quinidine), IC (flecainide, propafenone), and III (sotalol, amiodarone) drugs are effective in preventing recurrent episodes of AVNRT, but the side effects of these agents, in particular their tendency to QT-interval prolongation and sudden death, make them less attractive options for the long-term management of AVNRT.

Percutaneous catheter ablation of the slow AV nodal pathway is now an established treatment for recurrent symptomatic AVNRT, and should be offered early in the natural history of the condition. Acute procedural success rates and long-term success rates are around 95%, with no requirement for ongoing medical prophylaxis against further episodes in those successfully treated. The procedure is minimally invasive, and performed by the transvenous route (usually femoral vein) and, as such, can be complicated by vascular injury and perforation, but this is uncommon (~0.5%). The other significant complication of slow pathway ablation for AVNRT treatment is inadvertent compact AV nodal ablation, resulting in complete heart block and the need for emergent permanent pacing. This also is a rare occurrence (~0.5%), but may be a significant consideration, especially in very young patients, for whom a permanent pacemaker would involve numerous device and lead revisions over the ensuing years.

Key points

The key points concerning AVNRT are as follows:

- AVNRT is one of the four types of SVT, the others being atrioventricular re-entrant tachycardia, focal (ectopic) atrial tachycardia, and atrial flutter.

- Symptoms include palpitations, dyspnoea, chest pain, dizziness, and syncope.
- AVNRT results from a re-entrant circuit which is normally made up of two AV nodal pathways with differing conduction and recovery properties and termed the slow and the fast AV nodal pathways.
- Typical AVNRT is an SVT with a short RP interval; retrograde atrial activation is via the faster of the two pathways, and hence P waves are either very closely related to the QRS complexes, or are buried within them (not seen).
- Atypical AVNRT is rare, and is an SVT with a long RP interval; P waves are seen after the QRS complexes. Retrograde atrial activation is via the slow pathway in this case, and antegrade activation of the His bundle is via the fast pathway.
- The QRS will be wide if there is preexisting bundle branch block (apparent on ECGs performed during sinus rhythm), or can be wide if rate-related bundle branch block is encountered during tachycardia, or in the presence of an accessory AV connection. But, generally, the QRS is narrow.
- Clues to the diagnosis of AVNRT involve the suggestion of dual AV nodal pathways at the start of the tachycardia, or on sinus rhythm ECGs. The RSR' pattern in V1 during tachycardia is very specific for typical AVNRT.
- Carotid sinus massage, other vagal manoeuvres, and IV adenosine may acutely terminate AVNRT, or may briefly slow the rate only.
- AV nodal blocking drugs are useful for prophylaxis, but side effects often limit the clinical utility of such drugs.
- Percutaneous transvenous catheter ablation of the slow AV nodal pathway is the treatment of choice for most patients with recurrent symptomatic AVNRT, and provides a long-term cure in over 95%. This technique is associated with a ~0.5% risk of adverse outcomes, including the need for a permanent pacemaker, and this needs to be fully discussed with the patient prior to considering this approach.

115 Atrioventricular re-entrant tachycardia

Michael Jones, Norman Qureshi, and Kim Rajappan

Definition of the disease

Atrioventricular (AV) re-entrant tachycardia (AVRT) is a type of supraventricular tachycardia (SVT), manifesting most commonly as a regular, narrow-QRS-complex tachycardia. It is usually a paroxysmal tachycardia, and is dependent upon the presence of an accessory electrical connection located between the atria and the ventricles (distinct and separate from the AV node–His–Purkinje system) and which is capable of atrioventricular (antegrade) or ventriculoatrial (retrograde) electrical conduction (or both). This pathway, together with the AV node–His–Purkinje system and the atrial and ventricular myocardium, forms a macro-re-entrant circuit that enables AVRT to occur.

AVRT can be **orthodromic (oAVRT; 95% of cases)**, in which case antegrade conduction occurs via the AV node–His–Purkinje system, and retrograde conduction via the accessory pathway; or **antidromic (aAVRT)**, in which case antegrade conduction occurs via the accessory pathway, and retrograde conduction via the AV node–His–Purkinje system. The latter type has a wide QRS complex during tachycardia, as the ventricles are exclusively activated by the accessory pathway and, as such, aAVRT can be mistaken for ventricular tachycardia. A third type of AVRT, termed 'pathway-to-pathway' AV nodal re-entrant tachycardia (AVNRT), is infrequently seen; two accessory pathways form the limbs of the re-entrant circuit, the QRS is fully pre-excited (just as with aAVRT), and the AV node–His–Purkinje system is a bystander (not involved in the tachycardia circuit).

Aetiology of the disease

As previously mentioned, AVRT arises as a consequence of an accessory electrical connection located between the atria and the ventricles and which is capable of electrical conduction in one or both directions. The majority of antegradely conducting (or '**manifest**') accessory pathways can also conduct retrogradely; only 5% of patients have pathways that only conduct antegradely.

A pathway only capable of retrograde conduction is termed '**concealed**', as it cannot be observed (does not manifest itself) on a routine sinus rhythm ECG (no delta wave). Up to 50% of accessory pathways that participate in AVRT can only conduct retrogradely.

The accessory connection can often be seen both macro- and microscopically as a band of myocardial fibres that traverse the annulus fibrosus; the only electrical structure that should normally traverse the annulus is the His bundle. Accessory pathways are believed to be congenital, representing incomplete separation of the atrial and the ventricular myocardium by the developing annulus fibrosus; however, there is also some evidence to suggest that an accessory connection can be acquired later in life.

In patients with AVRT, one or occasionally two or more accessory pathways are present, connecting the atria and the ventricles electrically. The most common location is the posterolateral mitral valve annulus, but other areas include the posteroseptal and anteroseptal spaces, and the tricuspid valve annulus.

During normal sinus rhythm, antegradely conducting accessory pathways may conduct the atrial impulse to the ventricle, where they insert. As this leads to premature activation of that part of the basal left or right ventricle, earlier than it would have been activated via the normal AV node, the 12-lead ECG is altered, with a widening of the QRS; this widening reflects the early basal ventricular activation (termed 'pre-excitation') **which occurs at the same time (i.e. fuses with) activation of the rest of the ventricles by**

the AV node–His–Purkinje system. This feature is called a **delta wave** and represents a slurring, and usually a shortening, of the PR interval. The extent to which this occurs, or the degree of pre-excitation (i.e. the amount of QRS widening/magnitude of the delta wave), depends on the location of the accessory pathway, the sinus rate, and the electrical conduction properties (velocity) of the atria and the AV node; for example, a left lateral accessory pathway may only encounter an atrial depolarization when the impulse has already conducted through the AV node and depolarized a large volume of the ventricles; thus, the contribution of pre-excitation to the ECG is relatively small in this case. The opposite is true of pathways located close to the sinus node and AV node. It is quite common to see variable degrees of pre-excitation on serial ECGs, given that the relative contribution of the AV node (largely determined by autonomic tone, which is variable) to ventricular activation will vary continuously over time. A distant (i.e. left free wall) accessory pathway that can conduct antegradely but does not manifest any delta waves on the ECG is termed a '**latent**' pathway. Most accessory pathways conduct very rapidly, and recover very rapidly, unlike AV nodal tissue.

During sinus rhythm, concealed accessory pathways (retrogradely conducting-only accessory pathways) do not alter the QRS width, but if premature ventricular complexes (VPCs) occur, retrograde P waves (atrial echo beats) can occasionally be seen following the VPC (as a consequence of retrograde conduction from the ventricle back up the pathway to the atria). These 'atrial echoes' can also be seen occasionally following a normally conducted QRS, and they manifest as a perturbation of the normal ST segment or T wave.

During normal sinus rhythm in a patient with a left-sided accessory pathway capable of bidirectional conduction, the sinus beat activate the ventricles by both the AV node and the accessory pathway, resulting in a fusion of ventricular activation and a delta wave on the surface 12-lead ECG. In the setting of a VPC, atrial activation may occur retrogradely via the accessory pathway, resulting in an atrial echo beat with an unusual P wave appearance, noted as a deflection in the terminal QRS/ST complex.

AVRT arises when an impulse (generally a premature atrial or ventricular depolarization) blocks (fails to conduct through) either the AV node or the accessory pathway, but still manages to conduct via the **other** pathway, often with a slower conduction speed than normal, thus permitting the other pathway (that had initially been unable to conduct the premature impulse) **to recover sufficiently to reconduct the impulse in reverse direction and so initiate tachycardia.**

Most commonly, this situation arises when a premature atrial beat blocks antegradely, completely, in the accessory pathway, manifesting as sudden and complete loss of the pre-excited appearance of the QRS for that beat (i.e. the QRS narrows to normal). The impulse conducts through the AV node, but with delay (a longer PR interval). This electrical delay in the AV node allows the accessory pathway to recover excitability completely, and so it conducts the ventricular depolarization back to that part of the atrium where the accessory pathway inserts. It can then re-enter the AV node antegradely, thus initiating oAVRT.

In oAVRT, a premature left atrial depolarization does not conduct down the accessory pathway (as the pathway is still refractory from the preceding sinus beat) but instead conducts down the AV node–His–Purkinje system, albeit more slowly (i.e. with a longer PR interval). Conduction then spreads through the ventricular myocardium, eventually reaching the basal left ventricle and the location of the accessory pathway. Given that the pathway has, by this time,

recovered from its refractoriness, it conducts the impulse backwards to the left atrium, thus initiating oAVRT.

Tachycardia initiation can also occur from the ventricle; a PVC blocks in the His–Purkinje system but conducts backwards up the accessory pathway and activates the atrium, thence eventually activating the AV node, His bundle, and ventricles and consequently initiating oAVRT.

In oAVRT, conduction to the ventricles (the antegrade limb) occurs via the normal AV node–His–Purkinje system, and retrograde conduction to the atria is via the accessory pathway. The reverse situation also arises, although it is less common; this is termed aAVRT. In aAVRT, ventricular activation occurs entirely over the accessory pathway, and the 12-lead ECG is fully pre-excited. The initiation of aAVRT generally results from a premature atrial beat which blocks in the AV node but conducts to the ventricles via the accessory pathway, giving rise to a fully pre-excited 12-lead ECG appearance (the ventricles are entirely activated by the accessory pathway, with no contribution from the AV node). The His–Purkinje system, AV node, and, finally, the atria are then activated retrogradely, thus resulting in aAVRT.

Typical symptoms of the disease, and less common symptoms

The most common symptoms of AVRT are palpitations, dizziness, dyspnoea, chest pain, fatigue, and syncope. As with AVNRT, the type and severity of symptoms depends in part on the rate of the tachycardia, and the presence of any associated heart disease. AVRT tends to be faster than AVNRT, but a great deal of overlap exists. In the case of persistent junctional reciprocating tachycardia (PJRT), owing to the slow conduction properties of the accessory pathway, incessant tachycardia is often present and, if the tachycardia is not diagnosed early, patients may present later in life with symptoms of heart failure from having developed a tachycardia-mediated cardiomyopathy.

Demographics of the disease

AVRT accounts for roughly 35% of all cases of SVT, and is therefore the second most common form of narrow-complex SVT, after AVNRT, which represents 50%–60% of SVT cases. The overall incidence of antegradely conducting accessory pathways detected on ECGs is between 0.01% and 0.31%; however, this does not necessarily correlate with symptomatic tachycardia predisposition. AVRT affects all ages, but the incidence decreases with age, with a mean age of symptom onset in the thirties. The incidence of accessory pathways in first-degree relatives of patients with pre-excitation is 3.4%, significantly higher than in the general population. Although pre-excitation appears to be lost in nearly one-quarter of cases over time, the relationship of this observation to symptom frequency is unclear.

Natural history, and complications of the disease

Of patients with A–V bypass tracts, between 40% and 80% will manifest tachycardias at some stage, with the tachycardia most commonly being oAVRT. aAVRT is much less common and, interestingly, atrial fibrillation or flutter may be the initial arrhythmia noted in 5%–10% of these patients, rather than AVRT.

Up to 50% of patients with AVRT will experience atrial fibrillation at some stage; the reasons for this are not clear. Overt pre-excitation (antegradely conducting accessory pathways) is associated with atrial fibrillation five times more than concealed pathways of a similar location are.

Antegradely conducting accessory pathways are often capable of very rapid and frequent conduction of atrial arrhythmias to the ventricles. This is an important consideration in assessing the potential for the accessory pathway to induce ventricular fibrillation in the setting of atrial fibrillation. Similarly, in the setting of atrial flutter, 1:1 atrio-ventricular conduction can occur, resulting in ventricular rates of 300 min⁻¹. Ventricular fibrillation and sudden death can occur in a small percentage of these patients. The incidence of sudden death (SCD) in patients with antegrade pre-excitation is quite low, ranging from 0%

to 0.39% annually. Most patients with an accessory pathway and who have survived an aborted episode of SCD have a history of AVRT or atrial fibrillation. The main predictors of risk include the refractory period of the pathway (i.e. how quickly the pathway can recover from one depolarization and conduct another), and the shortest R to R interval seen during atrial fibrillation; an effective refractory period of <250 ms, measured at an electrophysiology study, and a minimum R to R interval less than 250 ms during an episode of atrial fibrillation are considered to be markers of increased risk. Conversely, a pathway that demonstrates intermittent pre-excitation is not likely to be dangerous, as the refractory period and minimum R-to-R intervals are unlikely to be <250 ms if studied at an electrophysiology study. As such, patients of this latter type rarely require an invasive study for the purpose of risk stratification.

Concealed bypass tracts (retrogradely conducting only) can be fast-conducting or (much less commonly) slowly conducting. The former gives rise to paroxysmal SVT with a long RP (and therefore short PR) interval, and the latter can result in constant re-entrant tachycardia and a tachycardia-mediated cardiomyopathy (PJRT is one such type, often seen in children or adolescents).

Accessory pathways can be associated with other congenital cardiac disease, most notably Ebstein's anomaly (which is associated in 10% of cases with pre-excitation). Right-sided accessory connections seem to be much more commonly associated with congenital heart disease than left-sided ones are (45% compared to 5%).

Approach to diagnosing the disease (including diagnostic pitfalls)

AVRT, like AVNRT, manifests most commonly as a regular, narrow-QRS-complex tachycardia on the ECG, with or without apparent P waves. Differentiating AVRT from other types of SVT can be difficult, but there are some additional clues that can suggest AVRT as the diagnosis; for example, the presence of delta waves on the baseline 12-lead ECG favours AVRT, as does a long RP interval. Also, if any periods of AV block are seen (i.e. two or three P waves per QRS complex), this effectively excludes AVRT from the diagnosis, given that AVRT requires the atrium and the ventricle as integral parts of the tachycardia circuit. Atrial tachycardia and flutter, on the other hand, do not require the ventricular myocardium to sustain the arrhythmia (which is confined to the atria); therefore, periods of AV block can be seen during ongoing tachycardia. Often, the only way to firmly establish AVRT as the diagnosis is to perform an invasive electrophysiology study.

Occasionally, antegradely conducting accessory pathways are present in patients who experience other tachycardias, and this can give rise to other forms of 'pre-excited' tachycardia that can make diagnosis challenging. For example, a patient with atrial flutter, atrial tachycardia, or AVNRT may have an antegradely conducting accessory pathway (either manifest or latent during sinus rhythm) which causes a degree of QRS widening during tachycardia, but which is not itself a part of the tachycardia mechanism. Pre-excited atrial fibrillation is another example of a bystander accessory pathway which carries with it certain specific risks needing to be considered, as previously described.

'Gold-standard' diagnostic test

The gold-standard diagnostic test for pre-excitation on the ECG and AVRT is the invasive electrophysiology study.

Acceptable diagnostic alternatives to the gold standard

There are currently no other diagnostic tests that can definitively diagnose AVRT, other than an invasive electrophysiological investigation.

Other relevant investigations

Given the association between accessory pathways and congenital cardiac abnormalities, especially Ebstein's anomaly, echocardiographic

investigation should be considered in all patients with accessory pathways, especially right-sided pathways, as the association is stronger here. No other specific investigations are routinely indicated; however, some patients may warrant investigation for coronary ischaemia (if chest pain and ischaemic ECG changes are noted during episodes of AVRT).

Prognosis, and how to estimate it

Over time, some patients lose the pre-excited appearance to their ECG. The likelihood of experiencing symptomatic arrhythmia relates to the age at diagnosis, with older patients less likely to experience AVRT than patients diagnosed with pre-excitation at an early age. The risk of SCD in the setting of atrial fibrillation and an antegradely conducting accessory pathway is discussed in 'Natural history, and complications of the disease'.

Treatment and its effectiveness

Acute management

The immediate treatment for an episode of AVRT should focus on termination. In the first instance, so-called vagal manoeuvres can be tried; for example, the Valsalva manoeuvre and carotid sinus massage are often effective in terminating an episode, especially if they are attempted early. Failing these, acute pharmacotherapy can be administered, with the same intention of acutely terminating the arrhythmia. Adenosine is probably the best initial choice of drug, and needs to be administered as a rapid IV bolus via a proximal vein, given the very short plasma half-life of this drug. Adenosine can induce premature atrial extrasystoles, and can reinduce AVRT. Other choices of agent include verapamil, and then flecainide. In the setting of hypotension or haemodynamic instability, DC cardioversion is appropriate, if the other measures have failed or are inappropriate.

In the setting of a wide-QRS tachycardia in a patient suspected of having an accessory pathway, it is important to determine whether or not atrial fibrillation is in fact the underlying arrhythmia—for the reason that any drug which is administered in this situation and which has AV nodal blocking properties (i.e. beta blockers, centrally acting calcium-channel blockers, digoxin, adenosine) will cause AV nodal block, thus preferentially causing ventricular activation to occur exclusively via the accessory pathway (without actually terminating the underlying atrial fibrillation). The effect of this can be the induction of ventricular fibrillation, and SCD. In the situation of an irregular, rapid, wide-complex tachycardia, IV flecainide is the drug of choice, after which DC cardioversion should be chosen as the best management.

Prevention of recurrences

The decision regarding when to institute prophylactic treatment against recurrent SVT episodes is difficult, and essentially depends on the degree to which the symptoms are interfering with a particular patient's life and work. For example, some patients are easily able to terminate episodes rapidly with a vagal manoeuvre, without the need for medications or presentations to the emergency room. These patients do not need to take regular prophylaxis against further episodes. On the other hand, if episodes are frequent and intrusive, or cannot be terminated with vagal manoeuvres, beta blockers and non-dihydropyridine calcium-channel blockers are frequently prescribed, given their (relatively) superior safety and side-effect profile when compared to Class I and III antiarrhythmic agents. The benefits of these drugs, on the other hand, may be limited, as they do not affect accessory pathway function directly—rather, they slow AV nodal transit and might possibly (in the case of beta blockers) reduce the catecholamine-mediated premature atrial complexes that can induce episodes of AVRT.

If these agents are ineffective, then Class Ic antiarrhythmic agents (flecainide, propafenone) are the next treatment of choice, but the pro-arrhythmic potential of these drugs (especially in patients with structural or ischaemic heart disease) limits their use. Amiodarone and sotalol are also effective in the long-term prophylaxis of episodes of AVRT, but long-term toxicity, in the case of amiodarone, and pro-arrhythmia, in the case of sotalol (QT prolongation and

torsades-de-points risk) make these drugs less attractive for long-term management.

Electrophysiology studies and percutaneous catheter ablation of the accessory pathway is now an established treatment for recurrent symptomatic AVRT, and should be considered early in the natural history of the condition. Acute procedural success rates and long-term success rates are around 95%, with no requirement for ongoing medical prophylaxis against further episodes in those successfully treated. Additionally, the performing of an electrophysiology study enables risk stratification of the pathway. The procedure is minimally invasive, and is performed by the transvenous route (usually via the femoral vein); as such, it can be complicated by vascular injury and perforation, but this is uncommon (~0.5%). The other significant complication of SVT ablation in general terms is inadvertent compact AV nodal ablation, resulting in complete heart block and the need for permanent pacing. This also is a rare occurrence (~0.5%), but may be a significant consideration, especially in very young patients, for whom a permanent pacemaker would involve numerous device and lead revisions over the ensuing years.

Key points

The key points to note about AVRT are as follows:

- AVRT is one type of SVT, the others being AVNRT, focal (ectopic) atrial tachycardia, and atrial flutter.
- Symptoms include palpitations, dyspnoea, chest pain, dizziness, and syncope
- AVRT results from a re-entrant circuit, made up of the AV node and an accessory pathway between the atria and ventricles. The pathway, AV node, and ventricular and atrial myocardia are all integral parts of the re-entry circuit—as such, AVRT can only ever be seen with a 1:1 atrioventricular relationship—**any periods when the A:V or V:A ratio is 2:1 or more excludes AVRT as the diagnosis.**
- The accessory connection can be **manifest** (delta waves on the sinus rhythm ECG), **latent** (no delta waves seem but pathway is still capable of antegrade conduction), or **concealed** (the pathway can only conduct backwards and so is not apparent on sinus-rhythm 12-lead ECG).
- The delta wave represents a **fusion** of ventricular activation events during sinus rhythm, with some taking place via the AV node, and some taking place via the accessory pathway.
- **oAVRT** utilizes the AV node antegradely, and the accessory pathway conducts retrogradely; **aAVRT** does the reverse (antegrade conduction is via the pathway, and retrograde is via the AV node).
- oAVRT is usually a narrow-QRS-complex SVT (unless bundle branch block has occurred), with P waves seen to follow the QRS complexes in a 1:1 relationship. The RP interval is variable, but is usually longer than that seen in AVNRT.
- aAVRT has a wide and fully pre-excited QRS morphology, as all the ventricular activation is taking place via the accessory pathway.
- Certain patients with antegrade-conducting accessory pathways are at a slightly elevated risk of SCD, as a consequence of very rapid conduction of atrial arrhythmias (generally coincidental atrial fibrillation) to the ventricles, thus inducing ventricular fibrillation. The risk marker for this possibility is a minimum R to R interval during atrial fibrillation of <250 ms, and (at electrophysiology study) an accessory pathway refractory period of <250 ms.
- AVRT in the absence of atrial fibrillation or flutter is not considered an indication for anticoagulation per se.
- Carotid sinus massage, other vagal manoeuvres, and IV adenosine may acutely terminate AVRT. Many patients are successfully managed in the long term with self-administered vagal manoeuvres, which terminate episodes of AVRT but do not reduce the frequency of recurrent episodes.
- AV nodal blocking drugs are frequently used for prophylaxis, but efficacy is often low. Class I and III antiarrhythmic agents are effective, but pro-arrhythmic side effects and long-term toxicities make these less attractive long-term management options.

- Percutaneous transvenous catheter ablation of the accessory pathway is the treatment of choice for many patients with recurrent symptomatic AVRT, provides a long-term cure in over 95%, and, at the very least, can risk stratify the accessory pathway. This technique is associated with a ~0.5% risk of adverse outcomes, including the need for a permanent pacemaker. As such, the pros and cons of an invasive approach need to be fully discussed with the patient prior to considering this approach.

116 Atrial fibrillation

Michael Jones, Norman Qureshi, and Kim Rajappan

Definition of the disease

Atrial fibrillation is a tachycardia arising in the atria, with atrial electrical activity occurring chaotically and continuously, without any effective atrial contraction occurring. The effects of this are an irregular ventricular rate, loss of the atrial contribution to ventricular filling, and the pooling of blood in the atria, thus increasing the risk of thrombus formation. The ventricular rate may be fast, slow, or of normal speed, depending on the state of the patient's atrioventricular conduction.

Atrial fibrillation is classified as paroxysmal (self-terminating within 7 days), persistent (lasting longer than 1 week, or requiring cardioversion to terminate), long-standing (continuous, lasting for ≥ 1 year when it is decided to adopt a rhythm control strategy), or permanent (cardioversion unable to terminate durably to sinus rhythm).

Aetiology of the disease

Atrial fibrillation can arise in structurally normal hearts ('lone' atrial fibrillation) but, more commonly, it occurs in the setting of structural heart disease, namely, as an atrial myopathic process which can be found at microscopic level, even in lone atrial fibrillation patients. This atrioathy is associated with progressive and diffuse changes in electrical conduction velocity and tissue refractoriness (time to recovery of excitability), which results in non-uniform anisotropic conduction of electrical impulses. Or, to put it another way, the atrial tissue progressively develops diffusely and non-uniformly distributed slowing in electrical conduction velocity, but tissue recovery becomes markedly quicker. The complex, multilayered anatomy of the atrial muscular wall itself increases the electrophysiological significance of this anisotropy. In addition to these factors, there exists a diffusely distributed relative imbalance in cholinergic and sympathetic innervation of the atria. These three factors are currently believed to provide the cellular basis for sustained fibrillatory atrial electrical conduction.

The triggering event for episodes of atrial fibrillation has been shown to be high frequency bursts of electrical activity that arise in the very proximal parts of the pulmonary veins, near to where they enter the left atrium. These electrical discharges conduct out from the pulmonary veins into the left atrium, and initiate an episode of atrial fibrillation. The result is disorganized and constantly changing atrial activation patterns, at 'rates' of between 200 and 500 min^{-1} . The AV node normally conducts sinus rhythm with a 1:1 atrial systole:ventricular systole ratio; during atrial fibrillation, the intrinsic physiology of the AV node protects against 1:1 conduction of the fibrillation waves to the ventricles (which would result in ventricular fibrillation and death if it did occur); nevertheless, the ventricular rates are generally elevated in atrial fibrillation, compared to normal sinus rhythm. During an episode of atrial fibrillation, the sinus node is essentially overdrive-suppressed by the fibrillation (i.e. it is constantly penetrated and reset by the fibrillation waves, and does not discharge).

Medical conditions that predispose to developing atrial fibrillation include chronic hypertension/hypertensive heart disease, ischaemic heart disease, heart failure/dilated cardiomyopathy, rheumatic/valvular heart disease, hypertrophic cardiomyopathy, congenital heart disease, pulmonary embolism, myocarditis, pericarditis, obstructive sleep apnoea, obesity, hyperthyroidism, alcoholism, and a family history of atrial fibrillation (genetic factors).

Typical symptoms of the disease, and less common symptoms

Atrial fibrillation may be (a) completely asymptomatic, (b) symptomatic secondary to predisposing medical conditions (e.g. hyperthyroidism),

(c) symptomatic secondary to the sequelae of atrial fibrillation (e.g. left ventricular failure, thromboembolism), or (d) symptomatic directly as a consequence of the atrial fibrillation itself. The latter type can include all of the following symptoms: palpitations, dyspnoea, fatigue, effort intolerance, chest pain, presyncope, syncope, and weakness.

While some paroxysms of atrial fibrillation may be associated with some or all of these symptoms, others are completely asymptomatic, even in the same patient. An important consideration is syncope, which can indicate any of the following: a significant pause after termination of a paroxysm of atrial fibrillation (slow recovery of the sinus node, especially in the elderly); very slow atrioventricular conduction of atrial fibrillation (e.g. in response to excessive AV nodal blocking medication); very rapid atrioventricular conduction in patients with diastolic heart dysfunction, outflow tract obstruction, or rapidly conducting accessory AV connections; or the presence of another arrhythmia, such as ventricular tachycardia, in the setting of left ventricular systolic dysfunction.

Demographics of atrial fibrillation

The overall prevalence of atrial fibrillation is currently around 1%. Atrial fibrillation is more common in men, in all age groups, and the incidence and prevalence increase with age; in those aged over 80, the prevalence is 9%. The overall prevalence appears to be increasing over time.

Natural history, and complications

The natural history of atrial fibrillation is quite variable, and depends to a significant degree on the correction of any predisposing medical conditions (i.e. control of hypertension and hyperthyroidism, correction of valvular heart lesions). Nevertheless, atrial fibrillation tends to progress over time from infrequent to more frequent paroxysms, to persistent episodes requiring cardioversion, and eventually to permanent atrial fibrillation. The expression, 'atrial fibrillation begets atrial fibrillation', refers to the progressive atrioathy and left atrial dilatation that accompany increasing atrial fibrillation burden, such that the electrophysiological abnormalities in atrial myocytes progressively worsen with higher atrial fibrillation burden, and thus predispose to ever more atrial fibrillation. To an extent, the reverse is also true (sinus rhythm begets sinus rhythm, with improvement in the cellular electrophysiological abnormalities).

Untreated, atrial fibrillation may result in (a) no complications (truly silent atrial fibrillation); (b) thromboembolic complications, such as stroke or peripheral arterial or coronary arterial embolization; (c) left ventricular dilatation, impaired systolic contractility, functional mitral incompetence, and heart failure symptoms, especially if ventricular rates have been generally fast ($>100 \text{ min}^{-1}$); and (d) progressive slowing of ventricular rates with advancing age (due to degenerative fibrosis of the AV node), resulting in increasing effort intolerance, fatigue, and, eventually, syncope.

Approach to diagnosing the arrhythmia, including clinical clues, through concentrating on the ECG diagnosis

Atrial fibrillation is a clinical diagnosis in the first instance, based upon the examination finding of an irregularly irregular pulse and usually associated with variation in the intensity of the heart sounds and in the intensity (to palpation) of the carotid and radial pulses. Blood pressure is also variable, beat to beat.

Figure 116.1 ECG showing atrial fibrillation. Panel (a) shows coarse atrial fibrillation (which can mimic atrial flutter), and panel (b) fine atrial fibrillation.

Reproduced with permission from David A. Warrell, Timothy M. Cox, and John D. Firth, *Oxford Textbook of Medicine*, Latest update: May 2017, Figure 16.4.24, Oxford University Press, Oxford, UK, Copyright © 2017.

The diagnosis of atrial fibrillation requires confirmation by ECG in all cases (Figure 116.1); the absence of organized atrial activity (no uniform P waves, although the atrial activation can often appear quite coarse and of high amplitude, especially in Lead V1) is diagnostic. The ventricular response is usually irregular, but may not always be (i.e. in the setting of ventricular pacing in a patient with underlying atrial fibrillation).

Atrial fibrillation should be suspected in patients describing palpitations, dyspnoea, or effort intolerance and who have risk factors for atrial fibrillation, as described in 'Aetiology of the disease'. Patients may not be in atrial fibrillation at the time of clinic review; therefore, ambulatory monitoring should be performed to attempt making the diagnosis. This can take the form of a 24-hour Holter monitor, a ≥ 2 -week external event recorder, or an implantable subcutaneous loop monitor—the choice depending on the frequency of symptoms, and the difficulty and significance of making the diagnosis in each case (i.e. it might not be justified in some patients to proceed to invasive monitoring procedures).

Other arrhythmias may appear irregularly irregular on clinical examination, namely, atrial flutter and atrial tachycardia with variable AV nodal conduction. Prolonged examination should reveal periods of regularity, at different rates; in these cases, however, only the ECG provides a definitive diagnosis.

Other diagnoses that should be considered

Atrial flutter frequently coexists with atrial fibrillation in the same patient, and can produce symptoms which are similar to those of atrial fibrillation. Most other clinical arrhythmias can also produce symptoms similar to those of atrial fibrillation, including supraventricular tachycardia (ectopic atrial tachycardia, multifocal atria tachycardia, AV nodal re-entrant tachycardia, and AV re-entrant tachycardia), and ventricular tachycardia. The ECG provides the definitive diagnosis of atrial fibrillation and distinguishes it from the other tachyarrhythmias.

'Gold-standard' diagnostic test

The gold-standard diagnostic test for atrial fibrillation remains the ECG; the finding of no definite P waves and, frequently, an irregular ventricular rhythm, is diagnostic.

Acceptable diagnostic alternatives to the gold standard

There are currently no other diagnostic tests that can definitively diagnose atrial fibrillation, other than electrocardiographic or invasive electrophysiological investigation.

Other relevant investigations

Echocardiography should be performed in all cases, to investigate for valvular heart disease, hypertensive heart disease, intra-cardiac shunts (an agitated saline study may be required if clinical suspicion of a shunt is high), left ventricular size and function, left atrial dimension, pulmonary pressures, right-heart function, and pericardial appearance. Full blood examination and clotting studies are mandatory, to exclude anaemia and define baseline coagulatory function (important if anticoagulation or antiplatelet therapy is being considered). Renal function and electrolyte testing are essential, as a prelude to the safe use of many relevant medications (angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor antagonists, calcium-channel and beta blockers, digoxin, direct rennin inhibitors, diuretics, etc.). Baseline liver function is mandatory also, prior to the institution of vitamin K analogue therapy, or amiodarone/dronedaron therapy.

Other investigations may be indicated, depending on the clinical setting; a suspicion of coronary disease or the desire to use Class I antiarrhythmic drugs might mandate an exercise treadmill test, a myocardial perfusion scan, or a coronary angiogram; the need to assess heart-rate control in long-term rate-controlled atrial fibrillation might require a 24-hour, ambulatory Holter monitor and an exercise treadmill test; alternatively, an invasive electrophysiology study may be required, if pre-excitation is suspected, or if distal conduction system disease is suspected in the context of unexplained syncope. Finally, transoesophageal echocardiography may be indicated in the setting of elective cardioversion, if anticoagulation has been subtherapeutic, to exclude the presence of left atrial appendage thrombus.

Prognosis

The data from the Framingham and other epidemiological studies have suggested a slight reduction in life expectancy in sufferers of atrial fibrillation, but whether this is largely due to the comorbid conditions that predispose to atrial fibrillation is unclear.

If the atrial fibrillation is left untreated, there is an increased risk of thromboembolic events in paroxysmal, persistent, and permanent atrial fibrillation patients, and this risk increases with age, gender, and comorbid conditions. The CHA₂DS₂-VASc scoring algorithm is currently the most widely accepted means of determining the long-term anticoagulation requirements of any individual patient. Treatment with antiplatelet or anticoagulant therapy has a definite and favourable impact on the risk of thromboembolism, but at the cost of a higher risk of bleeding. This bleeding risk profile is slightly improved with newer direct-acting oral anticoagulants (DOAC) anticoagulants (DOAC), such as dabigatran, a

direct thrombin inhibitor, or rivaroxaban, apixaban and edoxaban which target Factor Xa directly. Before prescribing long-term anticoagulation, consideration of the bleeding risk and potential for falls must be made. In the case of falls risk and bleeding, recent data suggest that a very high burden of falls is needed before the risks of anticoagulation outweigh the benefits in patients at high risk of stroke.

There are as yet no conclusive data that reverting atrial fibrillation to sinus rhythm and attempting to maintain sinus rhythm in the long term is associated with any improvement in morbidity or mortality in the majority of patients. Trials of drug therapy to maintain sinus rhythm have not demonstrated a superiority of rhythm control over rate control strategies. This is in part due to the difficulty in restoring and maintaining sinus rhythm in these patients with the drugs currently available for this purpose, the side effects/toxicities of these currently available antiarrhythmic drugs, and the significant patient crossover that has occurred in these studies (i.e. many patients in the rate control arm of the study inadvertently ending up in sinus rhythm for the majority of the study, but still analysed in their original cohort).

There may be prognostic benefits to restoring and maintaining sinus rhythm by catheter ablation, in terms of reduced stroke risk and less heart failure in certain populations, but this is still under investigation in large prospective clinical trials and, at present, these techniques are only offered on the basis of improving atrial fibrillation symptoms that cannot be managed effectively with medical therapy.

Uncontrolled rapid ventricular rates over a prolonged period can lead to a tachycardia-mediated cardiomyopathy, which to a large degree is reversible with correction (slowing) of ventricular rates.

Treatment and its effectiveness

The treatment of atrial fibrillation involves four considerations: (1) emergency vs non-emergent management, (2) management of symptomatic paroxysmal atrial fibrillation, (3) decisions on a rate control or a rhythm control strategy in recurrent persistent atrial fibrillation, and (4) the requirements for anticoagulation.

Atrial fibrillation can present as an emergency in some settings: a paroxysm of atrial fibrillation can result in a precipitous fall in cardiac output in certain patients (e.g. those with severe aortic stenosis, severe mitral stenosis, severe hypertensive heart disease with diastolic impairment, or outflow tract obstruction). Significant hypotension and shock in the setting of atrial fibrillation should prompt a search for such underlying conditions. Emergency cardioversion to sinus rhythm is often required in these cases.

In the setting of rapidly conducted atrial fibrillation which requires urgent rate control, where cardioversion is not felt necessary, many medications are efficacious; IV beta blockade with 1 mg aliquots of metoprolol or atenolol, or 1 mg aliquots of verapamil, titrated to ventricular rate, are effective in reducing ventricular rates acutely, but these agents are contraindicated in patients in shock or with significant hypotension—in which case, digoxin is a safer alternative, but often lacks potency in acute rate control. Amiodarone is another alternative here, as it does not cause significant hypotension, but there is a risk of acutely restoring sinus rhythm with its use, and this may not be desirable. In addition to medications for rate control, a search for the cause of the rapidly conducted atrial fibrillation should be made (e.g. sepsis, hypovolaemia, anaemia, hypoxia, etc.) and corrected.

Atrial fibrillation can be conducted very rapidly to the ventricles in patients who have accessory A–V connections capable of conduction at fast rates—this is termed 'pre-excited atrial fibrillation'. This can lead to shock, the induction of ventricular fibrillation, and death. Emergency cardioversion is frequently required in these cases also. The key to diagnosing pre-excited atrial fibrillation is the presence of a very fast ventricular rate, which is also irregular, with QRS complexes continuously varying in width (reflecting differing degrees of fusion of ventricular activation, via the AV node and the AV bypass tract). Another clue is gained from previous ECGs performed during sinus rhythm, which will usually reveal evidence of pre-excitation (a delta wave). In this situation of pre-excited atrial fibrillation, alone of all tachyarrhythmias, the administration of AV nodal blocking agents (adenosine, verapamil, diltiazem, and digoxin) can be fatal, as it leads to near-complete ventricular activation via the bypass tract at very fast rates, and the induction of ventricular fibrillation as a consequence.

The next consideration is the management of paroxysmal atrial fibrillation. In addition to addressing predisposing medical conditions and identifying triggers for episodes, the options include conservative management (rest, relaxation) if symptoms are mild, or cardioversion (electrical or pharmacological) if symptoms merit this. Medications commonly used for chemical cardioversion include Class I and III antiarrhythmic drugs; in the ambulatory setting, patients often self-treat with 'pill-in-the-pocket' therapy, using flecainide or propafenone, primarily. The absence of significant coronary disease and myocardial scar is considered a prerequisite for the safe use of these drugs, as they can be pro-arrhythmic in such patients. In the emergency room, flecainide, propafenone, ibutilide, sotalol, and amiodarone are all available for acute cardioversion. A newer agent, vernakalant, is promising and demonstrates high acute cardioversion rates, but is not yet widely available.

For patients experiencing frequent paroxysms that require termination, regular daily medication with antiarrhythmic drug therapy is often used, and potential medications include flecainide, propafenone, sotalol, and dronedarone. Amiodarone is still used in this setting, but concerns regarding the drug's multiple toxicities limit its use. In some countries dofetilide and ibutilide are available. Regular antiarrhythmic medication use is effective in a large number of patients for controlling symptoms of atrial fibrillation.

For those who fail to respond to drug therapy or who tolerate it poorly, the next option is percutaneous catheter ablation (left atrial ablation, consisting of pulmonary venous antral electrical isolation and sometimes additional linear and focal ablation). This technique can eliminate atrial fibrillation in 70%–80% of patients, but may require more than one procedure, and carries with it some risks, including vascular trauma, cardiac tamponade, stroke, pulmonary vein stenosis, atrio-oesophageal fistula formation, gastroparesis from oesophageal nerve injury, post-procedure iatrogenic atrial arrhythmias, and even death. Nevertheless, it is an effective treatment in highly symptomatic patients for whom drug therapy has been ineffective or poorly tolerated.

For those patients requiring cardiac surgical treatment for another reason (e.g. coronary bypass grafting, valve surgery), consideration should be given to performing an intra-operative atrial ablation procedure (termed the 'maze' procedure) as a part of the surgery. Some centres also offer surgical maze procedures as stand-alone procedures, but the added risks of an open surgical procedure compared to those of a percutaneous transcatheter approach limit this to a small proportion of patients only.

In patients with long-lasting recurrent persistent or permanent atrial fibrillation, where the restoration of sinus rhythm has been unsuccessful by definition, management options include catheter ablation, as previously described, if a rhythm control strategy is desired, or rate control of the atrial fibrillation. In the case of rate control, AV nodal blocking medications are used in the first instance, consisting of beta blockade, calcium-channel blockade, and digoxin. Occasionally, these medications can result in episodes of symptomatic bradycardia, and a ventricular pacemaker is required. In some cases, drugs alone are insufficient to slow AV nodal conduction, or are poorly tolerated—in these cases, ventricular pacing is implemented, followed by AV nodal ablation. In this case, a patient becomes completely dependent on the pacemaker for the generation of a cardiac rhythm.

As previously mentioned, some patients with atrial fibrillation remain asymptomatic for many years, but eventually present with symptoms of bradycardia. The finding is usually one of AV nodal and/or conduction system disease, and permanent ventricular pacing is usually indicated.

Anticoagulation

Anticoagulation and cardioversion

In the setting of acute cardioversion, thromboembolic risk depends on the duration of the current atrial fibrillation episode, and patient-specific risk factors for stroke. As they presently stand, European Society of Cardiology (ESC) guidelines recommend at least 3 weeks of warfarin (international normalized ratio (INR) 2–3) or uninterrupted DOAC administration prior to and 4 weeks after cardioversion (electrical or pharmacological), if atrial fibrillation has been present for ≥ 48 hours. If the duration of atrial fibrillation is definitely less than 48 hours, but the patient is at high stroke risk, heparin or low molecular weight heparin is recommended pericardioversion,

and warfarin/DOAC post cardioversion, in the long term. Finally, if the duration is definitely less than 48 hours, and patient is at low risk for stroke, then pericardioversion anticoagulation is optional, and post-procedure anticoagulation is unnecessary.

An alternative to 3 weeks of pretreatment with warfarin/DOAC is precardioversion transoesophageal echocardiography, which can be used to exclude the presence of a left atrial appendage thrombus—if a thrombus is present, then, obviously, cardioversion is deferred (at least 3 weeks, during which time anticoagulation is administered, followed by repeat transoesophageal echocardiography) but, if there is no thrombus, cardioversion can take place with pericardioversion anticoagulation and with at least 4 weeks of warfarin/DOAC post cardioversion.

Long-term anticoagulation

The decision to anticoagulate in the long term depends on the presence of stroke risk factors (Table 116.1), namely, patient age, sex, history of prior stroke, diabetes, heart failure, vascular disease, and hypertension. Currently, these risk factors are weighted and summed according to the CHA₂DS₂-VASc algorithm, and the score used to determine the merits of aspirin, vitamin K antagonist/DOAC, or no anticoagulation. The greater the number of risk factors, the higher is the yearly stroke risk—one risk factor gives a 1.3% yearly risk of stroke, whereas all nine give a risk of 15.2% per annum. Consideration must always be made of the risk of bleeding on anticoagulation therapy, and the HASBLED score can help in this respect (see Table 116.2 and Figure 116.2); while it is not used to

Table 116.1 The CHA₂DS₂-VASc scoring system for determining risk for stroke in atrial fibrillation patients

a) The risk factor based approach expressed as a point based scoring system, with the acronym CHA ₂ DS ₂ -VASc (Note: maximum score is 9 since age may contribute 0, 1 or 2 points)		
Risk factor	Score	
Congestive heart failure/LV dysfunction	1	
Hypertension	1	
Age ≥75	2	
Diabetes mellitus	1	
Stroke/TIA/TE	2	
Vascular disease ^a	1	
Age 65–74	1	
Sex category (i.e., female gender)	1	
Maximum score	9	
b) Adjusted stroke rate according to CHA ₂ DS ₂ -VASc score		
CHA ₂ DS ₂ -VASc score	Patients (n = 73538)	Stroke and thromboembolism event rate at 1 year follow-up (%)
0	6369	0.78
1	8203	2.01
2	12771	3.71
3	17371	5.92
4	13887	9.27
5	8942	15.26
6	4244	19.74
7	1420	21.50
8	285	22.38
9	46	23.64

Abbreviations: LV, left ventricular; TE, thromboembolism; TIA, transient ischaemic attack.

Note: Actual rates of stroke in contemporary cohorts may vary from these estimates.

Stroke, TIA, or systemic embolism and age ≥75 years are regarded as major risk factors, and others are described as clinically relevant non-major risk factors.

preclude a patient from anticoagulation, it helps in making decision regarding frequency of follow-up, and consideration of alternatives to anticoagulation, where available.

For those patients at high risk of stroke, but who are intolerant of or unfit for anticoagulation, another technology is available, namely the left atrial appendage occlusion device. This device is placed percutaneously into the left atrial appendage, and deployed, thus excluding the appendage from the left atrial blood, and thereby reducing the risk of cardiac thromboembolic events. Although still being investigated, preliminary data suggest that this technique reduces stroke in these patients to a degree similar to that obtained via anticoagulation.

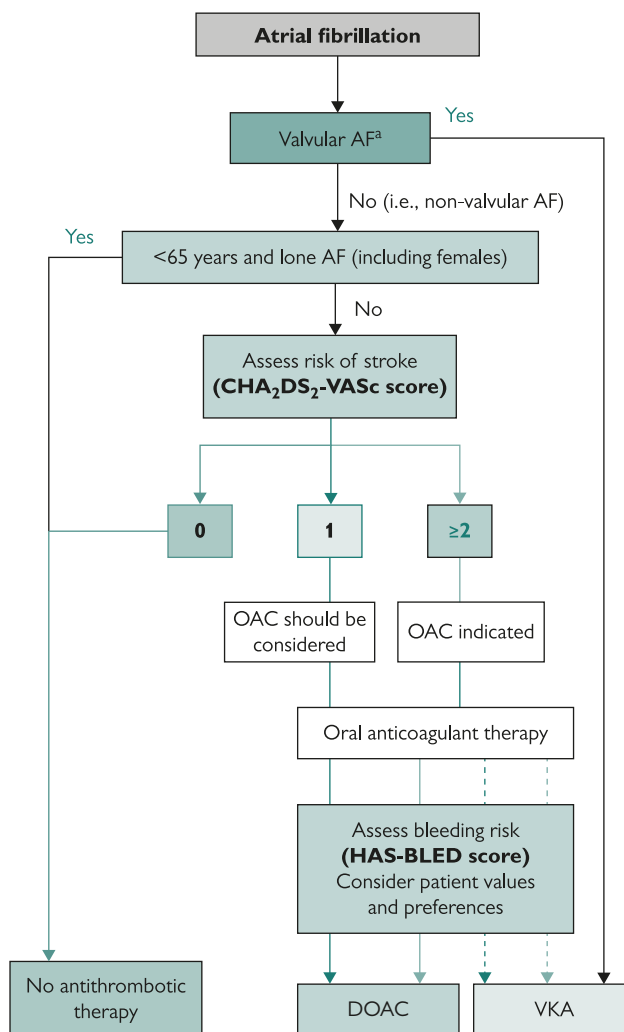

These guidelines are revised periodically, and it is important to be familiar with the latest recommendations.

Normally, once a decision has been made to anticoagulate, this is continued throughout the patient's life, as there is still no technique which can definitively cure atrial fibrillation and be sufficient to eliminate ongoing stroke risk and so enable the discontinuation of anticoagulation.

Key points

The key points concerning atrial fibrillation are as follows:

- Atrial fibrillation is defined by rapid and chaotic atrial activity, usually with an irregular ventricular response rate, which may be fast, slow, or of normal speed.
- The clinical significance of atrial fibrillation relates to the risk of thromboembolism and stroke, the risk of uncontrolled rapid ventricular rates (which can lead to a cardiomyopathy), and the risk of excessively slow ventricular rates (and possible syncope).
- Atrial fibrillation requires an ECG for diagnosis in all cases. The absence of uniform P waves is diagnostic of atrial fibrillation.
- The use of **adenosine** or **carotid sinus massage** results in a transient slowing of the ventricular rate, but has no effect on atrial activity.
- Differentials in the diagnosis for atrial fibrillation include atrial tachycardia, atrial flutter, AV nodal re-entrant tachycardia, and atrioventricular re-entrant tachycardia.
- Atrial fibrillation almost never terminates with a closely coupled sinus beat following the termination of atrial fibrillation; if this is seen, then question whether atrial fibrillation is the correct diagnosis (i.e. ventricular tachycardia or another supraventricular tachycardia may be the correct explanation).
- Ventricular pacing may obscure the underlying presence of atrial fibrillation; in any case of pacing on an ECG, look carefully for evidence of atrial activity.
- The need for anticoagulation depends upon the setting (emergent vs long term), and patient-specific risk factors, which are currently

Antiplatelet therapy with aspirin plus clopidogrel, or—less effectively—aspirin only, should be considered in patients who refuse any oral anticoagulant or cannot tolerate anticoagulants for reasons unrelated to bleeding. If there are contraindications to OAC or antiplatelet therapy, left atrial appendage occlusion, closure or excision may be considered.

assessed by the CHA₂DS₂-VASc score. The decision to anticoagulate is individualized to the patient in every case, and involves the family physician and outpatient services significantly.

- Currently, the main indication for catheter ablation is in drug refractory, symptomatic patients.

117 Atrial flutter

Michael Jones, Norman Qureshi, and Kim Rajappan

Definition of the disease

Atrial flutter is the term given to one of the four types of supraventricular tachycardia (SVT); in it, atrial activation occurs as a consequence of a continuous 'short circuit': a defined and fixed anatomical route, resulting in a fairly uniform atrial rate, and uniform atrial flutter waves on the ECG.

The ventricles are not a part of this arrhythmia circuit, and ventricular activation is variable, dependent on atrioventricular (AV) nodal conduction. Given that the atrial rate is essentially uniform (e.g. 300 min^{-1}), ventricular activation tends to be regular (i.e. 150 min^{-1} , 100 min^{-1} , 75 min^{-1} , etc. if the atrial rate is 300 min^{-1}), or regularly irregular if changes are occurring in the fraction of conducted impulses to the ventricles. When AV nodal conduction permits only 4:1 conduction or less, atrial flutter is usually obvious but, when ventricular rates are higher (150 min^{-1} or more), the flutter waves can be obscured by the QRS complexes, making diagnosis more difficult.

Atrial flutter is of two types: typical and atypical (Figure 117.1). Typical atrial flutter is a right atrial tachycardia, with electrical activation proceeding around the tricuspid valve annulus. This arrhythmia is dependent on a zone of slow electrical conduction through the cavotricuspid isthmus (the tissue lying between the origin of the inferior vena cava and the posterior tricuspid valve). The resulting circuit can be either **anticlockwise** (activation proceeds up the inter-atrial septum, across the atrial roof, down the free wall, and then through the cavotricuspid isthmus to the basal septum) or **clockwise** (down the inter-atrial septum and around the circuit in the opposite direction). Anticlockwise typical atrial flutter is more common.

Atypical atrial flutter refers to all other atrial flutters, and this includes other right atrial flutters (e.g. pericristal flutter), left atrial flutters, post-ablation or post-surgical flutters, and pulmonary vein flutters.

The feature common to all types of flutter and which differentiates flutter from other types of SVT is the presence of a macro-re-entrant anatomical circuit around which the electrical impulse travels continuously and repeatedly, thereby generating the flutter. Even though typical atrial flutter has a fairly obvious and specific appearance on the ECG, atypical flutters do not, and often it is only possible to differentiate atypical flutter from atrial tachycardias by invasive electrophysiology studies, as the ECG alone may be insufficient.

Aetiology of the disease

The cellular change that predisposes to the development of atrial flutter is the presence of regions of atrioopathy (scarring, and the presence of tissue with disordered electrical conduction properties), which provide the substrate for re-entry (short circuiting). The underlying etiologies include long-standing hypertension, chronic lung disease, valvular heart disease, left ventricular hypertrophy, coronary disease, pericarditis, prior cardiac surgery, pulmonary embolism, hyperthyroidism, diabetes, and congestive heart failure. Atypical atrial flutter occurs more commonly in patients with prior cardiac surgery or ablation procedures, and is rare in structurally normal hearts.

Typical symptoms of the disease, and less common symptoms

Atrial flutter can be paroxysmal (occurring in self-limiting bursts) or persistent, and can be an asymptomatic and incidental finding on a 12-lead ECG. Symptoms include palpitations, presyncope, syncope, dyspnoea, exertional intolerance, fatigue, and chest discomfort. Symptoms are more common when ventricular rates are fast, or when AV nodal conduction is poor (and significant ventricular pauses occur).

Figure 117.1 ECG of typical right atrial flutter. Arrows indicate flutter waves (in this case, typical anticlockwise right atrial activation).

As there is the potential during flutter for blood to pool in the left atrium and in particular, the left atrial appendage, thrombosis and embolization can occur.

Demographics of atrial flutter

The incidence of atrial flutter is around 88 per 100 000 per year, although the epidemiology is still not fully explored. It makes up 10% of all SVT presentations to the emergency room. The male to female ratio is 2:1, and prevalence increases significantly with age.

Natural history, and complications

Atrial flutter can occur paroxysmally, remain persistent and stable for prolonged periods, or alternate with a closely related but distinct arrhythmia, atrial fibrillation. If ventricular response rates to atrial flutter remain elevated for prolonged periods, a tachycardia-mediated cardiomyopathy can result, which can usually be reversed with ventricular rate control (slowing). The risk of intra-cardiac thrombus formation parallels that of atrial fibrillation, and can lead to arterial embolic complications and stroke.

As with atrial fibrillation, some patients can present late in life with atrial flutter and high-grade conduction block, requiring a permanent ventricular pacemaker.

Approach to diagnosing the arrhythmia, including clinical clues, through concentrating on the ECG diagnosis

The ECG appearance is classic in the majority of cases of atrial flutter, and consists of sawtooth flutter waves, of a uniform morphology, usually with an isoelectric segment between individual waves (in the case of typical flutter). Given that atrial septal activation is the major determinant of the P wave vector, anticlockwise flutter is associated with negative flutter waves in the inferior leads and V6, and positive waves in V1, with the reverse seen for clockwise flutter. The atrial rate is usually 300 min⁻¹, but this can vary considerably, depending on the presence of atrial scarring or distension, and drug therapy (slowing conduction velocity).

If ventricular rates are too fast to clearly see the flutter waves, then, by increasing AV nodal block briefly (with vagal manoeuvres (carotid sinus massage) or with IV adenosine) the flutter waves will become apparent. Adenosine must be avoided if the presence of an antegradely conducting accessory pathway is suspected (due to the possibility of precipitating 1:1 conduction down the pathway, leading to shock and possible ventricular fibrillation).

Other diagnoses that should be considered

Atrial flutter leads to symptoms which are very similar to those of other tachyarrhythmias, and so an ECG diagnosis is imperative to make a definitive diagnosis of atrial flutter. If the ECG is still inconclusive, then dynamic manoeuvres such as carotid sinus massage, or the acute administration of adenosine, can be helpful.

'Gold-standard' diagnostic test

Despite the ECG often appearing highly suggestive of atrial flutter, in some cases, only an invasive electrophysiology study can differentiate atrial flutter from atrial tachycardia, or other SVTs. This is especially the case when the flutter appears atypical, and the patient has a history of prior cardiac surgery or ablation therapy. Whether invasive electrophysiology is warranted in any particular situation depends upon the precise mechanism of the SVT in that particular case.

Acceptable diagnostic alternatives to the gold standard

Atrial flutter can only be diagnosed from the ECG, or at invasive electrophysiology study.

Other relevant investigations

Echocardiography should be routinely performed, to look for structural heart disease and to quantify left ventricular size and function. Blood tests (full blood count, thyroid function tests, renal function, and electrolytes) should be directed at revealing any underlying aetiology and, where clinically appropriate, chest radiography and an assessment for coronary ischemia should be performed. Baseline coagulation studies should be performed prior to commencing anticoagulation.

Prognosis

Atrial flutter can be well tolerated for years, and is often an incidental finding on an ECG. On the other hand, it can have disabling symptoms as previously described. For patients with poor ventricular rate control, a tachycardia-mediated cardiomyopathy can result, which is generally reversible with treatment. The risk of stroke/arterial embolization differs between patients and, generally speaking, the decision to anticoagulate is based on the same algorithms as are used for atrial fibrillation.

Treatment and its effectiveness

Treatment of atrial flutter involves management of the arrhythmia, and management of thromboembolic risk (i.e. requirement for anticoagulation).

The decision to commence long-term anticoagulation is based upon an assessment of individual patient risk, using the CHA₂DS₂-VASc risk calculator, in the same manner as for atrial fibrillation, and taking into account the patient's bleeding risk. Management of the arrhythmia is directed towards either a rhythm-control strategy (the restoration and maintenance of sinus rhythm), or a rate-control strategy (permitting flutter to continue, but ensuring ventricular rates are controlled).

If atrial flutter is persistent, sinus rhythm can be restored acutely by external electrical cardioversion. The risk of thromboembolism associated with cardioversion depends on the duration of the episode of flutter, and the patient's own specific risk of stroke, which is calculated according to the CHA₂DS₂-VASc risk calculator. For low-risk patients who have been in flutter for less than 48 hours, cardioversion may be attempted without anticoagulation, and there is no requirement for post-cardioversion anticoagulation. If the flutter has been present for >48 hours, then cardioversion should be deferred until at least 3 weeks of therapeutic anticoagulation have passed (international normalized ratio (INR) 2–3 for warfarin, or compliant with a direct-acting oral anticoagulant (DOAC) for the same period), and anticoagulation should be continued for at least 4 weeks post-cardioversion; alternatively, a transoesophageal echocardiogram can be performed to exclude the presence of left atrial thrombus, and the cardioversion performed on heparin periprocedure, with warfarin administered for at least 4 weeks post-cardioversion. For high-risk patients, heparin should be administered periprocedurally, and warfarin/DOAC should be continued indefinitely, in the absence of a major contraindication. In an emergency situation, cardioversion may be performed without anticoagulation beforehand and without a transoesophageal echocardiogram, if the benefit (restoring haemodynamic stability) is believed to outweigh the risk of stroke; but this should be performed with periprocedural heparinization, and warfarin/DOAC should be administered for at least 4 weeks post procedure. These guidelines are revised periodically, and it is important to be familiar with the latest recommendations.

Cardioversion can also be achieved pharmacologically, using the same agents as are used for the cardioversion of atrial fibrillation. Care must be taken to avoid merely slowing the atrial flutter rate, as AV nodal conduction can increase to 1:1, leading to syncope (from sudden rapid ventricular rates). As such, pharmacological cardioversion of atrial flutter should be performed with an AV nodal blocking medication co-administered.

While there is no study that clearly establishes the superiority of long-term rhythm control over long-term rate control, rhythm control by ablation does have certain advantages—namely, typical atrial flutter is readily amenable to percutaneous catheter ablation, which

is curative in 91%, with a fairly low rate of periprocedural complications (an overall 0.5% risk of adverse outcomes, including bleeding, pericardial effusion and tamponade, stroke, and complete heart block). This is different from the case with catheter ablation of atrial fibrillation, where the risks are higher, and procedural success rates lower. Atypical atrial flutter is also amenable to catheter ablation, in selected cases.

Despite atrial flutter ablation being highly effective, and recurrence rates low, a successful ablation does not necessarily imply that anticoagulation is no longer indicated, and this should be explained to any patient contemplating an invasive treatment strategy.

Long-term rhythm control may also be attempted with antiarrhythmic drugs, but caution needs to be exercised in this case; Class III agents may prolong the QT interval, and can precipitate polymorphic ventricular tachycardia (torsades de pointes) and sudden death, and Class I agents slow conduction velocity and, by slowing the flutter rate, can lead to 1:1 conduction through the AV node, as previously described. The risks and benefits of antiarrhythmic drug therapy in patients with atrial flutter need to be carefully weighed in each case.

Rate control of persistent and permanent atrial flutter is a reasonable management option, and the same medications as are used for atrial fibrillation are used in atrial flutter. Nevertheless, rate control in atrial flutter can often prove difficult, owing to the unpredictable nature of the ventricular response in the setting of additional AV nodal blocking medications; unlike the case of atrial fibrillation, where doses and drugs can be titrated fairly accurately to average ventricular response rates, in atrial flutter, sudden unpredictable increases in AV nodal block can occur with the addition of more medications. In such cases, where flutter ablation is not desired, is not feasible, or is unsuccessful, a permanent ventricular pacemaker may be required to provide rate support, in the setting of multiple AV nodal blocking medications. Quite commonly, an AV node ablation by percutaneous transvenous catheter technique is performed in these cases, to eliminate the need for ongoing pharmacological AV nodal blockade.

Key points

The key points regarding atrial flutter are as follows:

- Atrial flutter is defined by rapid, regular, and uniform atrial activity, manifesting on the ECG as continuous flutter waves.
- Atrial flutter results from a macro-re-entrant atrial circuit, which is a fixed anatomical route for ongoing electrical re-entry to occur.
- Typical atrial flutter is a right-atrial arrhythmia, dependent on slow conduction through the cavotricuspid isthmus, and is either anticlockwise or clockwise in direction of conduction around the circuit.
- Atypical atrial flutter refers to all other atrial flutter (i.e. not right-atrial-isthmus dependent), and is therefore a heterogeneous group, including peripulmonary venous atrial flutter, perimitral atrial flutter, pericristal atrial flutter, peri-coronary-sinus atrial flutter, peri-scar atrial flutter, and pericardiotomy atrial flutter.
- The clinical significance of atrial flutter is the same as for atrial fibrillation—the risk of thromboembolism and stroke, and the need to control the ventricular rate.
- Anticoagulation requirements are treated in the same manner as for atrial fibrillation—that is, a risk score is calculated according to the CHA₂DS₂-VASc scoring algorithm, and a decision regarding the need for anticoagulation, aspirin, or neither of these is made on this basis. As for atrial fibrillation, additional considerations regarding anticoagulation apply in the setting of planned cardioversion to sinus rhythm.
- Both rhythm control and rate control are acceptable management options for recurrent persistent atrial flutter; however, unlike the case for atrial fibrillation, percutaneous ablation techniques are of low risk and very high efficacy, and are associated with a very low long-term arrhythmia recurrence rate.

118 Ventricular tachyarrhythmias: Ventricular tachycardia and ventricular fibrillation

Michael Jones, Norman Qureshi, and Kim Rajappan

Definition of the disease

Ventricular tachycardia

Ventricular tachyarrhythmias are abnormal patterns of electrical activity arising from the ventricular tissue (myocardium and conduction tissue). Ventricular tachycardia (VT) is an abnormal rapid heart rhythm originating from the ventricles. The rhythm may arise from the ventricular myocardium and/or from the distal conduction system. The normal heart rate is usually regular, between 60 and 100 bpm, and there is synchronized atrial and ventricular contraction. In VT, the ventricles contract at a rate greater than 120 bpm and typically from 150 to 300 bpm, and are no longer coordinated with the atria. There is still organized contraction of the ventricles in VT, with discrete QRS complexes. It is a potentially life-threatening arrhythmia, with the risk of degenerating into ventricular fibrillation (VF) and resulting in sudden cardiac death. It is characterized by a broad-complex tachycardia (BCT) on ECG. VT can be classified according to morphology, duration of episodes, and haemodynamic status; it can also be classified as idiopathic.

Classification of VT according to morphology

Monomorphic VT occurs when the shape of the QRS complexes repeats itself in each and every lead of a 12-lead ECG, usually originating from the same focus (or ventricular exit site) and representing either increased automaticity or re-entry as underlying mechanisms. An example is right ventricular outflow tract (RVOT) VT, which has a characteristic pattern on 12-lead ECG, with QRS complexes of left bundle branch (LBBB) morphology, and an inferior axis. Polymorphic VT refers to VT with beat-to-beat variations in the contours of the QRS complexes. Torsades de pointes (TdP) is a term reserved for polymorphic VT occurring in the context of a prolonged resting QT interval (prolonged repolarization) and early after-depolarizations. The variation in the QRS morphology and axis in TdP takes the form of a progressive, sinusoidal, cyclic alteration of the QRS axis. The peaks of the QRS complexes appear to 'twist' around the isoelectric line of the recording, hence the term TdP, or 'twisting of points'. Bidirectional VT is classically seen in catecholamine polymorphic VT (CPVT), where there is beat-to-beat alternation of the QRS axis.

Classification of VT according to duration of episodes

Sustained VT is usually defined either as that which lasts longer than 30 seconds, or which requires an intervention for termination. A group of three to five beats of non-sustained ventricular tachycardia (NSVT) are often termed a 'salvo'. NSVT in the setting of ischaemic heart disease has been well described and is used as a prognostic marker in risk stratification of sudden cardiac death (SCD). Haemodynamically stable VT that may last for hours is termed 'incessant', and very frequent episodes of VT requiring cardioversion or multiple therapies from an implantable cardioverter defibrillator (ICD) in situ is termed a 'VT storm'.

Classification of VT according to haemodynamic status

Pulseless VT is VT leading to haemodynamic collapse, without sufficient cardiac output to maintain vital organ function, including consciousness, and often leads to cardiac arrest. It is recognized as one of the shockable rhythms on the Advanced Life Support algorithm. Some VT is associated with a good cardiac output, and may even be asymptomatic—termed 'pulsed VT'. However, such patients' clinical course may still be complicated by pulseless VT or VF in the medium-to-long term.

Classification of VT as idiopathic

VT can occur in patients with structurally normal hearts, and this is often termed 'idiopathic VT'. A significant proportion of patients with idiopathic VT have an underlying 'electrical disorder' as part of the inherited arrhythmogenic syndromes.

VF and ventricular flutter

VF is a grossly disorganized, rapid ventricular rhythm condition which results in uncoordinated contraction of the ventricles, with subsequent loss of cardiac output, and haemodynamic collapse. It has been described as 'chaotic asynchronous activity of the heart' (Figure 118.1). It was originally thought to be as a result of simultaneous independent multiple wavelets that follow random, continuously changing pathways through the myocardium. However, experimental evidence now supports the model of organized centres of 'rotors' representing unstable cardiac excitation as the underlying mechanism of sustaining VF. It usually terminates fatally within 3 to 5 minutes unless

Figure 118.1 Ventricular tachyarrhythmia often deteriorates into ventricular fibrillation, a lethal heart rhythm.

corrective interventions are undertaken. It is the most common arrhythmia noted in patients with out-of-hospital cardiac arrest (up to 75%). It can occur as a primary arrhythmia or, more frequently, as a result of degeneration of VT. The characteristic ECG finding of VF is that of irregular undulations of varying contour and amplitude, with an absence of distinct QRS complexes, ST segments, and T waves. Fibrillatory waves of low amplitude (termed fine ventricular fibrillation) are present when VF is prolonged, and then all electrical activity ceases (asystole) as an agonal event. Ventricular flutter looks like a sine wave with large regular oscillations at a rate of between 150 and 300 bpm (often 200 bpm); it can be difficult to distinguish between ventricular flutter and rapid VT but the difference between the two is often academic.

Aetiology of the disease

More than 50% of those with symptomatic VT have ischaemic heart disease (either acute ischaemia or scar-related VT). The next-largest group has an underlying cardiomyopathy (dilated cardiomyopathy (DCM), hypertrophic cardiomyopathy (HCM), arrhythmogenic right ventricular cardiomyopathy (ARVC), or infiltrative cardiomyopathies, such as sarcoidosis). The others fall into the following groups: inherited arrhythmogenic syndromes (channelopathies), congenital heart disease (tetralogy of Fallot), idiopathic VT/VF, and VT due to drugs (sympathomimetic agents, antiarrhythmics, QT-prolonging agents) or electrolyte imbalances.

The exact electro-anatomical substrates of ventricular tachyarrhythmias in the conditions associated with SCD are discussed in detail in Chapter 120. They are largely a consequence of structural heart disease, with breakdown of normal conduction patterns, both within the myocardium and within the specialized conduction system of the heart. The general principles of cardiac arrhythmia mechanisms prevail, with abnormal automaticity as a result of hypoxia and

increased sympathetic nervous system stimulation, and activation of re-entrant pathways as a result of scarring (which provides a slowly conducting substrate) and differential conduction properties in both myocardial and conduction tissue. A re-entry mechanism accounts for the majority of monomorphic VT. Triggered activity occurs by a non-re-entrant mechanism that appears to be due to after-depolarizations (early and delayed) and is thought to arise from abnormal ionic currents (e.g. long-QT syndrome and Brugada syndrome) and calcium handling (CPVT).

In this section, we will discuss the aetiology and pathophysiology of idiopathic VT and VF, and bundle branch re-entry VT, which is a specific kind of VT that can be seen in those with structural heart disease, as these have not been covered in other sections of the book.

Idiopathic VT

Idiopathic VT, defined as monomorphic VT in patients with no underlying structural heart disease, can have characteristic ECG morphologies based on the foci of the VT: outflow tract tachycardias, annular tachycardias, and fascicular tachycardias (Figure 118.2). These types of VT often respond well to drug therapy, and are amenable to ablative therapy when medical therapy fails. In outflow tract tachycardias (responsible for 75%–90% of idiopathic VT), the monomorphic VT originates from either the left ventricular outflow tract (LVOT) or the RVOT or, more infrequently, above the pulmonary valve or in the aortic cusps. RVOT VT has a typical LBBB appearance in V1 and an inferior axis in the frontal plane. When multiple VT morphologies are present, the possibility of other disease processes (e.g. ARVC) should be considered. The mechanism responsible is cyclic-AMP-triggered activity resulting in early depolarizations or after-depolarizations. A similar tachycardia mimicking RVOT VT can be identified in the LVOT, but with a right bundle branch block (RBBB) morphology (see Figure 118.2). VTs arising from the mitral and the

tricuspid valve annuli account for approximately 4%–7% of idiopathic VTs. When the VTs arise from the mitral valve, they have, typically, an RBBB morphology; when they arise from the tricuspid valve, they have a typical LBBB morphology.

Fascicular tachycardia (also known as fascicular VT or idiopathic left VT) arises from the left posterior septum, close to the left posterior fascicle, and is characterized by a RBBB morphology on ECG, with a leftward axis (left anterior fascicular block) and a relatively narrow QRS. This VT is often verapamil sensitive, suggesting that the relevant mechanism relates to the slow inward current in either a small re-entrant circuit (see Figure 118.3) or delayed after-depolarizations. Fascicular tachycardias may be a heterogeneous group, with several mechanisms responsible, and are relatively uncommon.

Bundle branch re-entry VT

Bundle branch re-entry VT is a form of monomorphic, sustained VT which occurs in those with structural heart disease. It is more common in non-ischaemic DCM than in ischaemic DCM. In it, there is conduction delay in the His–Purkinje system, thus creating a substrate for a macro-re-entry involving the bundle branches (see Figure 118.4). This is usually manifest as interventricular delay on ECG during sinus rhythm (LBBB), with or without atrioventricular (AV) nodal disease. Conduction retrogradely over the left bundle system, and antegradely over the right bundle, constitute the most common form, resulting in an LBBB morphology during VT (similar to sinus rhythm; see Figure 118.5). It is important to recognize this as it responds poorly to medical therapy but may be eliminated by catheter ablation. Myocardial VT may concomitantly exist. It is very uncommon in the absence of myocardial disease. The patient profile may still warrant ICD therapy, depending on the presence of underlying DCM, and symptoms.

Idiopathic VF

Idiopathic VF is defined as VF occurring on a background of a structurally normal heart. It has an incidence of 1% of all out-of-hospital cardiac arrests, and 14% of all VF cardiac arrests in those >40 years old. It has been associated with early repolarization, and has been

considered to be part of a spectrum of J-point elevation disorders, including Brugada syndrome. The mechanism of arrhythmogenesis with early repolarization is unclear in this patient group. In a few patients, VF has been triggered by short-coupled premature

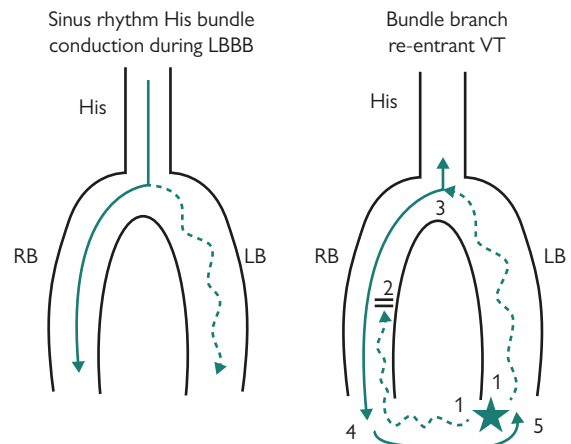

Figure 118.4 Substrate for macro-re-entry in bundle branch re-entry ventricular tachycardia. The His bundle (His), right bundle (RB), and left bundle (LB) are shown, on the left with sinus rhythm with left bundle branch block (LBBB), and on the right with bundle branch re-entrant ventricular tachycardia (VT). On the right, a ventricular ectopic (indicated by the star) initiates slow retrograde conduction in the LB, and across retrogradely in the RB (indicated by '1'). The retrograde conduction in the RB blocks (indicated by '2'). The slowly conducting retrograde LB wavefront reaches the RB and conducts antegradely (indicated by '3'), and further distally (indicated by '4'); by this time, the LB is able to conduct retrogradely once again, and a re-entrant circuit is completed.

ventricular complexes (PVCs), which are often from Purkinje fibres, which can be targeted in ablative therapy.

Typical symptoms of the disease, and less common symptoms

Symptoms occurring during VT depend on the haemodynamic consequences produced by the VT, and several factors influence this: the ventricular rate; the time spent in tachycardia; the presence and severity of any underlying heart disease; and autonomic factors. The localization and the direction of spread of ventricular depolarization can also be important. Patients may present with palpitations, breathlessness (increased pulmonary venous pressures and pulmonary congestion), presyncope/syncope (diminished cerebral perfusion), or cardiac arrest. Some patients may experience chest pain, which may reflect underlying ischaemia as the precipitant of VT, or due to the rhythm itself (rate-related ischaemia). In some instances, patients may tolerate their VT well with adequate haemodynamics, but may drift into heart failure over time. In addition, an incessant VT which is haemodynamically tolerated may itself cause a DCM. This may develop over weeks and months, and resolves with management of the VT. Likewise, those with frequent ventricular ectopy/bigeminy in the absence of high rates can also develop a reversible form of dilated cardiomyopathy. Should there be independence of atrial activity from the ventricular contractions (AV dissociation occurs in some 60% of VTs), patients may report neck fullness (corresponding to cannon A waves, when ventricular and atrial contractions occur synchronously, resulting in raised central venous pressures). Physical examination when AV dissociation is present in a patient in VT may reveal, in addition to cannon A waves in the jugular venous pressure, variable first heart sound, and blood pressure. VF presents with syncope, seizures, apnoea, and, eventually, if left untreated, cardiac arrest and death.

Demographics of the disease

Fifty per cent of all cardiac deaths are sudden, and the majority of SCDs are as a result of ventricular tachyarrhythmias. As previously mentioned, VF is the most common arrhythmia in patients with out-of-hospital cardiac arrest.

Approach to diagnosing the disease

The diagnosis of VT is made on electrocardiography, on a 12-lead ECG, telemetry rhythm strip, or other forms of ambulatory ECG monitoring. VT is a differential diagnosis of a BCT. The other differential diagnoses of a BCT (Figure 118.6) are:

- supraventricular tachycardia (SVT) with aberrancy (preexisting or functional bundle branch block)
- SVT with pre-excitation, including pre-excited atrial fibrillation (see Figure 118.7)
- antidromic Atrioventricular reciprocating tachycardia (AVRT)
- pacemaker-mediated tachycardia (PMT)
- accelerated idioventricular rhythm
- ECG-lead motion artefact

Despite the numerous established criteria in the differentiation of VT from SVT with aberrant conduction, the correct diagnosis of a BCT remains a challenge, but is crucial in acute as well as long-term management (e.g. the administration of verapamil to treat BCT misdiagnosed as SVT with aberrancy may result in severe hypotension and haemodynamic collapse). The commonest cause of a BCT is VT, which represents up to 80% of BCTs presenting in the emergency department. Hence, a BCT should be treated as VT unless proven otherwise. The likelihood of a particular diagnosis is significantly affected by a number of factors, including features on the ECG, and the presence or absence of structural heart disease. A history of

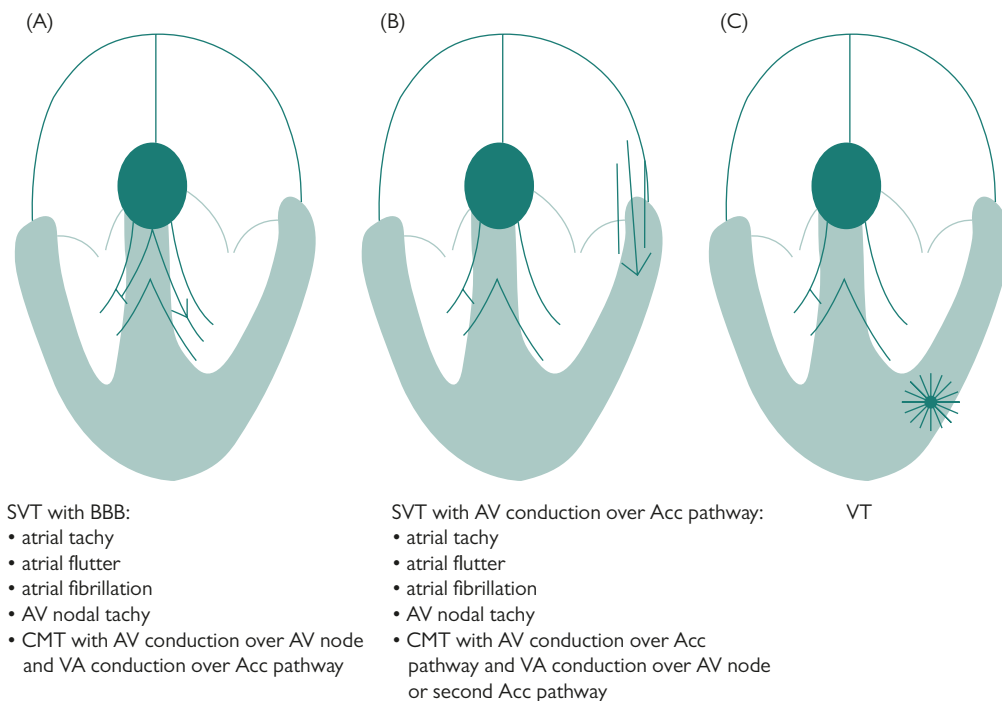

Figure 118.6 Different types of supraventricular tachycardia: (A) supraventricular tachycardia with bundle branch block; (B) supraventricular tachycardia with atrioventricular conduction over an accessory pathway; (C) ventricular tachycardia resulting in a broad QRS tachycardia; Acc, accessory; AV, atrioventricular; BBB, bundle branch block; CMT, circus movement tachycardia; SVT, supraventricular tachycardia; tachy, tachycardia; VA, ventriculo-atrial; VT, ventricular tachycardia.

Figure 118.7 The ECG shows a broad, complex irregular tachycardia with right-axis deviation and a variable R–R interval which is consistently <250 ms. No discernible P waves are seen but inspection of the QRS complexes show pre-excitation. The terminal portion of the rhythm strip (not recorded simultaneously with the rest of the 12-lead ECG) shows degeneration of the pre-excited atrial fibrillation into ventricular fibrillation (onset denoted by black arrow) and therefore records the exact moment and cause of cardiac arrest.

ischaemic heart disease with previous myocardial infarction or heart failure has a positive predictive accuracy of 95% for VT, and can serve as a good discriminator as to the cause of a BCT. The response of the BCT to vagal manoeuvres and/or adenosine is also useful. With VT, there is no response to vagal manoeuvres or adenosine. Termination of the tachycardia with vagal manoeuvres or adenosine strongly suggests a supraventricular origin. Adenosine may not terminate the BCT, but can result in sufficient AV nodal blockade, unmasking the underlying atrial rhythm (e.g. atrial flutter or atrial tachycardia with aberrancy). As with narrow-complex tachycardias, adequate doses of adenosine must be given to achieve AV node blockade. However, unlike the case with narrow-complex tachycardias, an eventual lack of response to increasing doses of adenosine must indicate a VT as opposed to a SVT mechanism.

There are well-described ECG findings that are of value in differentiating the causes of a BCT, but most of these are not 100% specific or sensitive. The following are ECG features of a BCT favouring VT:

- QRS complexes >140 ms for a RBBB tachycardia (a predominantly positive QRS complex in Lead V1)
- QRS complexes >160 ms for a LBBB tachycardia (a predominantly negative deflection in Lead V1)
- a superior frontal plane axis in RBBB tachycardia, and a right inferior axis in LBBB tachycardia
- evidence of AV dissociation
- capture/fusion beats
- negative/positive concordance

In addition, the 12-lead ECG in sinus rhythm may also be helpful. Pre-excitation indicates an antegradely conducting accessory pathway and may suggest an SVT with pre-excitation (antidromic AVRT or pre-excited AF), although the accessory pathway could be a bystander in terms of the BCT. The presence of Q waves in a territory consistent with coronary artery disease (i.e. a QR (Coumel) complex) may indicate myocardial infarction and consequent scarring as a substrate for VT, and the presence of an identical QRS morphology during tachycardia is very suggestive of VT involving this area of scarring.

In summary, the diagnostic approach to VT involves the clinical history, ECG analysis, and the incorporation of adenosine testing

(see 'PMT'). These depend on the clinical predicament of the patient. Always consider whether the apparent tachycardia is artefactual (Figure 118.8).

Other diagnoses that should be considered

Accelerated idioventricular ventricular rhythm

The term 'accelerated idioventricular rhythm' (AIVR) describes an ectopic ventricular rhythm with three or more consecutive ventricular premature beats with a rate faster than the normal ventricular intrinsic escape of 30–40 bpm but slower than that of VT (usually between 100 and 120 bpm). It differs from VT by its mode of onset, which is with a long coupling interval, and its offset, which is by a gradual decrease of the ventricular rate or increase of the sinus rate. Frequently, the mechanism seems to be related to enhanced automaticity in the His–Purkinje fibres and/or myocardium and associated with vagal excess and decreased sympathetic activity. When the enhanced automaticity in the His–Purkinje system or myocardium exceeds the sinus rate, accelerated idioventricular rhythm (AIVR) manifests as the dominant rhythm. There is some overlap between AIVR and some slow VT. It is generally a transient rhythm, rarely of haemodynamic consequence and requiring treatment. It has a good prognosis, and can occur in any form of structural heart disease and, occasionally, in those with no structural heart disease. Rarely, AIVR can degenerate into VT or VF. In patients with poor left ventricular systolic dysfunction, AIVR can lead to haemodynamic compromise due to the loss of AV synchrony, or a relatively rapid heart rate. It is most commonly seen in those with coronary artery disease and occurs in up to 25% of patients during an acute myocardial infarction, as a marker of successful reperfusion. It is also seen in digoxin toxicity.

PMT

PMT in patients with a dual-chamber pacemaker can result in a BCT. It may be obvious if clear ventricular pacing spikes are observed on an ECG of a BCT. However, with the use of bipolar pacemaker leads, the pacing spike may be subtle and difficult to observe on an

ECG. There are two mechanisms that underlie PMT. One involves the 'tracking' of an atrial tachyarrhythmia and normally occurs in a patient with a dual-chamber pacemaker in the setting of complete heart block. Should these patients develop any atrial tachyarrhythmias (atrial fibrillation/atrial flutter/atrial tachycardia), the atrial lead will sense the atrial activity and trigger ventricular pacing at the pacemaker's maximal preprogrammed rate (upper tracking rate), which is usually between 120 and 140 bpm in older patients. If a programmer is not available, a magnet placed over the pacemaker generator deactivates the sensing facility on the pacemaker leads, and induces asynchronous pacing at the preset demand rate, thus allowing diagnosis of the atrial tachyarrhythmia. If a programmer is available, the pacemaker can be reset to the VVI mode, and this will prevent the 'tracking' of the atrial tachyarrhythmia. In most pacemakers now, there is a mode-switch facility, and the pacemaker switches from the DDD to the VVI mode once it detects a high atrial rate (at a preprogrammed setting). The second mechanism occurs when a premature ventricular beat is conducted retrogradely via the AV node, resulting in atrial depolarization (occurring after the atrial refractory period). The atrial lead senses this, and the pacemaker initiates ventricular pacing, which continues as an endless-loop tachycardia. This once again results in a BCT (see Figure 118.9); placing a magnet over the pacemaker generator will terminate this loop, as it will disable the atrial lead sensing facility. Adenosine or Valsalva manoeuvres may or may not terminate this tachycardia, depending on whether the ventriculo-atrial block is sensitive to them. This problem is overcome by altering the post-ventricular atrial refractory period.

Other relevant investigations

Once the diagnosis of VT has been made, the following investigations may be performed to guide further management: resting 12-lead ECG, assessment of left ventricular systolic function, and assessment of cardiac ischaemia.

Resting 12-lead ECG

The 12-lead ECG, once the patient has been successfully cardioverted to sinus rhythm (or, in some cases, atrial fibrillation), is important for elucidating the potential cause of the VT.

Evidence of myocardial ischaemia/infarction

The presence of an ST-segment shift (elevation or depression) suggests myocardial ischaemia or infarction may be the cause of the VT/VF, although cardiac ischaemia may be a representation of a patient's compromised haemodynamics as a result of the VT. Urgent coronary angiography should be considered in such instances. In addition, the presence of Q waves in a territory consistent with coronary artery disease (i.e. a QR (Coumel) complex) may indicate myocardial infarction and scarring as a substrate for VT, and the presence of an identical QRS morphology during tachycardia is very suggestive of VT involving this area of scarring.

Presence of ventricular pre-excitation

As previously mentioned, ventricular pre-excitation indicates an antegradely conducting accessory pathway and may suggest an SVT with pre-excitation (antidromic AVRT or pre-excited AF), although the accessory pathway could be a bystander in terms of the BCT.

Evidence of underlying inherited arrhythmogenic syndrome

As previously discussed, there are particular ECG changes which might prompt the consideration of the diagnosis of an inherited arrhythmogenic syndrome. A prolonged or shortened QT interval may suggest a diagnosis of long-QT syndrome or short-QT syndrome, respectively. The characteristic ECG changes associated with Brugada syndrome (e.g. coved ST elevation with T-wave inversion) may be present and may be helpful in achieving the diagnosis. ARVC should be considered as an underlying diagnosis if an epsilon wave is detected.

Assessment of left ventricular systolic function

Transthoracic echocardiography

In a patient presenting with VT, in addition to the symptoms of presentation, the other crucial information required is whether the patient has a structurally normal heart. Apart from the implications this has for the type of VT, if a patient has a severely impaired left ventricular systolic function, they may be a candidate for ICD implantation. This information can be provided by transthoracic echocardiography.

Figure 118.9 ECG demonstrating a pacemaker-mediated tachycardia (paced ventricular rhythm with retrograde P waves at the terminal portion or just after the T wave on Leads II, III, aVF, and V1 (note the QRS morphology of the left bundle branch block, and the superior axis, consistent with right ventricular apical pacing).

Cardiac MRI

Like transthoracic echocardiography, cardiac MRI (CMRI) is primarily used to assess cardiac structure and function. However, CMRI allows for a more detailed assessment of the myocardial structure than transthoracic echocardiography does, particularly via late gadolinium enhancement imaging. This gives information on myocardial composition (i.e. areas of scarring, fibrosis, oedema, and infiltration), which is helpful not only in demonstrating the substrate for VT (e.g. in re-entrant VT), but also in achieving the diagnosis (e.g. in ARVC).

Assessment of cardiac ischaemia

It is important to exclude underlying cardiac ischaemia as the cause or precipitant of ventricular tachyarrhythmias, as it may need to be treated primarily.

Coronary angiography

Coronary angiography is inevitably performed in patients presenting with ventricular tachyarrhythmias, especially if features of the history or other investigations suggest underlying coronary artery disease (e.g. ST-segment shift on ECG, or regional wall motion abnormality on transthoracic echocardiography). The presence of coronary artery disease, if demonstrated on coronary angiography, will need to be interpreted in the context of the clinical predicament before any revascularization is contemplated. Other functional investigations, such as myocardial perfusion scanning, stress echocardiography, or stress CMRI, may be useful in such instances.

Prognosis, and how to estimate it

Numerous approaches have been used to assess the prognosis of those with ventricular tachyarrhythmias, depending on the underlying disease process. Prognostication largely involves risk stratification for SCD and decision on ICD implantation, and may involve invasive and non-invasive assessments, as well as genotyping. These are discussed in greater detail in Chapter 120. Except in patients with inherited arrhythmogenic syndromes (channelopathies), HCM, or ARVC, left ventricular function is the strongest predictor of outcome. In patients with an ischaemic cardiomyopathy and NSVT, the sudden-death mortality rate is almost 30% at 2 years. In general, the prognosis for patients with idiopathic VT, in the absence of either a long QT or structural heart disease, is excellent, and therapy is often directed against symptoms. Their major risk is due to poorly timed syncope spells.

Treatment and its effectiveness

The management of VT/VF and aborted SCD have dramatically changed over the past decade as the evidence base has expanded. Management decisions can be divided into those for immediate action (i.e. termination of VT), and those for long-term management (i.e. prevention of recurrence and SCD).

Acute management of sustained VT

Treatment of VT may either be directed towards ending an episode of VT or preventing any future episodes from occurring, and subsequent consideration for an ICD to prevent SCD. The severity of the clinical symptoms dictates the urgency with which VT must be treated, regardless of the arrhythmia mechanism. VT associated with cardiac arrest (pulseless VT) should be treated in accordance to the Advanced Life Support algorithm, with immediate electrical cardioversion. It also suggests IV amiodarone as a first-line adjunctive anti-dysrhythmic in shock-resistant pulseless VT.

In pulsed VT, immediate assessment of the patient's haemodynamic state and end-organ perfusion is a priority. Their level of consciousness (cerebral perfusion), symptoms of chest pains (which may reflect underlying cardiac ischaemia and coronary hypoperfusion), and presence of pulmonary congestion are important indices. VT which leads to angina, left heart failure, right heart failure, low blood pressure, shock, or symptoms of hypoperfusion of the brain (leading to a lowered Glasgow Coma Score and/or confusion) should be treated with prompt electrical cardioversion. If the haemodynamic

status is stable, rhythm conversion may be achieved via either electrical cardioversion or medical therapy with IV antiarrhythmic agents. Figure 118.10 shows an algorithm for the management of tachycardias, including BCT and VT, as produced by the Resuscitation Council (UK). Electrical cardioversion (synchronized) is simple and safe, with close to 100% efficacy and with no risk of haemodynamic depression and the proarrhythmia associated with antiarrhythmic drug therapy. It is ideally performed under general anaesthesia (GA), but can be done with benzodiazepines and opiates if necessary. It may be delayed if a patient has not been fasting, or other contraindications to GA are present. Acute termination of VT can also be achieved with IV antiarrhythmic agents such as amiodarone, lidocaine, and procainamide (not available in the UK), although they are generally ineffective, and many patients end up requiring electrical cardioversion. If left ventricular systolic function is impaired, using amiodarone and then lidocaine is better than using procainamide, due to its potential to exacerbate congestive cardiac failure. With associated ongoing myocardial ischaemia, it is recommended that lidocaine be used as the primary antiarrhythmic drug, as the mechanism in this case rather than being re-entry is thought to be abnormal automaticity. In TdP-type VT, magnesium sulfate may be effective if the QT is found to be pathologically lengthened. Magnesium is rarely effective in those with a normal QT interval. Amiodarone is suggested as the first-line antiarrhythmic agent by the Resuscitation Council (UK).

In cases of VT associated with a background of a previous myocardial infarction (i.e. the mechanism is likely to be that of re-entry), overdrive pacing (pacing of the ventricle by using a temporary pacing lead inserted into the right ventricle at a rate higher than that of the VT) can end the episode of tachycardia. This is especially useful in recurrent VT, where multiple electrical cardioversions have been attempted, and allows time for antiarrhythmic drug therapy to take its effect (e.g. even IV preparations of amiodarone may take 12–48 hours to work). However, a risk of this overdrive pacing approach is that the VT may increase its rate to that of ventricular flutter or even VF. In the treatment of recurrent appropriate ICD discharges or a VT storm, sedation and intubation may be helpful when IV antiarrhythmic agents and beta blockade have failed to control the ventricular tachyarrhythmias. Neuroaxial modulations via thoracic epidural anaesthesia and surgical left-cardiac sympathetic denervation have been also shown to be effective. Emergency VT ablation ('primary VT ablation') can also be considered when other treatment modalities have failed.

Once the VT is terminated, remediable factors contributing to VT initiation and maintenance should be sought and corrected. VT can be triggered by cardiac ischaemia (acute myocardial infarction is found in 20% of patients with a VF arrest), electrolyte imbalances, decompensation of congestive cardiac failure (likely as a result of myocardial stretch), relative bradycardias (as sinus bradycardia or AV block may promote the occurrence of PVCs and ventricular tachyarrhythmias), and drugs.

Long-term therapy for the prevention of recurrence

The aim of long-term therapy is to prevent the recurrence of symptomatic VT, and SCD. The key factors influencing treatment include comorbidity, symptom severity, and the extent of structural heart disease, and they determine whether medical therapy (antiarrhythmic drug therapy, and drugs to treat underlying disease), ICD implantation, and catheter ablation should be considered. Often, combinations of these treatments are implemented when structural heart disease is present.

Antiarrhythmic drug trials have been largely ineffective, especially in those with left ventricular systolic dysfunction, and some antiarrhythmic drugs have been shown to paradoxically increase sudden-death mortality in such patients. Beta blockers can diminish the incidence of ventricular tachyarrhythmias and improve survival in those with VF and symptomatic VT. In patients with VF which is refractory to beta blockers, other antiarrhythmic agents should be considered. Class I Vaughn-Williams antiarrhythmic agents may paradoxically increase mortality in such patients via proarrhythmia, especially in patients with underlying coronary artery disease. Current clinical practice favours the use of Class III antiarrhythmic agents

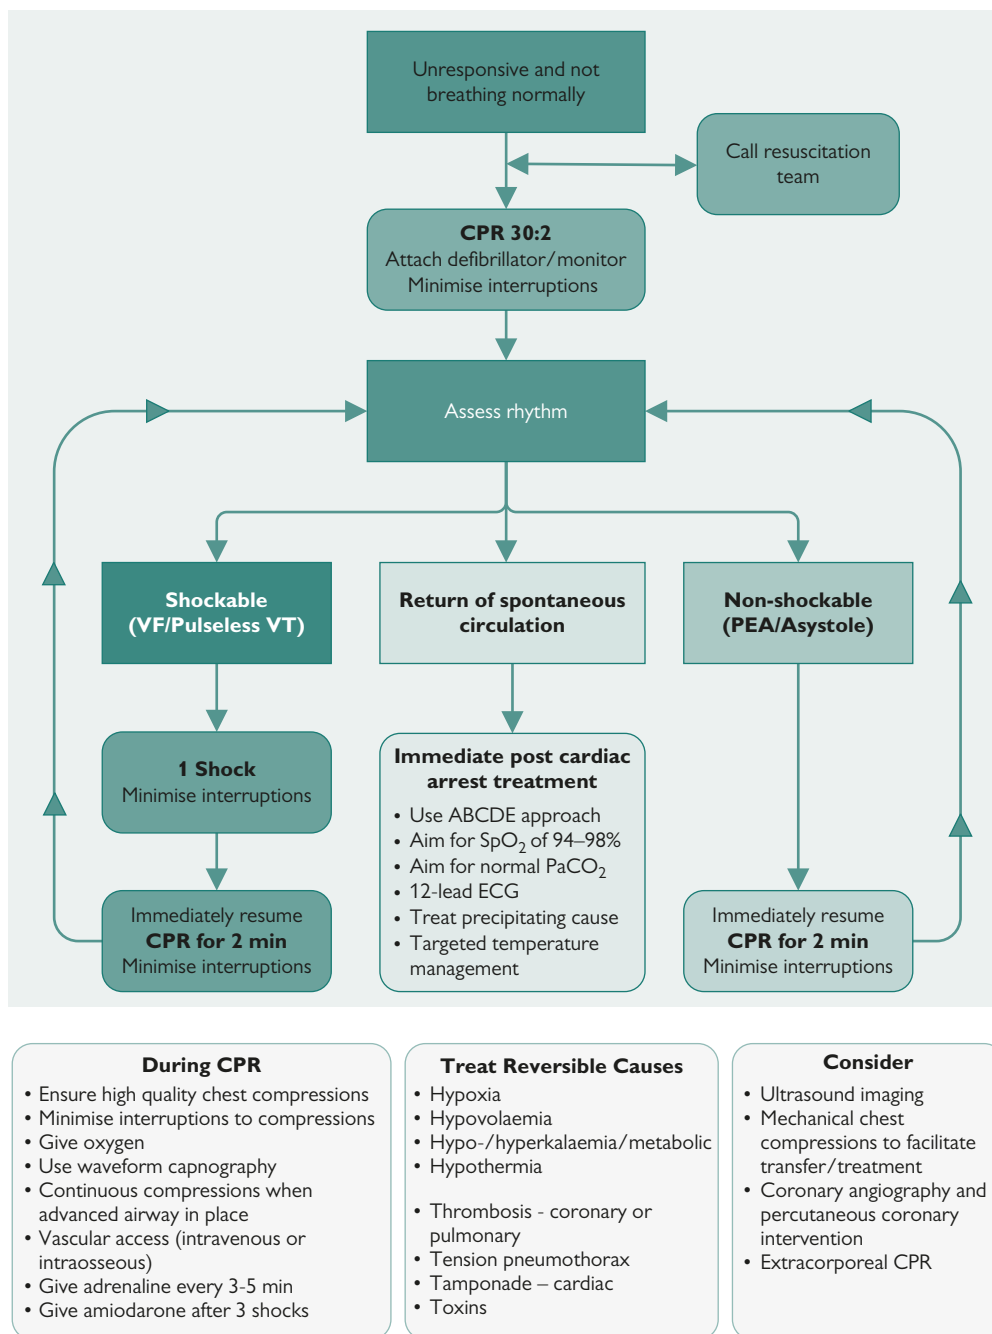

Figure 118.10 Adult advanced life support algorithm; PEA, pulseless electrical activity; VF, ventricular fibrillation; VT, ventricular tachycardia. Reproduced with the kind permission of the Resuscitation Council (UK).

(sotalol and amiodarone), which prolong myocardial depolarization through potassium-channel blockade and are preferred in those with reduced left ventricular systolic function. Amiodarone is a complex antiarrhythmic agent and is categorized as a Class III antiarrhythmic but has measurable Class I, II, and IV effects. Unlike the Class I antiarrhythmic agents, it seems to be safe for use in those with impaired left ventricular systolic function. The ACC/AHA/ESC guidelines state that, when used together with beta blockers, amiodarone is helpful for those with decreased left ventricular systolic function due to prior myocardial infarction, and with VT symptoms not responding to beta-adrenergic-blocking agents. In those with heart failure, the best proven, but non-specific, antiarrhythmic medical therapy includes, in

addition to beta blockade, the use of angiotensin-converting enzyme inhibitors and aldosterone antagonists. The idiopathic VTs often respond well to drug therapy, including calcium-channel blockers (verapamil) and beta blockers. Other specific drug therapies are recommended, each with its own evidence base, in the varying etiologies of ventricular tachyarrhythmias and are discussed in Chapter 120 (e.g. the use of quinidine in Brugada syndrome).

The use of ICDs has had a significant impact on the management of ventricular tachyarrhythmias, especially in the context of an aborted SCD (secondary prevention) and in patients with underlying cardiomyopathy/structural heart disease. ICDs may be indicated on prognostic grounds in many patients, irrespective of any other

treatment for their VT. The indications are discussed in further detail in Chapter 121, including their role in primary prevention of SCD, and these may be specific to the underlying cardiac disease process (see Chapter 120). Once implanted, an ICD can be used to diagnose ventricular tachyarrhythmias, and end them with defibrillation/cardiopersion shocks or anti-tachycardia pacing algorithms. These devices can also function as pacemakers in patients with bradyarrhythmias. There have been several large trials (e.g. CASH/AVID) comparing ICD therapy to conventional antiarrhythmic drug therapy in patients with structural heart disease with a history of ventricular tachyarrhythmias. These studies demonstrated the superiority of ICD therapy (reduction in mortality by a reduction in SCD) over antiarrhythmic drug therapy (amiodarone and sotalol), especially in patients with severe left ventricular dysfunction (left ventricular ejection fraction <35%) and haemodynamically unstable sustained VT. In patients who refuse an ICD, the next best treatment may be that of amiodarone, although there is no evidence base for this. For patients with ICDs in situ and who receive frequent ICD shocks due to recurrent VT, concomitant antiarrhythmic drug therapy may be indicated to reduce the incidence of VT episodes or to slow the VT rate and so allow it to be more amenable to being pace terminated. On occasion, multiple antiarrhythmic agents may be required (e.g. amiodarone and flecainide concomitantly). Catheter ablation should also be considered in such circumstances. In a proportion of patients considered for ICD implantation, cardiac resynchronization therapy may also be indicated.

A key treatment in those with recurrent VT is catheter ablation. The EHRA/HRS Expert Consensus on Catheter Ablation of Ventricular Arrhythmias suggests the use of catheter ablation early in the therapy of those with recurrent VT. Previously, catheter ablation was often contemplated when pharmacological options had been exhausted, often following significant morbidity to the patient from recurrent VT and ICD therapies. Advances in technology with the use of three-dimensional activation mapping techniques and understanding of VT substrates (incorporating endocardial

and epicardial approaches) now allow for ablation of multiple and unstable VTs with good outcomes and safety, even in those with advanced heart disease. Ablation is used to treat symptomatic VT rather than to reduce the risk of SCD. Catheter ablation of certain types of idiopathic VT (i.e. where there is a structurally normal heart) is very effective and is recommended in those who are drug resistant/intolerant or who refuse long-term drug therapy. Abnormal or triggered activity is the most likely mechanism, and in these patients focal ablation is often curative, with success rates of greater than 90% if the presenting rhythm disturbance is inducible in the electrophysiology laboratory. It is often important to give consideration to haemodynamic stability of the VT. The use of percutaneous left ventricular assist devices allows for the maintenance of VT which would otherwise result in haemodynamic instability, and thus enable more extensive mapping to be performed. There are also strategies to ablate VF or polymorphic VT in certain patient groups where focal triggers from the Purkinje system and RVOT play a role in the initiation of VF. Once again, this approach is used as an adjunct to ICD implantation.

119 Bradyarrhythmias

Kim Rajappan

Definition of bradyarrhythmia

A bradyarrhythmia is defined as a rhythm disturbance which results in a heart rate of less than 60 bpm, although it is important to note that many healthy people have a resting heart rate that is less than 60 bpm. The forms of bradyarrhythmia that need to be considered are sinus bradycardia, sinus node disease, sick sinus syndrome, and atrioventricular (AV) block.

Definition of sinus bradycardia

Sinus bradycardia is a rhythm which arises from the sinus node but has a ventricular rate less than 60 bpm (see Figure 119.1).

Definition of sinus node disease

Sinus node disease may also manifest itself as a sinus bradycardia, but is often accompanied by other aspects of abnormal sinus node function. The most common of these is sinus arrest. This is defined as a longer-than-normal pause between two consecutive cardiac cycles (>3 seconds), with an absence of sinus node activity between the two cycles; that is, no P waves are seen (unlike the case in AV block, where the sinus node continues to fire, so P waves are seen but there is no ventricular activity).

Definition of sick sinus syndrome

Sick sinus syndrome is a collection of heart rhythm disorders; it includes sinus bradycardia, sinus tachycardia, and alternating bradycardia and tachycardia.

Definition of AV block

First-degree AV block

In first-degree AV block, the PR interval is fixed and prolonged. The normal PR interval is 0.12–0.2 seconds; in first-degree AV block, there is a fixed PR interval >0.2 seconds. (Note that the upper limit of the PR interval in children is age dependent and often abnormal if >160 ms in very young children.) Every atrial impulse is conducted to the ventricles in first-degree AV block; however, conduction is delayed within the AV node.

Second-degree AV block

Second-degree AV block is characterized by atrial impulses (generally occurring at a regular rate) which fail to conduct to the ventricles. **Möbitz type I** second-degree AV block, also known as the **Wenckebach** phenomenon, is defined by progressive prolongation of the PR interval with dropped beats (i.e. the PR interval gets longer and longer until finally one beat drops; see Figure 119.2A). **Möbitz type II** second-degree AV block is defined as a PR interval that remains unchanged and is not normally prolonged but where the P wave suddenly fails to conduct to the ventricles, often in a regular fashion (e.g. every second P wave has a dropped beat (in 2:1 second-degree AV block), every third P wave has a dropped beat (in 3:1 second-degree AV block), etc.; see Figure 119.2B) Another, less-recognized, form of second-degree AV block consists of multiple P waves occurring in a row and which should conduct, but do not. The conduction ratio can be three P waves to one conducted beat, or higher, but the PR interval of each of the conducted beats remains

Figure 119.1 12-lead ECG showing sinus bradycardia.

Figure 119.2 12-lead ECGs showing (A) Mobitz type I (Wenckebach) and (B) Mobitz type II second-degree atrioventricular block.

constant. This form of second-degree AV block is clinically distinct from complete heart block in that, in this form, the P waves that conduct to the QRS complexes occur at fixed intervals, unlike the case in third-degree AV block (see 'Third-degree AV block').

Third-degree AV block

Third-degree AV block, also known as complete heart block, is diagnosed when no supraventricular impulses are conducted to the ventricles. In individuals with this, the P waves can normally be identified and seen to demonstrate sinus rhythm, dissociated from the QRS complexes (see Figure 119.3). Ventricular contraction is driven by a pacemaker in junctional (bordering the AV node) or ventricular myocardium. A junctional escape rhythm is typically at a rate of 40–50/min, with a narrow QRS complex, while a ventricular escape rhythm is 30–40/min or slower, with a broad QRS complex. A ventricular escape rhythm is less reliable, with a higher probability of prolonged pauses.

Aetiology of bradyarrhythmia

Aetiology of sinus bradycardia

Sinus bradycardia is often caused by the administration of drugs which depress impulse generation by the sinus node (e.g. beta blockers, calcium-channel blockers, and ivabradine). In addition, athletes often have sinus bradycardia as a physiological response. Other causes of sinus bradycardia include increased vagal tone, hypothermia, hypothyroidism, epileptic seizures (during the postictal state), increased intracranial pressure, and, rarely, infections such as diphtheria, acute rheumatic fever, and viral myocarditis.

Aetiology of sinus node disease

Sinus node disease is a condition that often occurs as people age. However, it may be seen in patients at a younger age.

Figure 119.3 12-lead ECG showing third-degree atrioventricular block (complete heart block).

Aetiology of sick sinus syndrome

Sick sinus syndrome is relatively uncommon. It tends to occur in people older than 50. The most common mechanism is thought to be a non-specific, scar-like degeneration of the heart's conduction system, predominantly affecting the atria. In children, sick sinus syndrome is most commonly seen after cardiac surgery, especially where this involves the atria. Coronary artery disease, hypertension, and aortic and mitral valve diseases may be associated with sick sinus syndrome, which is probably related to associated fibrosis within the conduction system.

Aetiology of AV block

AV block can occur at the level of the AV node or at the level of the His–Purkinje system. The AV node (AVN), which lies in the floor of the right atrium, allows electrical impulses to be transmitted from the sinus node to the ventricles with 1:1 conduction. The AVN consists of three parts: the atrionodal region (which is a transitional zone), the nodal region (which is quite compact), and the nodal-His region (which contains the penetrating His bundle). Conduction is slowest through the nodal region. The AVN is supplied by the right coronary artery (in 90% of individuals) or the left circumflex artery (in 10% of individuals), and is innervated by both sympathetic and parasympathetic fibres. The His–Purkinje system comprises the bundle of His, the right and left bundle branches, and the Purkinje fibres, which travel subendocardially to connect with ventricular myocytes; the conduction system enables synchronous ventricular activation.

First-degree AV block and Möbitz type I second-degree AV block usually reflect conduction delay within the AVN, while Möbitz type II second-degree AV block typically reflects conduction delay in the His–Purkinje system. Third-degree AV block may be due to conduction block in the AV node and/or His–Purkinje system.

High vagal tone (e.g. during sleep) may cause first-degree or Möbitz I second-degree AV block in healthy people. Möbitz I second-degree AV block may also occur physiologically at high heart rates (e.g. with rapid atrial pacing).

Causes of AV block may be classed as congenital or acquired, and, if acquired, acute or chronic.

Congenital AV block is rare, occurring in 1:22 000 births. This form of heart block, in the absence of major structural abnormalities, is often associated with maternal antibodies to Ro/SSA and La/SSB, secondary to maternal SLE. It is most commonly diagnosed between

18 and 24 weeks' gestation and may be first degree, second degree, or third degree. Mortality approaches approximately 20%, with most surviving children requiring pacemakers.

Acquired acute causes of AV block include ischaemia of the AV node and conduction system in the setting of acute coronary syndrome, adenosine administration, drug toxicity (beta blockers, digoxin, verapamil) and hyperkalaemia. Acute injury of the AV node and conduction system may occur in Lyme disease, other causes of acute myocarditis, and infective endocarditis with aortic root abscess. Surgical aortic valve replacement, percutaneous transcatheter aortic valve implantation, repair of congenital cardiac defects, and cardiac trauma may also result in injury of the conduction system. Catheter ablation of the AV node is a therapeutic procedure (combined with pacemaker implantation) used to treat selected patients with atrial fibrillation associated with rapid ventricular rates.

Acquired chronic AV block is most often due to idiopathic conduction system fibrosis (Lenegre–Lev syndrome), or in association with extensive calcification of the mitral annulus or aortic valve. Chronic ischaemic heart disease, infiltrative disorders such as sarcoidosis or haemochromatosis, and cardiomyopathies may involve the conduction system and result in AV block. AV block may be seen in association with neuromuscular disorders (e.g. myotonic dystrophy) and spondyloarthropathies.

Typical symptoms of bradyarrhythmia

Symptoms of sinus bradycardia

Bradycardia is not necessarily symptomatic. However, the slow heart rate arising from any of the bradyarrhythmias can reduce cardiac output, causing symptoms such as presyncope, dizziness, chest pain, hypotension, vertigo, confusion, fatigue, dyspnoea, and syncope. The slow heart rate may also lead to other escape rhythms, including junctional, ectopic atrial, or ectopic ventricular rhythms. Profound bradycardia may predispose the affected individual to R-on-T ectopy and potentially life-threatening torsades de pointes.

Symptoms of sinus node disease

As previously mentioned, sinus node disease may manifest as a sinus bradycardia, but is often accompanied by other abnormal sinus node functions, the most common of which is sinus arrest (see 'Definition of sinus node disease').

Symptoms of sick sinus syndrome

In sick sinus syndrome, symptoms may include palpitations, because of the associated tachycardia component.

Symptoms of AV block

First-degree AV block is usually asymptomatic and an incidental finding on ECG; examination may reveal a soft first heart sound. Second-degree AV block can be asymptomatic or may cause palpitation and effort intolerance; presyncope/syncope may result from intermittent higher degrees of AV block. Acquired third-degree AV block typically causes effort intolerance, and may result in presyncope/syncope from bradycardia or prolonged pauses. Syncope related to AV block (Stokes–Adams attack) is characteristically of abrupt onset; secondary anoxic seizures may occur.

Demographics/natural history of the arrhythmia

Sinus bradycardia

Studies have found that 50%–85% of highly trained athletes have benign sinus bradycardia, as compared to 20%–30% of the general population studied.

Sinus node disease

Sinus node disease often occurs as people age, although it may be seen in patients at a younger age. It is often accompanied by other aspects of abnormal sinus node function, most commonly sinus arrest.

Sick sinus syndrome

In sick sinus syndrome, the patient's heart rate may be very slow at any time, but can also be very variable. Blood pressure may be affected but not consistently. The presence of sick sinus syndrome may cause heart failure symptoms to occur or worsen.

AV block

The incidence of AV block increases with age, and is more common in patients with underlying coronary or structural heart disease. There is a 60% female preponderance in congenital third-degree AV block, but a 60% male preponderance with acquired AV block. No clear racial trends exist for any bradyarrhythmias including AV block, although some systemic conditions associated with AV conduction demonstrate racial variation and therefore may affect prevalence (e.g. sarcoidosis).

First-degree AV block is seen in 0.5%–2.0% of healthy 20-year-olds, and 5% of healthy 60-year-olds. Möbitz type I second-degree AV block is seen in 1%–2% of healthy young people during sleep.

Approach to diagnosing the arrhythmia

Diagnosing sinus bradycardia

The diagnosis of sinus bradycardia is definitively confirmed by ECG, with a rate <60 bpm and which is normally regular, with P waves that are normal in morphology, and a normal PR interval.

Diagnosing sinus node disease

Sinus node disease is often accompanied by other aspects of abnormal sinus node function. The most common of these is sinus arrest, which is defined as a longer-than-normal pause between two consecutive cardiac cycles (>3 seconds), with an absence of sinus node activity between the two cycles.

Diagnosing sick sinus syndrome

Sick sinus syndrome is diagnosed when the symptoms occur only during episodes of arrhythmia. However, this often can be difficult to prove. An ECG may show various abnormal heart rhythms related to this syndrome. Holter monitoring is can be useful to diagnose sick sinus syndrome because of the episodic nature of the disorder.

Extremely slow heart rate and prolonged pauses may be seen during monitoring, along with episodes of atrial tachycardias. An intracardiac electrophysiology study is a very specific test for this disorder, although it is often unable to confirm the diagnosis and is usually not needed in current clinical practice. Exercise testing has been used to assess sinus node function but has not proven effective as a screening tool for this syndrome.

Diagnosis of AV block

AV block is diagnosed on the ECG, on the basis of the features described in 'Definition of AV block'. The hallmark feature of third-degree AV block is that no relationship exists between the P waves and the QRS complexes (i.e. they are completely dissociated). The frequency of the P waves (atrial rate) is normally, but not always, higher than the frequency of the QRS complexes (ventricular rate). In atrial fibrillation, this can be difficult to diagnose, or differentiate from just a slow ventricular response to the atrial fibrillation itself, but it is normally characterized by a very regular slow ventricular rhythm, as opposed to the slight irregularity of slowly conducted atrial fibrillation.

Other relevant investigations

Ambulatory ECG monitoring is indicated in symptomatic patients with first-degree or Möbitz type I second-degree AV block, to detect higher degrees of AV block or associated sinus node disease that may warrant pacemaker implantation. In patients with presyncope/syncope suspected of being due to AV block (e.g. because of the finding of a bundle branch block on ECG or the presence of relevant structural heart disease), ambulatory ECG monitoring is indicated. The type of monitoring chosen depends on the frequency of symptoms and, in some patients, an implantable ECG loop recorder will be used.

In 2:1 AV block, which can be due to Möbitz I or II second-degree AV block, exercise ECG may be used to differentiate these: in Möbitz I, the conduction rate increases (due to adrenergically mediated enhanced conduction through the AV node) while in Möbitz II, it decreases, and so may result in a fall in heart rate.

In general, imaging studies do not provide a significant role in investigating bradyarrhythmias. However, they are needed to exclude underlying structural heart disease and assess left ventricular function, as this may determine the type of pacemaker used if required. Apart from a thorough clinical examination, a transthoracic echocardiogram is the initial investigation of choice to exclude structural heart disease. Where there is a suspicion of coronary heart disease, further investigation of this, with tests including coronary angiography, may be appropriate. Cardiac MRI may be used in patients where a suspicion of a myocardial infiltrative problem exists (e.g. younger patients), with or without other features of a condition that predisposes to heart block (e.g. sarcoidosis).

Intra-cardiac electrophysiological studies may be indicated in a patient with suspected AV block as the cause of syncope. Block that is below the AV node in the His–Purkinje system (so called infra-Hisian block) is more commonly associated with slower heart rates and greater risk of prolonged pauses/asystole. Invasive recording of AH (atrium–His) and HV (His–ventricle) intervals can be used to determine the degree of conduction abnormality and its location and to guide decision-making for pacemaker therapy. However, this is rarely necessary with the current availability of non-invasive monitoring techniques.

Electrolyte imbalance may also cause a variety of arrhythmias, including various forms of bradycardia, so these will normally be checked, and toxicology screening may be performed where there is sufficient suspicion. Where a systemic disorder is suspected, appropriate investigations may be performed.

Prognosis and how to estimate it

Patients with Möbitz II second-degree or third-degree AV block are at risk of syncope (which may result in major injury) and sudden cardiac death. Pacemaker implantation substantially reduces these risks and thus improves their prognosis.

For patients with sinus node disease first-degree AV block, or Mobitz I second-degree AV block, the prognosis for life expectancy largely depends on the presence and type of underlying cardiac disease. Progression of the degree of AV block may occur over time. First-degree AV block is associated with an increased incidence of atrial fibrillation.

Treatment and its effectiveness

Long-term medical therapy is not useful or indicated in bradyarrhythmias. Permanent pacing is the therapy of choice in advanced AV block, and/or symptomatic bradycardia (see Chapter 121). AV nodal blocking medications, such as beta blockers, may exacerbate the symptoms, and therefore need to be discontinued, if possible. Where the patient is symptomatic, and this has been proven to be due to the bradycardia drugs that may be causing the problem, it is common to implant a permanent pacemaker, so the drugs can be continued. Tachycardia associated with sick sinus syndrome may be treated with medication, but again, such treatment may exacerbate the bradycardia component, thus requiring pacemaker insertion. If tachycardia is the predominant problem, then catheter ablation may help.

Temporary transcutaneous or transvenous pacing is the treatment of choice in the emergency setting when there is a slow heart rate (and for asystole) caused by bradyarrhythmia, although transvenous

pacing is associated with significant morbidity and mortality. Atropine administration (0.5–1.0 mg) or isoprenaline infusion may improve AV conduction in emergencies with bradycardia but is not a long-term strategy, and normally these measures are only used as a bridge to permanent pacemaker implantation as soon as possible.

Consultation with a cardiologist or cardiac electrophysiologist is indicated in the case of advanced heart block or unexplained syncope. An electrophysiologist will be best placed to decide when invasive electrophysiology testing is needed to determine the level and/or magnitude of conduction disturbance.

Patients with first-degree or benign Mobitz I second-degree AV block do not require hospitalization. Patients with symptomatic second- or third-degree AV block may need hospitalization with monitoring. Transcutaneous or transvenous pacing may need to be used but, where there is an indication for permanent pacing, this needs to be expedited.

Patients with implanted pacemakers require routine follow-up to monitor pacemaker function and assessment for the occurrence of other arrhythmias such as atrial fibrillation.

120 Sudden cardiac death

Norman Qureshi and Kim Rajappan

Definition and demographics of sudden cardiac death

Sudden cardiac death (SCD) is defined as **unexpected** death due to a cardiac disease, in a patient with or without known cardiac disease, which occurs **within 1 hour** from the appearance of the **first** clinical symptoms. The sudden cessation of cardiac activity leads to haemodynamic collapse, typically due to sustained ventricular tachyarrhythmias. The event is described as an aborted SCD (or sudden cardiac arrest (SCA)) when an intervention (e.g. defibrillation) or spontaneous reversion restores circulation. The lack of uniformity with this definition complicates SCD statistics. By convention, the use of SCD to describe both fatal and non-fatal cardiac arrests persists.

SCD continues to be a leading cause of death in Western countries, and underlies 15%–20% of all deaths in adults in the developed world, and about half of all cardiovascular deaths. In the US, estimates of SCDs from retrospective death certificate analyses range from 300 000 to 350 000 annually, giving an incidence of 0.1%–0.2% per year amongst the population above the age of 35 years. Event rates are said to be similar in Europe, although worldwide incidence is difficult to estimate and varies in accordance to the prevalence of coronary heart disease (CHD). The incidence of SCD increases with age and underlying cardiac disease. There is also a male preponderance, with men 2–3 times more likely to experience SCD than women, and this reflects the higher incidence of CHD in men.

Aetiology of SCD

SCD usually occurs in the presence of underlying structural heart disease, although the specific causes vary with the age of the population studied. The overwhelming majority of SCD (up to 80%) in adults is attributable to CHD. Accordingly, the risks for SCD are predominantly the same as those of CHD, such as age, male gender, hypertension, dyslipidaemia, smoking, and diabetes mellitus. The frequency of CHD is, however, much lower in SCD in younger populations. Other structural heart disease, both acquired and inherited, account for about 10% of SCD. Many have been covered in other chapters in this book (see Part 3) but, in this chapter, we will discuss specific conditions where risk stratification of SCD is an important aspect of the management of the condition. These conditions include hypertrophic cardiomyopathy (HCM) and arrhythmogenic right ventricular cardiomyopathy (ARVC). There are instances of SCD in the absence of structural heart disease (primary electrical disorder), and these account for approximately 10%–12% of cases amongst populations under the age of 45, with a significantly lower proportion when older subjects are included. There have been significant developments made in the understanding of the genetic, molecular, and electrophysiological basis of SCD in this group of patients, in particular with respect to the inherited arrhythmia syndromes, and this will be discussed further.

Superimposed triggers seem to play a role in SCD in the presence of underlying anatomical and functional substrates. Ischaemia, electrolyte imbalance, drugs (especially antiarrhythmic agents), autonomic nervous system activation, and psychosocial factors can act in concert to disturb cardiovascular function and coalesce together to lead to fatal ventricular tachyarrhythmias. However, only a small percentage of patients with structural heart disease and inherited arrhythmogenic syndromes develop SCD, and the challenge is in the risk stratification of SCD in these patient groups. The most powerful predictor of SCD is significant left ventricular impairment from any cause.

CHD

SCD is the mechanism of death in over 60% of patients with known CHD, and accounts for up to 80% of all SCDs. The incidence of SCD is influenced by the clinical manifestations of CHD, with patients with previous myocardial infarction (MI) being most at risk, and intermediate risk for patients with angina but no previous MI. However, it has been estimated that, in 15%–25% of patients, the initial presentation of CHD is SCD. SCD can occur in the context of an acute coronary syndrome (ACS) or the setting of stable CHD in a patient with a previous MI with the myocardial scar serving as a substrate for ventricular tachyarrhythmias and SCD. An important distinction has to be made with the arrhythmic mechanisms, as the implications for those with an aborted SCD in either setting are different.

In the acute phase of an MI, SCD is usually as a result of acute ischaemia triggering lethal ventricular tachyarrhythmias, and the peak incidence of ventricular fibrillation (VF) within the first 48 hours. The degree of coronary artery stenosis required and the roles of 'vulnerable' atherosclerotic plaques and coronary artery thrombi are debated, but all can result in acute physiological derangements, destabilizing the electrical activity of the heart. Studies have suggested that, before reperfusion therapy, early VF in acute MI is independently associated with anterior MIs and the absence of preinfarction angina (preconditioning). Mechanical complications resulting in acute haemodynamic collapse (e.g. myocardial rupture with pericardial tamponade and septal defects; papillary muscle rupture; and ischaemic valvular dysfunction) may mimic sudden arrhythmic death. Extensive myocardial necrosis with cardiogenic shock may result in a similar consequence.

Following acute MI, the mechanism of SCD evolves as a result of adverse left ventricular remodelling. Myocardial scarring is the substrate for ventricular tachyarrhythmias as a result of regional and intramural re-entry circuits that incorporate areas of diseased myocardium and unexcitable scar tissue. Sustained ventricular tachycardia (VT) can accelerate and subsequently degenerate into VF. The development of heart failure as a result of adverse left ventricular remodelling, with progressive ventricular dilatation and worsening left ventricular systolic function, corresponds to progressive loss of cardiac output, and congestive cardiac failure is the second process underlying the risk of SCD post-MI. Neurohormonal pathways are activated, and this underlies progressive vasculopathy, left ventricular dysfunction, fibrosis, and progression of the disease. Dilatation of the left ventricle predisposes to electrical heterogeneity characterized by a temporal dispersion of repolarization predisposing to re-entrant tachyarrhythmias. It has been suggested that progressive pump failure, sudden arrhythmic death, and sudden death during episodes of clinical deterioration each account for a third of deaths in patients with heart failure. VT degenerating into VF is the most common cause of SCD, and a bradyarrhythmia or pulseless electrical activity (PEA) is responsible in 5%–33% of cases. Pump failure is an additional mechanism; in it, chronic ischaemia causes global hypoxia, giving rise to electrical instability and ectopy and thus leading to the generation of lethal ventricular tachyarrhythmias. An ACS can also be the precipitating factor in some patients with heart failure.

Other structural heart disease

Other structural heart diseases account for up to 10% of all SCDs, and these can be categorized into non-ischaemic cardiomyopathies, valvular heart disease, and congenital heart disease.

Dilated cardiomyopathy

Dilated cardiomyopathy (DCM) is increasingly common and has both primary and secondary forms. The causes are uncertain, and include viral, autoimmune, genetic, and environmental (alcohol and drugs) causes. SCD accounts for approximately a third of deaths in this group of patients, and the predominant mechanism seem to be ventricular tachyarrhythmia, although bradyarrhythmia and PEA have also been seen, especially in those with severe heart failure. Extensive subendocardial scarring resulting in left ventricular dilatation underlies the substrate for re-entrant tachyarrhythmias. As with ischaemic cardiomyopathy, the risk of SCD increases with the decline in left ventricular systolic function, which probably serves as a function of other risk factors such as sympathetic tone, neurohormonal activation, and electrolyte disturbances. Drugs used to treat heart failure, such as antiarrhythmic agents, inotropes, and diuretics (potentially causing electrolyte disturbances), can act as triggers to ventricular tachyarrhythmias.

Hypertrophic cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is an inherited heart muscle disorder caused by mutations (>45) in sarcomeric proteins, resulting in myocyte disarray and myocardial hypertrophy. The commonest form of inheritance is autosomal dominant with incomplete penetrance. Most cases are accounted for by mutations in genes encoding beta-myosin heavy chains and cardiac troponin T. SCD is the most important threat in this population, with 50%–60% of deaths being sudden; the incidence of SCD in patients with HCM is 2%–4% per year in adults, and 4%–6% in children and adolescents. In addition, HCM is the commonest cause of SCD in those under the age of 30; in the vast majority of those cases, the patients had been asymptomatic prior to SCD occurring. In a significant number of patients with HCM, SCD occurs during or after strenuous exercise. HCM is also the single most common cause of SCD in young athletes, and autopsy series have suggested it accounts for up to 36% of cases. Hence, it is an important disease to screen for in athletes.

The mechanism of SCD in HCM is not well understood, and was initially thought to be a result of obstruction of the left ventricular outflow tract as a result of catecholamine activity, but subsequent studies have suggested that patients with non-obstructive HCM are at high risk of SCD as well, primarily via ventricular tachyarrhythmias. The mechanism of arrhythmia is unclear. Myocyte disarray and fibrosis may provide the arrhythmogenic substrate, with the triggers being ischaemia, left ventricular outflow-tract obstruction, vascular instability, and cellular energy depletion. Non-sustained VT is common and is seen in up to 20% of this population. Sustained VT is, however, rare and may suggest the presence of a left ventricular apical aneurysm. Current guidelines advise a primary-prevention implantable cardioverter defibrillator (ICD) in high-risk patients, who are defined as patients having two or more risk factors (severe left ventricular hypertrophy with a septal thickness of 3 cm or greater; family history of SCD; syncope; abnormal blood-pressure response to exercise; and non-sustained VT on ambulatory monitoring). Recent studies have suggested a potential for mutation analysis as part of the risk stratification for SCD in HCM, as there appear to be high-risk genotypes for SCD, particularly related to troponin T. In addition, the extent of late gadolinium enhancement, which reflects fibrosis, on cardiac MRI (CMRI) is currently being studied as an independent prognostic factor in SCD. At this time, there is no definitive evidence to support the use of pharmacological therapy in reducing the risk of malignant arrhythmias in HCM patients, and its use is mainly adjunctive in patients with ICDs.

ARVC/dysplasia

ARVC/dysplasia (ARVC/D) is a rare but increasingly recognized inherited cardiomyopathy. It is characterized by the progressive replacement of cardiac myocytes by adipose and fibrous tissue and leads to electrical instability and ventricular arrhythmias in the early stages, and reduced contractility and heart failure in the later stages. The tissue replacement can also affect the left ventricle, with relative

sparing of the septum. The prevalence in the general adult population has been estimated at 1 in 1000, with men being affected more often in a ratio of 3:1. It is an important cause of SCD in young adults and, in some series, it accounts for up to 11% of cases overall and 22% of cases in athletes. There appears to be some discordance to the geographical prevalence of ARVC; this is more likely a result of under-recognition of the disease rather than a true difference in genetic prevalence. In up to 50% of patients with ARVC, a positive family history can be elicited. ARVC is predominantly inherited as an autosomal dominant disease but with incomplete and age-related penetrance, and variable forms of clinical expression. Autosomal recessive inheritance has also been described, often in association with a cutaneous phenotype (Navos disease). Gene identification studies helped the elucidation of the pathophysiology of the disease and have defined ARVC as a disease of the desmosome, an adhesive junction between cells. Mutations in key components of the desmosome, including plakoglobin (most common desmosomal mutation), desmoplakin, and plakophilin, have been reported to result in the phenotype of ARVC.

The diagnosis of ARVC is challenging. Definitive diagnosis requires histologic confirmation of transmural fibrofatty replacement of the right ventricle at post-mortem or surgery. This is clearly not practical in the clinical setting and, due to the patchy nature of the disease, endomyocardial biopsy is not highly sensitive. In 1994, an international task force proposed criteria for the clinical diagnosis of ARVC, to facilitate recognition and interpretation of the frequently non-specific clinical features of ARVC. Structural, histological, electrocardiographic, arrhythmic, and familial features of the disease were incorporated into the criteria and subdivided into major and minor categories according to the specificity of their association with ARVC. There has since been a modification, and the 2010 revised task force criteria incorporates new knowledge and technology to improve diagnostic sensitivity while maintaining diagnostic specificity. Both the original and revised criteria are divided into major and minor criteria, and are subdivided into the following six categories:

- global and/or regional dysfunction and structural alterations
- tissue characterization of wall
- repolarization abnormalities on the ECG
- depolarization/conduction abnormalities on ECG
- arrhythmias
- family history

Definitive diagnosis requires the presence of two major criteria, one major plus two minor criteria, or four minor criteria from different categories. A comparison of original and revised task force criteria is given in Table 120.1.

Approximately half of patients with ARVC have a normal ECG at presentation but, within 6 years of presentation, almost all patients will have one of the characteristic ECG findings (ECG evolution). The characteristic ECG changes seen in ARVC patients include:

- prolonged QRS duration, particularly in V1 and V6, consistent with the delayed right ventricular (RV) activation (>110 ms)
- a pattern of incomplete or complete right bundle branch block
- a prolonged S-wave upstroke (interval from the nadir of the S wave to the isoelectric baseline is >55 ms)
- an epsilon wave (a reproducible distinct wave between the end of the QRS complex and the onset of the T wave) in the right precordial leads, particularly in V1 (major criterion in the 2010 revised task Force Criteria); this represents the low-amplitude signals caused by delayed activation of parts of the RV
- T-wave inversion (TWI) in the right precordial leads, with the extent of TWI correlated with the degree of RV enlargement

In addition, abnormalities in signal-averaged ECGs (SAECG) are also frequently detected in patients with ARVC, and have been proposed as a minor criterion on the 2010 revised task force criteria. Arrhythmias most frequently seen in ARVC include sustained or non-sustained VT with left bundle branch block morphology and frequent ventricular extrasystoles (>500/24-hour period).

The role of non-invasive imaging in the diagnosis of ARVC incorporates the use of echocardiography and CMRI. RV dilatation with
